Davidson's
Principles and Practice of
Medicine

22nd Edition

Sir Stanley Davidson (1894–1981)

This famous textbook was the brainchild of one of the great Professors of Medicine of the 20th century. Stanley Davidson was born in Sri Lanka and began his medical undergraduate training at Trinity College, Cambridge; this was interrupted by World War I and later resumed in Edinburgh. He was seriously wounded in battle, and the carnage and shocking waste of young life that he encountered at that time had a profound effect on his subsequent attitudes and values.

In 1930 Stanley Davidson was appointed Professor of Medicine at the University of Aberdeen, one of the first full-time Chairs of Medicine anywhere and the first in Scotland. In 1938 he took up the Chair of Medicine at Edinburgh and was to remain in this post until retirement in 1959. He was a renowned educator and a particularly gifted teacher at the bedside, where he taught that everything had to be questioned and explained. He himself gave most of the systematic lectures in Medicine, which were made available as typewritten notes that emphasised the essentials and far surpassed any textbook available at the time.

Principles and Practice of Medicine was conceived in the late 1940s with its origins in those lecture notes. The first edition, published in 1952, was a masterpiece of clarity and uniformity of style. It was of modest size and price, but sufficiently comprehensive and up to date to provide students with the main elements of sound medical practice. Although the format and presentation have seen many changes in 21 subsequent editions, Sir Stanley's original vision and objectives remain. More than half a century after its first publication, his book continues to inform and educate students, doctors and health professionals all over the world.

Readers may be interested to listen to an interview with Sir Stanley Davidson, which can be found on the Royal College of Physicians of Edinburgh website at: www.rcpe.ac.uk/library-archives/sir-stanley-davidson-1894-1981.

Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

Since *Davidson's Principles and Practice of Medicine* was first published in 1952, over two million copies have been sold and the book has acquired a large following of medical students, doctors and other health professionals all over the world. It has been translated into many languages, most recently Japanese, Russian, Italian and Polish, and has won numerous prizes, the last edition being highly commended in the British Medical Association Book Awards. *Davidson's* has endured because with each new edition it has evolved to provide comprehensive updated information in a concise and easy-to-read format.

From its beginnings, *Davidson's* has sought to explain the basis for medical practice. The integration of 'preclinical' science with clinical practice is now a feature of many undergraduate medical curricula, and many students use *Davidson's* from the outset of their medical course. In recognition of this, the first part of the book, 'Principles of Medicine', highlights the mechanisms of health and disease, along with the professional and ethical principles underlying medical practice. Many examples of clinical problems are included to bring the medical sciences to life for the new student and to rejuvenate the interest of the experienced clinician. The second part of the book, 'Practice of Medicine', covers the major medical specialties. Every chapter has been thoroughly revised for this edition to ensure that it reflects the 'cutting edge' of medical knowledge and practice and is pitched at a level of detail to meet the needs of candidates preparing for examination for Membership of the Royal College of Physicians or its equivalents. In recognition of the emerging specialty of Stroke Medicine, this topic is now covered in a separate chapter from Neurological Disease. Surgical approaches to disease management are mentioned in *Davidson's*, but readers are encouraged to consult the sister book, *Principles and Practice of Surgery*, for more details.

Many of the innovations introduced in recent editions have been warmly received. We have retained both a patient-orientated approach, in the ever-popular 'Clinical Examination' overviews and 'Presenting Problems' sections, alongside practical content, in 'Emergency' and 'Practice Point' boxes. Embedding horizontal themes within the book – for example, with the 'In Old Age' and 'In Pregnancy' boxes – has been applauded, and we have extended this approach by adding 'In Adolescence' boxes in relevant chapters; these emphasise key points in managing the transition of patients between paediatric and adult services.

We are proud of *Davidson's* international heritage. As well as recruiting authors from around the globe, particularly for topics such as Infectious Diseases and HIV, we have welcomed new members on to our International Advisory Board. These leading experts from 16 countries provide detailed comments that, along with the feedback received from our global readership, are crucial to our planning of every chapter in each new edition. We have also visited several medical schools on the Indian subcontinent and received invaluable feedback from students and teachers. We have addressed as many of these suggestions as possible in this edition.

Education is achieved by assimilating information from many sources and readers of this book can enhance their learning experience by using complementary resources. The StudentConsult platform continues to provide online access to the text and illustrations of the main edition. The book is also available in various eBook formats. *Davidson's* has had a long-standing association with its sister books, *Macleod's Clinical Examination* (now in its 13th Edition) and *Principles and Practice of Surgery* (now in its 6th Edition). The *Davidson's* 'family' has expanded with the publication of *Davidson's Essentials of Medicine*, a long-requested pocket-size version of the main text; *Davidson's Foundations of Clinical Practice*, a guide to starting work as a junior doctor; *Davidson's 100 Clinical Cases*, which contains cases directly based on the 'Presenting Problems' in the main text; and *Macleod's Clinical Diagnosis*, which describes a systematic approach to differential diagnosis of symptoms and signs. We congratulate the editors and authors of these books for continuing the tradition of concise, easily read and beautifully illustrated texts.

The regular introduction of new authors and editors to *Davidson's* is important to maintain the freshness of each new edition. On this occasion, Dr Ian Penman has joined the editorial team and 18 new authors have contributed material. We all take immense pride in producing an outstanding book for the next generation of doctors, and in continuing the great tradition first established by Sir Stanley Davidson and passed on by all the previous editors and authors, for what remains one of the world's leading textbooks of medicine.

Index 1313

List of presenting problems

These presentations represent the most common reasons for referral to each medical specialty and are described in the 'Presenting Problems' sections of all system-based chapters. The same approach has also been employed in several of the chapters in the 'Principles of Medicine' section, reinforcing the close connection between clinical problems and fundamental mechanisms of disease.

Abnormal investigation results

Acid–base, 443
- Metabolic acidosis, 445

Emeritus Professor of Medicine, Tripoli University; Consultant Endocrinologist, Alafia Clinic, Tripoli, Libya

Ian J. Simpson
Emeritus Professor of Medicine, Faculty of Medical and Health Sciences, University of Auckland; Nephrologist, Auckland City Hospital, Auckland, New Zealand

Dr S.G. Siva Chidambaram
Professor of Medicine, Institute of Internal Medicine, Madras Medical College and Rajiv Gandhi Government General Hospital, Chennai, India

Arvind K. Vaish
Professor and Head, Department of Medicine, King George's Medical University, Lucknow, India

Subhash Varma
Professor and Head, Department of Internal Medicine, Postgraduate Institute of Medical Education and Research, Chandigarh, India

Introduction

The first section of the book, 'Principles of Medicine', describes the basis on which medicine is practised and the fundamental mechanisms determining health and disease which are relevant to all medical specialties. The second section, 'Practice of Medicine', is devoted to individual medical specialties. Each chapter has been written by experts in the field to provide the level of detail expected of trainees in their discipline. To maintain the book's virtue of being concise, care has been taken to avoid unnecessary duplication between chapters.

The system-based chapters follow a standard format, beginning with an overview of relevant clinical examination, followed by an account of functional anatomy, physiology and investigations, then the common presentations of disease, and details of the individual diseases and treatments of that system. Where appropriate, the chapters in the first section follow a similar format; in chapters which describe the immunological, cellular and molecular basis of disease, this problem-based approach brings the close links between modern medical science and clinical practice into sharp focus.

The methods used to present information are described below.

Clinical examination overviews

The value of good clinical skills is highlighted by a two-page overview of the important elements of the clinical examination at the beginning of most chapters. The left-hand page includes a mannikin to illustrate key steps in examination of the relevant system, beginning with simple observations and progressing in a logical sequence around the body. The right-hand page expands on selected themes and includes tips on examination technique and interpretation of physical signs. These overviews are intended to act as an aide-mémoire and not as a replacement for a detailed text on clinical examination, as provided in the sister title, *Macleod's Clinical Examination*.

Presenting problems

Medical students and junior doctors must not only learn a great many facts about various disorders, but also develop an analytical approach to formulating a differential diagnosis and a plan of investigation for patients who present with particular symptoms or signs. In *Davidson's* this is addressed by incorporating a 'Presenting Problems' section into all system-based chapters. Nearly 300 presentations are included, which represent the most common reasons for referral to each medical specialty. The same approach has been used in several of the chapters in the 'Principles of Medicine' section, to reinforce the close connection between clinical problems and fundamental mechanisms of disease. Many patients present with symptoms such as weight loss, dizziness or breathlessness, which are not specific to a particular system; these are described in the most relevant chapter and cross-referenced elsewhere. A list of presenting problems may be found on pages vii–viii.

Boxes

Boxes are a popular way of presenting information and are particularly useful for revision. They are classified by the type of information they contain, using specific symbols.

General Information

These include causes, clinical features, investigations, treatments and other useful information.

Evidence-based Medicine

Clinicians base their practice on the best available evidence, which needs to be up to date, relevant, authoritative and easily accessible. Over 120 evidence-based medicine (EBM) boxes are included in this edition. They contain recommendations that are supported by evidence obtained from meta-analysis of several randomised controlled trials (RCTs) or one (or more) high-quality RCT, and therefore conform to 'Grade A' criteria, as described in Chapter 1 (p. 8).

Practice Point

There are many practical skills that students and doctors must learn. These vary from inserting a nasogastric tube to reading an ECG or X-ray, or interpreting investigations such as arterial blood gases or thyroid function tests. 'Practice Point' boxes provide straightforward guidance on how these and many other skills can be acquired and applied.

Emergency

These boxes describe management of many of the most common emergencies in medicine.

In Old Age

In most developed countries, older people comprise 20% of the population and are the chief users of health care. While they contract the same diseases as those who are younger, there are often important differences in the way they present and how they are best managed.

Chapter 7, 'Ageing and Disease', concentrates on the principles of managing the frailest group who suffer from multiple comorbidity and disability, and who tend to present with non-specific problems such as falls or delirium. However, many older people also suffer from specific single-organ pathology. 'In Old Age' boxes are thus included in each chapter and describe common presentations, implications of physiological changes of ageing, effects of age on investigations, problems of treatment in old age, and the benefits and risks of intervention in older people.

In Pregnancy

Many conditions are different in the context of pregnancy, while some arise only during or shortly after pregnancy. Particular care must be taken with investigations (for example, to avoid radiation exposure to the fetus) and treatment (to avoid the use of drugs which harm the fetus). These issues are highlighted by 'In Pregnancy' boxes distributed throughout the book.

In Adolescence

Although Paediatric Medicine is not covered in *Davidson's*, many chronic disorders begin in childhood and adult physicians often contribute to multidisciplinary teams that manage young patients 'in transition' between paediatric and adult health-care services. This group of patients often presents a particular challenge, due to the physiological and psychological changes that occur in adolescence and which can have a major impact on the disease and its management. Adolescents can be encouraged to take over responsibility from their parents/carers in managing their disease, but are naturally rebellious and often struggle to adhere to the impositions of chronic treatment. To highlight these issues, we have introduced this new box format in the 22nd Edition.

Terminology

Recommended International Non-proprietary Names (rINNs) are used for all drugs, with the exception of adrenaline and noradrenaline. However, British spellings have been retained for drug classes and groups (e.g. amphetamines not amfetamines).

Units of measurement

The International System of Units (SI units) is the recommended means of presentation for laboratory data and has been used throughout *Davidson's*. However, we recognise that many laboratories around the world continue to provide data in non-SI units, so these have been included in the text for the commonly measured analytes. Both SI and non-SI units are also given in Chapter 29, which describes the reference ranges used in Edinburgh's laboratories. It should be appreciated that these reference ranges may vary from those used in other laboratories.

Finding what you are looking for

A contents list is given on the opening page of each chapter. In addition, the book contains numerous cross-references to help readers find their way around, along with an extensive index of over 15000 subject entries. The online text available on StudentConsult (www.studentconsult.com) allows for detailed searches of the content by keyword. A list of up-to-date reviews and useful websites with links to management guidelines appears at the end of each chapter.

Acknowledgements

We are indebted to former authors who have stepped down from this edition. They include Dr Chris M.C. Allen, Dr Jeffrey K. Aronson, Dr Jane Collier, Professor Martin Dennis, Professor Michael Doherty, Professor B. Miles Fisher, Professor Brian M. Frier, Dr Ian Grant, Professor Christian J. Lueck, Dr Brian McClelland, Dr Kelvin Palmer, Professor Jonathan Rees, Dr Olivia Schofield, Mr Laurence H. Stewart, Dr George Webster and Dr Edmund Wilkins.

We are grateful to members of the International Advisory Board, all of whom provided detailed suggestions which have improved the book. Several members have stepped down and we would like to thank them for their support during the preparation of previous editions. They include Professor Jan D. Bos, Professor Y.C. Chee, Professor W.F. Mollentze, Professor Dato' Tahir Azhar, Professor C.F. Van der Merwe, Dr G. Wittert and Professor M.E. Yeolekar.

Detailed chapter reviews were commissioned to help plan this new edition and we would like to acknowledge all those who assisted, including Dr Sam Alfred, Dr Rustam Al-Shahi Salman, Professor Harry Campbell, Dr Richard Casasola, Dr Gavin Clunie, Professor Michael Eddleston, Dr Catherine Elliot, Professor David Gawkrodger, Professor Jeremy Hall, Dr Amy Hughes, Professor Alan Jardine, Dr Uwe Kornak, Dr Stuart McLellan, Dr Scott Murray, Dr Rak Nandwani, Dr David Patch, Professor Donald Salter, Professor John Simpson, Mr Grant Stewart and Professor Ian Weller.

As part of the publisher's review, students and doctors from medical schools in the UK, Europe, Africa and Asia have provided valuable feedback on this textbook and their comments have helped shape this new edition. We hope we have listed all those who have contributed and apologise if any names have been accidentally omitted. We are indebted to the following for their enthusiastic support: Alessandro Aldera, Sabreen Ali, Syed Hyder Ali, Ashish Kumar Amant, Abdullah Ansaari, Ruhith Ariyapala, James Armstrong, Charu Dutt Arora, Akshay Athreya, Gavin Baillie, Anna Kate Barton, Kapil Battista, Katrina Bell, Andrew Beverstock, B. Bharadwaj, Charlie Billington, Lili Bird, Dwaipayan Biswas, Rudradeep Biswas, Sagnik Biswas, Tamoghna Biswas, Tom Brazel, Mark Karlsson Cairns, Rachel Callaghan, Elizabeth Carr, Richard Cassidy, Yen-Jei Chen, Sudip Chowdhury, Sarah Clay, Danielle Clyde, Andrew Cochrane, Amanda Collins, Guy Conlon, India Cox, Prafulla M. Davangere, Emma Donoghue, Kate Doughty, Jemima Horsley Downie, Simon Durkin, Padmaraj Duvvuri, Ahmad Farooqui, Ruth Fergie, Alice Finlayson, James Fraser, Saad Ahmed Fyyaz, David Gall, Raj Ghoniya, Alice Graham, Paul Gray, Vaibhav Gupta, Vibhuti Gupta, Sarah Guthrie, Ailsa Hamilton, V. Vadhan, Ela Varasi, Siddarth Varshney, Arun Kumar Vasa, Monica Vijayakumar, Andrew Wilson, Vincent Wong, James Wood, Sara Zafar and Jim Zhong.

We would like to extend our thanks to the many readers who contacted us with suggestions for improvements. Their input has been invaluable and is much appreciated; they are unfortunately too numerous to mention individually.

We are grateful to colleagues who have generously provided many of the illustrations that appear in this edition. They are acknowledged on the next page.

We are especially grateful to all those working for Churchill Livingstone, in particular Laurence Hunter, Wendy Lee and Robert Britton, for their endless support and expertise in the shaping, collation and illustration of this edition. We would also like to thank Louisa Talbott for her efficient project management, Susan Boobis for her labours in compiling the extensive index and Ruth Noble for expert proofreading.

Complementary and alternative medicine 15

Since the time of Hippocrates, the role of the doctor has extended beyond the narrow remit of curing patients of their ailments. Good medical practice, or the art of medicine, hinges on recognising and respecting the breadth of physical, cultural, spiritual, experiential and psychosocial characteristics of each patient, and understanding their impact on the patient's beliefs, attitudes and expectations. Doctors must deliver appropriate care which considers the technical complexities of modern treatment, and at the same time deals with the communication and interpersonal needs of the patient, at a time when he or she may feel most vulnerable. In addition to the diagnosis and treatment of illness, the scope of medicine has expanded to preventing disease through measures such as screening, vaccination and health promotion. Doctors are centrally involved in tackling lifestyle-related issues of the modern world, such as obesity, alcohol excess, cigarette smoking and sexual health.

Medical professionalism has been described in the UK by a Royal College of Physicians working party (2005) as 'a set of values, behaviours and relationships that underpin the trust the public has in doctors'. They stated that doctors should be committed to integrity, compassion, altruism, continuous improvement, excellence, and working in partnership with members of the wider health-care team. They perceived that medical professionalism was relevant to leadership, education, career pathways, appraisal and research.

This chapter outlines how doctors must provide patients and their families with relevant but complex information, discuss management options, and reach appropriate clinical decisions, commensurate with the available resources. It also describes processes to develop, maintain and assure medical professionalism.

MEDICAL PRACTICE

The doctor–patient relationship

The contents of this book are not all based on indisputable contemporary evidence; many reflect wisdom and understanding distilled over hundreds of years and passed from generation to generation of doctors. This perceived wisdom lies at the heart of the way that doctors and patients interact; it demands respect, and if the doctor also displays compassion, sets the scene for the development of trust.

Due to the complexities of many chronic diseases and treatments, and the multifaceted impact of illness on a patient, there is an increasing role for health care to be delivered by a multidisciplinary team (Box 1.1). This model of care recognises the different skills of each allied health professional and focuses patient care beyond surgical procedures or pharmacological manipulation. The doctor usually takes the lead in determining the overall direction of care but must also:

- guide the patient through the unfamiliar landscape, language and customs of clinical care
- interpret, synthesise and convey complex information
- help patients and families to participate fully in the decision-making process.

In many clinical disciplines, doctors from several specialties form a multidisciplinary team in order to formulate a treatment plan. In oncology, for example, this ensures that various modalities of treatment (surgical, oncological and palliative) are considered.

1.1 Members and roles of a multidisciplinary team

Professional	Roles
Doctor	Diagnosis and treatment Overall coordination of care
Specialist nurse	Patient and family support Information-giving
Physiotherapist	Improving physical function Physical rehabilitation
Occupational therapist	Maximising skills and abilities Complex re-enablement
Speech and language therapist	Optimising communication Swallowing assessment
Dietitian	Nutritional advice Parenteral feeding support
Pharmacist	Safe prescribing Complex medicines delivery
Social worker	Coordination of home care Financial advice
Clinical psychologist	Cognitive interventions Psychological support
Pastoral care	Psychological support Spiritual support

The doctor–patient relationship is in itself therapeutic; a successful consultation with a trusted and respected practitioner will have beneficial effects irrespective of any other therapy given. The doctor–patient relationship is multilayered, dynamic and bilateral (Fig. 1.1).

Regulatory bodies, such as the UK General Medical Council, seek to define the medical side of the doctor–patient relationship in terms of the 'Duties of a Doctor' (Box 1.2). It is common for medical schools to require undergraduate students to sign an ethical code of conduct based on statements like this.

Difficulties in the doctor–patient relationship

Regardless of experience and skill, it is inevitable that, at some point in a doctor's career, the doctor–patient relationship will break down. There can be many reasons for this; sometimes, these are beyond the control of the clinician, but often conflict arises when there is a genuine or perceived failure of the doctor to meet one or more of the duties outlined in Box 1.2. It is important to recognise a breakdown in the relationship quickly and, whenever possible, identify the reason. If patients are unhappy with an aspect of their care, they are entitled to a prompt, open, constructive and honest response that includes an explanation and, if appropriate, an apology. It is also important to reassure the patient that the issues raised will not adversely affect their future care.

Often, an acknowledgement that something is wrong and demonstration of a desire to put things right are sufficient to rectify any conflict. However, the longer

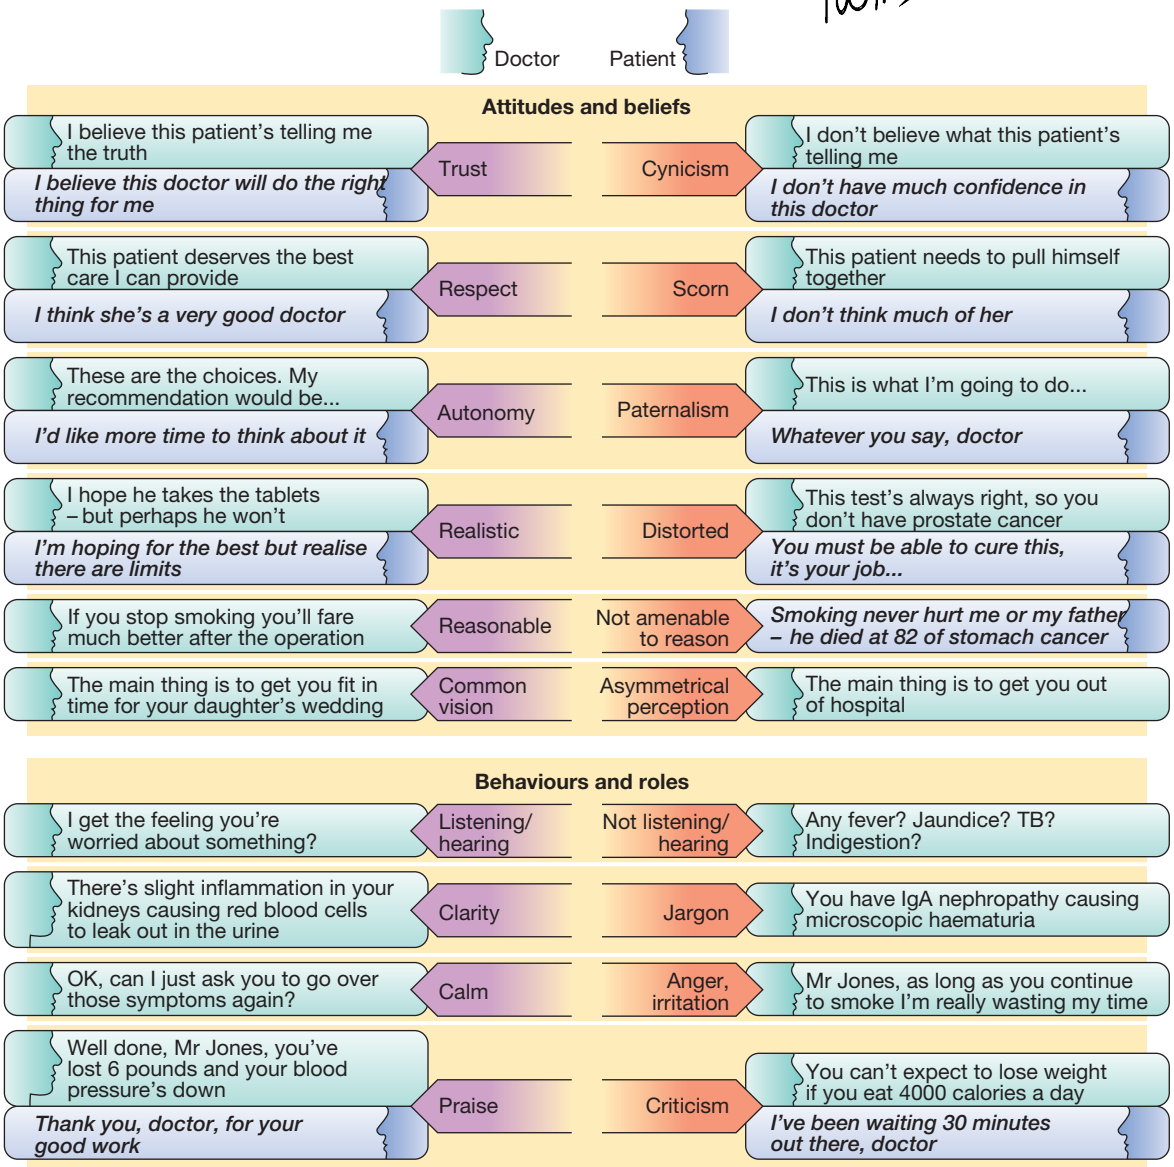

Fig. 1.1 Some aspects of the doctor–patient relationship.

1.2 The duties of a doctor registered with the UK General Medical Council

Patients must be able to trust doctors with their lives and health. To justify that trust you must show respect for human life and make sure your practice meets the standards expected of you in four domains.

Knowledge, skills and performance

- Make the care of your patient your first concern.
- Provide a good standard of practice and care.
  - Keep your professional knowledge and skills up to date.
  - Recognise and work within the limits of your competence.

Safety and quality

- Take prompt action if you think that patient safety, dignity or comfort is being compromised.
- Protect and promote the health of patients and the public.

Communication, partnership and teamwork

- Treat patients as individuals and respect their dignity.
  - Treat patients politely and considerately.
  - Respect patients' right to confidentiality.
- Work in partnership with patients.
  - Listen to, and respond to, their concerns and preferences.
  - Give patients the information they want or need in a way they can understand.
  - Respect patients' right to reach decisions with you about their treatment and care.
  - Support patients in caring for themselves to improve and maintain their health.
- Work with colleagues in the ways that best serve patients' interests.

Maintaining trust

- Be honest and open and act with integrity.
- Never discriminate unfairly against patients or colleagues.
- Never abuse your patients' trust in you or the public's trust in the profession.

You are personally accountable for your professional practice and must always be prepared to justify your decisions and actions.

one takes to address a problem, the more difficult it becomes to resolve. The patient may continue to be dissatisfied with the doctor and it may be most appropriate for another colleague to take over their care. It is important to reflect on such incidents, to identify whether one would approach a similar challenge differently next time.

Communication and other clinical skills

Communication lies at the heart of good medical practice. The most technically capable clinician will fail in the duty of care if he or she is unable to communicate effectively with patients or relatives, since this is essential for accurate history-taking, information-giving and decision-making. Likewise, the delivery of holistic care requires effective communication with other doctors and members of the multidisciplinary team. Clear and appropriately detailed clinical note-keeping is essential, as are timely and accurate written communications between professionals.

Failures in communication may lead to poor health outcomes, strained working relations, dissatisfaction among patients, their families and health professionals, anger and litigation. The majority of complaints received by health-care professionals could have been avoided by effective communication. Box 1.3 lists some common barriers to good communication.

Developing communication skills to facilitate accurate history-taking and information-giving takes many years and requires frequent personal reflection on previous consultations. A detailed account of history-taking, clinical examination and communication skills is beyond the scope of this chapter but is provided in Davidson's sister book, *Macleod's Clinical Examination*. However, some communication principles are discussed below and these can be applied to most consultations.

The main aim of a medical interview is to establish a factual account of the patient's illness. The clinician must allow the patient to describe the problems without overbearing interrogation, but should try to facilitate the process with appropriate questions (Box 1.4). Techniques such as an unhurried approach, checking prior understanding, making it clear that the interviewer is listening, the use of silence when appropriate, recapping on what has been said, and reflection of key points back to the patient are all important. A major requirement is to express complex information and concepts in language with which the patient can readily engage. Non-verbal communication is equally important. The patient's facial expressions and body language may betray hidden fears. The clinician can help the patient to talk more freely by smiling or nodding appropriately.

Beyond the factual account of symptoms, the clinician should also explore patients' feelings, determine how they interpret their symptoms, unearth their concerns and fears, and explore their expectations before suggesting and agreeing a plan of management. Clinicians should demonstrate understanding, sensitivity and empathy (i.e. imagine themselves in the patient's position). Most patients have more than one concern and will be reluctant to discuss potentially important issues if they feel that the clinician is not interested or is likely to dismiss their complaints as irrational or trivial.

1.3 Some barriers to good communication in health care

The clinician

- Authoritarian or dismissive attitude
- Hurried approach
- Use of jargon
- Inability to speak first language of patient
- No experience of patient's cultural background

The patient

- Anxiety
- Reluctance to discuss sensitive or seemingly trivial issues
- Misconceptions
- Conflicting sources of information
- Cognitive impairment
- Hearing/speech/visual impediment

1.4 Communication skills in the medical interview

- **Open questions** allow patients to express their own thoughts and feelings, e.g. 'How have you been since we last saw you?', 'Is there anything else that you want to mention?'
- **Closed questions** are requests for factual information, e.g. 'When did this pain start?'
- **Leading questions** invite specific responses and suggest options, e.g. 'You'll be glad when this treatment is over, won't you?'
- **Reflecting questions** help to develop or expand topics, e.g. 'Can you tell me more about your family?'
- **Active listening** encourages further dialogue, e.g. 'Go on,' 'I see,' 'Hmm' etc.
- **Requesting clarification** encourages further detail, e.g. 'How do mean?', 'In what way?' etc.
- **Summarising** ensures accurate understanding, e.g. 'Tell me if I've got this right.'

Specific communication scenarios, such as breaking bad news or dealing with aggression, require additional targeted strategies (see *Macleod's Clinical Examination*).

While many common clinical conditions can be identified on the basis of the history from the patient, the process of physical examination remains important in most clinical scenarios. Physical examination is an important characteristic of the doctor–patient relationship, at best benefiting from and reinforcing trust, but at worst a focus of complaint when the doctor–patient relationship has not been established or has broken down. Key findings on physical examination pointing to disease in specific body systems are described in the relevant chapters of this book.

Using investigations

Modern medical practice has become dominated by sophisticated and often expensive investigations. It is easy to forget that the judicious use of these tools, and the interpretation of the data that they provide, are crucially dependent on good basic clinical skills. Indeed, a test should only be ordered if it is clear that the result will influence the patient's management and the perceived value of the resulting information exceeds the

anticipated discomfort, risk and cost of the procedure. Clinicians should therefore analyse their patient's condition carefully and draw up a provisional management plan before requesting any investigations.

The 'normal' (or reference) range

Although some tests provide qualitative results (present or absent, e.g. faecal occult blood testing, p. 857), most provide quantitative results (i.e. a value on a continuous numeric scale). In order to classify quantitative results as normal or abnormal, it is necessary to define a 'normal range'. Many quantitative measurements in populations exhibit a bell-shaped, or Gaussian, frequency distribution (Fig. 1.2); this is called a 'normal distribution' and is characteristic of biological variables determined by a complex mixture of genetic and environmental factors (e.g. height) and of test results (e.g. plasma sodium concentration). A normal distribution can be described by the mean value (which places the centre of the bell-shaped curve on the x axis) and the standard deviation (SD, which describes the width of the bell-shaped curve). Within each SD away from the mean, there is a fixed percentage of the population. By convention, the 'normal range' is defined as those values which encompass 95% of the population, i.e. the values within 2 SDs above and below the mean. If this convention is used, however, 2.5% of the normal population will have values above, and 2.5% will have values below, the normal range; for this reason, it is more precise to describe 'reference' rather than 'normal' ranges.

'Abnormal' results, i.e. those lying beyond 2 SDs from the mean, may occur either because the person is one of the 2.5% of the normal population whose test result is outside the reference range, or because he or she has a disease characterised by a different result from the test. Test results in 'abnormal' populations also have a bell-shaped distribution with a different mean and SD (see Fig. 1.2). In some diseases, there is typically no overlap between results from the normal and abnormal population (e.g. elevated serum creatinine in renal failure, p. 467). In many diseases, however, there is overlap, sometimes extending into the reference range (e.g. elevated serum thyroxine in toxic multinodular goitre, p. 753). In these circumstances, the greater the difference between the test result and the limits of the reference range, the higher the chance that the person has a disease, but there is a risk that results within the reference range may be 'false negatives' and results outside the reference range may be 'false positives'.

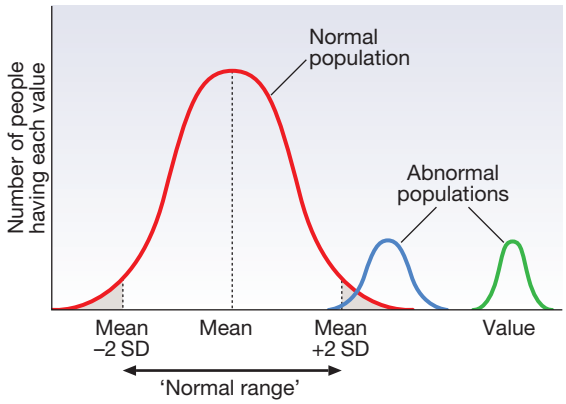

Fig. 1.2 Normal distribution and 'normal' (reference) range. For many tests, the frequency distribution of results in the normal healthy population (red line) is a symmetrical bell-shaped curve. The mean ± 2 standard deviations (SD) encompasses 95% of the normal population and usually defines the 'normal range' (or 'reference range'); 2.5% of the normal population have values above, and 2.5% below, the reference range (shaded areas). For some diseases (blue line), test results overlap with the normal population or even with the reference range. For other diseases (green line), tests may be more reliable because there is no overlap between the normal and abnormal population.

Each time a test is performed in a member of the normal population there is a 5% (1 in 20) chance that the result will be outside the reference range. If two tests are performed, the chance that one of them will be 'abnormal' is 10% (2 in 20), and so on; the chance of an 'abnormal' result increases as more tests are performed, so multiple indiscriminate testing should be avoided.

In practice, reference ranges are usually established by performing the test in a number of healthy volunteers who are assumed to be a random sample of the normal population. Not all populations are the same, however, and while it is common to have different reference ranges for men and women or children and adults, clinicians need to be aware that reference ranges defined either by test manufacturers or even within the local laboratory may have been established in small numbers of healthy young people who are not necessarily representative of their patient population.

For some tests, the clinical decision does not depend on whether or not the patient is a member of the normal population. This commonly applies to quantitative risk factors for future disease. For example, higher plasma total cholesterol levels are associated with a higher risk of future myocardial infarction (p. 583) within the normal population. Although a reference range for cholesterol can be calculated, cholesterol-lowering therapy is commonly recommended for people with values within the reference range; the 'cutoff' value at which therapy is recommended depends upon the presence of other risk factors for cardiovascular disease. The reference range for plasma cholesterol is therefore redundant and the phrase 'normal plasma cholesterol level' is unhelpful. Similar arguments apply for interpretation of values of blood pressure (p. 583), bone mineral density (p. 1065) and so on.

Some quantitative test results are not normally distributed, usually because a substantial proportion of the normal population will have an unrecordably low result (e.g. serum prostate-specific antigen, p. 518), and the distribution cannot be described by mean and SDs. Alternative statistical procedures can be used to calculate 95th centiles, but it is common in these circumstances to use information from normal and abnormal people to identify 'cutoff' values which are associated with a certain risk of disease, as described below.

Sensitivity and specificity

No test is completely reliable. All diagnostic tests can produce false positives (an abnormal result in the absence of disease) and false negatives (a normal result in a patient with disease). The diagnostic accuracy of a test can be expressed in terms of its sensitivity and its specificity (Box 1.5).

1.5 The accuracy of diagnostic tests

	Affected	Unaffected
Positive test	True +ve (a)	False +ve (b)
Negative test	False –ve (c)	True –ve (d)
Sensitivity (%) = [a/(a + c)] × 100 Specificity (%) = [d/(b + d)] × 100		
Positive predictive value = a/(a + b) Negative predictive value = d/(c + d)		
Likelihood ratio: positive test = sensitivity/(1 – specificity) negative test = (1 – sensitivity)/specificity		

Sensitivity is defined as the percentage of the test population who are affected by the index condition and test positive for it. In contrast, specificity is defined as the percentage of the test population who are healthy and test negative. A very sensitive test will detect most disease but may generate abnormal findings in healthy people; a negative result will therefore reliably exclude disease but a positive test is likely to require further evaluation. On the other hand, a very specific test may miss significant pathology but is likely to establish the diagnosis, beyond doubt, when the result is positive.

In choosing how a test is used to guide decision-making, there is an inevitable trade-off between emphasising sensitivity versus specificity. For example, defining an exercise electrocardiogram (p. 534) as abnormal if there is at least 0.5 mm ST depression will ensure that very few cases of coronary artery disease are missed but will generate many false-positive tests (high sensitivity, low specificity). On the other hand, a cutoff point of at least 2.0 mm ST depression will detect most cases of important coronary disease with far fewer false-positives. This trade-off can be illustrated by the receiver operating characteristic curve of the test (Fig. 1.3).

Predictive value

The predictive value of a test is determined by its sensitivity and specificity, and can be expressed in several ways. The positive predictive value is the probability that a patient with a positive test has the index condition, while the negative predictive value is the probability that a patient with a negative test does not have the condition (see Box 1.5). The likelihood ratio expresses the odds that a given finding would occur in a patient with, as opposed to a patient without, the index condition (see Box 1.5); as the odds rise above 1, the probability that disease is present rises.

The interpretation and the utility of a test are critically dependent on the circumstances in which it is used. Bayes' theorem dictates that the value of a diagnostic test is determined by the prevalence of the condition in the test population. The probability that a subject has a particular condition (the post-test probability) can be calculated if the pre-test probability and the sensitivity and specificity of the test are known (Box 1.6). A test is most valuable when there is an intermediate pre-test probability of disease. Clinicians seldom have access to such precise information but must appreciate the importance of integrating clinical and laboratory data.

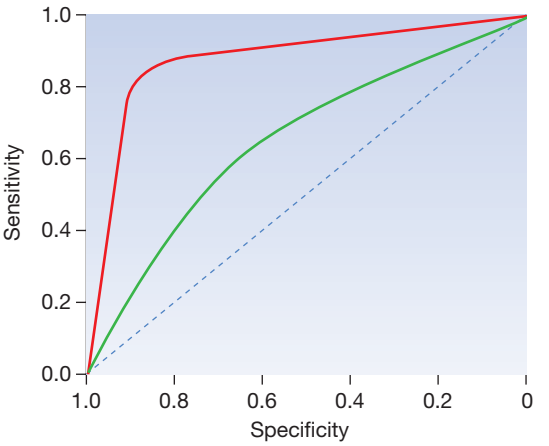

Fig. 1.3 Receiver operating characteristic graphs illustrating the trade-off between sensitivity and specificity for a given test. The curve is generated by 'adjusting' the cutoff values defining normal and abnormal results, calculating the effect on sensitivity and specificity and then plotting these against each other. The closer the curve lies to the top left-hand corner, the more useful the test. The red line illustrates a test with useful discriminant value and the green line illustrates a less useful, poorly discriminant test.

1.6 Bayes' theorem: post-test likelihood of disease

Positive test

$$\text{Post-test probability of disease} = \frac{\text{pre} \times \text{sens}}{(\text{pre} \times \text{sens}) + ((1 - \text{sens}) \times (1 - \text{spec}))}$$

Negative test

$$\text{Post-test probability of disease} = \frac{\text{pre} \times (1 - \text{sens})}{(\text{pre} \times (1 - \text{sens})) + ((1 - \text{pre}) \times \text{spec})}$$

(pre = pre-test probability of disease; sens = sensitivity; spec = specificity)

Example

Assume: Exercise tolerance testing for the diagnosis of coronary artery disease (CAD) (using cutoff of 2 mm ST depression) has 70% sensitivity (0.7) and 90% specificity (0.9) The pre-test odds of significant CAD in a 65-year-old woman with atypical angina on effort are 50% (0.5)

Post-test odds of significant CAD will be:

$$\text{Positive test } \frac{0.5 \times 0.7}{(0.5 \times 0.7) + (0.3 \times 0.1)} = 92\%$$

$$\text{Negative test } \frac{0.5 \times 0.3}{(0.5 \times 0.3) + (0.5 \times 0.9)} = 25\%$$

In contrast, the pre-test probability of significant coronary disease in a 45-year-old man with typical angina on effort would be 90%, with post-test odds of 95% in the event of a positive exercise test and 75% in the event of a negative test.

Screening

Many health-care systems run screening programmes to detect important (and treatable) disease in apparently healthy but at-risk individuals. These initiatives may be directed towards a single pathology (e.g. mammography for breast cancer, p. 280) or may comprise a battery

1.7 Factors that influence the cost-effectiveness of screening for a disease

- The prevalence of the disease in the target population
- The cost of the screening test
- The sensitivity and specificity of the screening test
- The availability and effectiveness of treatment
- The cost of not detecting and treating the disease

of tests for a wide range of conditions. Screening inevitably generates a number of false-positive results that require further, potentially expensive and sometimes risky, investigation. This may engender a good deal of anxiety for the patient and create dilemmas for the clinician; for example, it may be difficult to determine how to evaluate minor abnormalities of the liver function tests in an otherwise healthy person (p. 935).

Some of the criteria that must be considered before deciding if the wider costs of a screening programme can be justified are listed in Box 1.7.

Estimating and communicating risk

Medical management decisions are usually made by weighing up the anticipated benefits of a particular procedure or treatment against the potential risks. To allow patients to contribute to the decision-making process, health professionals must be able to explain risk in an accurate and understandable way.

Providing the relevant biomedical facts is seldom sufficient to guide decision-making because a patient's perception of risk is often coloured by emotional, and sometimes irrational, factors. Most patients will have access to information from a wide variety of sometimes conflicting sources, including the Internet, books, magazines, self-help groups, other health-care professionals, friends and family. The clinician must be aware of and sensitive to the way in which these resources influence the individual, while building trust with the patient, clarifying the problem and conveying the key facts.

Research evidence provides statistics but these can be confusing (Box 1.8). Relative risk describes the proportional increase in risk; it is a useful measure of the size of an effect. In contrast, absolute risk describes the actual chance of an event and is what matters to most patients. Terms such as 'common', 'rare', 'probable' and 'unlikely' are elastic. Whenever possible, clinicians should quote numerical information using consistent denominators (e.g. '90 of 100 patients who have this operation feel much better, 1 will die during the operation and 2 will suffer a stroke'). Positive framing ('There is a 99% chance of survival') and negative framing ('There is a 1% chance of death') may both be appropriate. A variety of visual aids can be used to present complex statistical information (Fig. 1.4).

Finally, it is essential to allow the patient to place his or her own weighting on the potential benefits and adverse effects of each course of action. Thus, some patients may choose to sacrifice a good chance of pain relief because they are not prepared to run even a small risk of paralysis, whilst others may opt to proceed with very high-risk spinal surgery because they find their current circumstances intolerable.

1.8 Explaining the risks and benefits of therapy

Would you take a drug once a day for a year to prevent stroke if:

- it reduced your risk of having a stroke by 47%?
- it reduced your chance of suffering a stroke from 0.26% to 0.14%?
- there was one chance in 850 that it would prevent you having a stroke?
- 849 out of 850 patients derived no benefit from the treatment?
- there was a 99.7% chance that you would not have a stroke anyway?

All these statements are derived from the same data and describe an equivalent effect.*

*MRC trial of treatment of mild hypertension (bendroflumethiazide vs placebo). BMJ 1985; 291:97–104.

Fig. 1.4 Visual portrayal of benefit and risks. The image refers to an operation that is expected to relieve symptoms in 90% of patients, but cause stroke in 2% and death in 1%. From Edwards, et al. 2002 – see p. 16.

Clinical decision-making

Assimilating symptoms, signs and results of investigations into a diagnosis and then planning treatment are highly complex tasks that require not only factual knowledge but also a highly developed set of skills in decision-making. Diagnostic decision-making is guided by Ockham's razor, originally expressed by the 14th-century Englishman William of Ockham as 'plurality should not be posited without necessity.' In short, all things being equal, the simplest explanation is the best. In practice, clinicians formulate hypotheses about the underlying diagnosis (or shortlist of diagnoses, the 'differential' diagnosis) during the consultation with the patient and refine this hypothesis both by collecting selected additional information and by choosing to ignore other information which they regard as irrelevant, in order to reach the most parsimonious diagnosis.

Decision-making in health care often operates under conditions of uncertainty, where it is uncertain what is wrong with the patient or which treatment is most appropriate. This can lead to variations in how clinicians

1.9 Heuristics in clinical decision-making

Availability

- The probability of an event is estimated based on how easily an individual can recall a similar event, e.g. a doctor judges that a patient has a particular disease because the case reminds him or her of a similar case seen recently
- This can lead to errors, as individuals often recall recent or vivid events more easily, rather than considering the likelihood of an event in the wider population

Representativeness

- The probability of an event is estimated based on how similar (or representative) it is of a wider category of events, e.g. a doctor judges that a patient has a particular disease because the patient's signs and symptoms are 'representative' of that disease
- This can lead to errors, such as neglecting to take into account the prevalence of the disease in a specific patient population

Anchoring and adjustment

- The probability of an event is estimated by taking an initial reference point (anchor) and then adjusting this to reach a final judgement about likelihood, e.g. a doctor judges that the likelihood of a patient having a particular disease is 60%. The doctor collects information (perhaps from diagnostic tests) and re-assesses his or her estimation on the basis of these results to reach a final diagnosis
- This can lead to errors, as final estimations of likelihood are linked to the original anchor, so if this is incorrect, the final judgement is also likely to be inaccurate

make decisions, and subsequently variations in the care that patients receive. Clinicians often employ a process of 'ad hoc' decision-making, where they use some form of global judgement about what might be the best course of action for an individual patient. These ad hoc decisions may be based on a number of factors, including what a clinician has been taught, his or her clinical experience of other patients with that particular disease, or what is common practice within a particular institution. However, such decisions may be governed by heuristics or bias, which may lead to errors. Heuristics are cognitive processes or 'rules of thumb' used unconsciously when making decisions (Box 1.9). Such processes may lead to mistakes, most commonly when there is a lack of evidence to inform practice. Whenever possible, clinical decision-making should be guided by evidence-based medicine.

Evidence-based medicine

Patient treatment should be based on the integration of best research evidence alongside clinical expertise and patient values. The discipline of evidence-based medicine (EBM) came into being in order to introduce a more systematic approach to the use of evidence in making clinical decisions. This was made possible by:

- the development of statistical methods to analyse data systematically
- recognition of the importance of analysing all data, both published and unpublished
- the development of databases of relevant information and systems by which to access such information.

1.10 Categories in evidence-based medicine (EBM)*

Levels of evidence (in descending order of strength)

Ia	Evidence obtained from meta-analysis of randomised clinical trials
Ib	Evidence obtained from at least one randomised controlled trial
IIa	Evidence obtained from at least one well-designed controlled study without randomisation
IIb	Evidence obtained from at least one other type of well-designed quasi-experimental study
III	Evidence obtained from well-designed non-experimental descriptive studies, such as comparative studies, correlation studies and case studies
IV	Evidence obtained from expert committee reports or opinions and/or clinical experiences of respected authorities

Grades of recommendation

A	Directly based on level I studies
B	Directly based on level II studies *or* extrapolations from level I studies
C	Directly based on level III studies *or* extrapolations from level I or II studies
D	Directly based on level IV studies *or* extrapolations from level I, II or III studies

*From the Scottish Intercollegiate Guidelines Network (SIGN; see www.sign.ac.uk). This scheme is widely used, although other modified schemes exist.

The principles of EBM are based on the tenet that well-formulated questions about medical management can be answered by:

- conducting high-quality randomised controlled trials
- tracing all the available evidence
- critically appraising the evidence
- applying the evidence to the management of the individual patient.

EBM categorises different types of clinical evidence and ranks them according to their freedom from the various biases that beset medical research. It therefore places greater emphasis on evidence from a meta-analysis of randomised controlled trials than on a series of case reports or expert opinion (Box 1.10).

Guidelines and protocols

The terms 'clinical guidelines' and 'protocols' are often used together, yet they are inherently different.

Guidelines

Clinical guidelines aim to guide clinicians on how to manage specific clinical scenarios using the best available evidence. They have been in existence throughout the history of medicine, although many were based on tradition or authority. A large number of local, national and international bodies have produced guidelines, following a range of different methodologies (see www.evidence.nhs.uk). Some are based on systematic reviews of the medical literature and others on consensus of expert opinion. When considering guidelines, it is important for clinicians to be aware of the strength of the evidence on which the recommendations are based (see Box 1.10).

Properly developed guidelines recognise that medicine is an art as well as a science and that the evidence on which the guidelines are based is, strictly speaking, only applicable to the study population in the trial(s). Clinicians must therefore use their judgement to ascertain whether the recommendations are applicable to the patient in front of them.

Some guidelines are formulated not only from evidence-based best practice but also from cost-effectiveness (see below). An example in the UK is guidance produced by the government-commissioned body, the National Institute for Health and Clinical Excellence (NICE; see www.nice.org.uk). These guidelines recognise that health services have limited resources, and that treatments should be prioritised which offer the greatest improvement in health for the largest number of people per unit of resource.

Protocols

Whilst guidelines recognise the individuality of the patient and help clinicians decide on which action is best, protocols are far more directive and are written to be followed exactly. Protocols usually apply in situations where the clinical decision has already been made and an intervention is then being instigated. Protocols aim to ensure that treatment will be identical, irrespective of where and by whom it is given. For example, a guideline may help a multidisciplinary team decide which modality of treatment is best for someone with lung cancer by evaluating the best evidence alongside the individual psychosocial needs of the patient. However, once a decision has been made in favour of a certain treatment, e.g. chemotherapy, the clinician will be expected to follow a strict protocol outlining dosages, routes of administration and monitoring.

Cost-effectiveness

The best available health care can be expensive. No country can now afford to provide unlimited state-of-the-art medicine for all its citizens. Health-care systems must therefore take account of the cost-effectiveness of the treatments they provide. This can create difficult dilemmas for clinicians, who may be asked to withhold expensive but effective therapies (e.g. implantable defibrillators) from individual patients on the basis that the money will do more good for more patients if it is spent elsewhere (e.g. offering angioplasty to all acute myocardial infarction patients). Assessing the cost-effectiveness of interventions and allocating resources accordingly follows ethical principles such as justice, which are covered in greater detail below.

Quality-adjusted life years

Outcomes from health care can be measured in terms of changes in the quality and quantity of life. Life expectancy is easily defined but quality of life is difficult to measure. Nevertheless, it is possible to construct a continuum between perfect health (score 1), survival with no quality of life (score 0), and states that are perceived to be worse than death (minus score). Quality and quantity of life can then be combined in a measure known as the quality-adjusted life year (QALY). For example, an intervention that results in a patient living an additional 4 years with an average quality of life rated as 0.6 on the continuum would yield 2.4 QALYs (4×0.6). Thus a cost per QALY can be calculated and compared with other interventions (p. 32). This approach is not perfect but offers a means of comparing the cost-effectiveness of a wide range of treatments.

Another useful measure is the disability-adjusted life year (DALY), which is used by the World Health Organization to quantify the overall burden of disease in populations; it cumulatively estimates the number of years lost due to ill health, disability and death.

Practising medicine in low-resource settings

The challenges associated with medical care in low-resource areas cluster in four domains:

- *Prevention versus cure*. Prevention is easier, cheaper and more effective than cure for many diseases. On the other hand, curative medicine is immediate, highly visible and glamorous. This tension is most evident when a disease is common and the benefits of prevention have yet to be realised. The allocation of adequate resources for long-term prevention needs both political will and social acceptance.
- *Acute versus chronic care*. Treating chronic illness can be time-consuming and less immediately gratifying than acute emergency medicine. Facilities for chronic care are therefore accorded a low priority in many health-care systems. Unfortunately, this often results in patients who require long-term care being denied treatment altogether or being managed inappropriately in the acute sector.
- *The ideal versus the possible*. Most medical management guidelines are derived from studies that were conducted in well-resourced health-care systems. In trying to apply this knowledge to the developing world, there are tensions between best practice and what is possible. For example, anticoagulant therapy (p. 1018) may pose risks that were not evident in the studies that underpin guidelines if it is prescribed in areas where reliable laboratories are not available and medications that interact with warfarin are commonly purchased 'over the counter'.
- *Channels of health-care provision*. In developing countries, health care may be delivered through government-run public clinics (usually free or subsidised) or non-governmental organisations (sometimes subsidised but usually privately funded). Many of the available services are too costly for the average patient. There is a need for constructive cooperation between all of the health-care sectors.

The best possible practice is that which can be delivered within the available resources in a specific setting. Compassionate care given with empathy, understanding and good communication is always within the physician's reach, even when resources are inadequate.

Medical ethics

Ethics has been described as the 'science' of morality, and defines systems of moral values. Medical ethics is

concerned both with the standards of conduct and competence expected of medical professionals, some of which are captured in legislation, and with the study of moral problems raised by the practice of medicine. Recent advances in biomedical science and their application to clinical care have thrown up many difficult ethical problems. These include human cloning, predictive genetic testing, eugenics, new reproductive technologies, antenatal screening, abortion, priority-setting, under-served populations, brain death, organ transplantation, end-of-life issues, and assisted suicide. Detailed discussion of these is beyond the scope of this chapter but a framework for the application of ethics to medical practice is described.

In general, ethical problems relate to the intentions or motives of those involved, their actions, the consequences of their actions, and the context in which their actions take place. Ethical problems can be analysed in a variety of ways, sometimes leading to different conclusions. To find the best solution, it may be necessary to apply several analytical approaches and attempt to reconcile the conclusions. In modern medical practice, there is not always time to do this systematically. However, the process of applying an ethical framework to a given situation is a key element in clinical decision-making and helps to ensure that a decision is both morally acceptable and legally defensible.

- *Virtue ethics* is concerned with the character of the persons involved and with their actions. Are my intentions (what my actions aim at) and my motives (what moves me to act) good or bad, wise or unwise, sensible or unrealistic, patient-centred or self-centred, and so on? Is the action I propose to take one which would be considered appropriate by a prudent doctor – or by a prudent patient? The focus here is on the characteristics of a virtuous person and the action they would take.
- *Deontological ethics* is concerned with whether a proposed action or course of action, in itself and regardless of its consequences, is right or wrong. Is it ever right or always wrong to kill, to tell a lie, to break a promise? Deontological (from the Greek for 'duty') considerations include rights as well as duties, and omissions as well as acts. An action is right if it is in accordance with an established moral rule or principle.
- *Teleological ethics* (or consequentialism) is concerned with the consequences of a proposed action. Are they likely to be good or bad, in the short term and long term, for the patient, doctor, family and society? What will promote a net balance of good over harm for the individual, as well as 'the greatest good for the greatest number'?

An ethical problem can therefore be addressed by trying to decide what a virtuous person would do, whether an action or course of action is right or wrong in itself, or what its consequences might be. Yet the circumstances in which any decision is made will vary, and what may be right in one context may be wrong in another. *Situation ethics* recognises this, emphasising the need to consider carefully the context (or situation) in which a course of action is chosen.

Ethics is applied to the practice of medicine in three broad areas:

- *Clinical ethics* deals with the relationship between clinicians and patients, as described below.
- *Public health ethics* deals with the health issues of groups of people – the community. Examples include the banning of smoking in public places, where the autonomy of the individual may be coerced for the greater good of the community.
- *Research ethics* deals with issues related to clinical research. This is to ensure not only that research is conducted safely but also that the rights of the participants are paramount. No research can be undertaken unless it has undergone ethical scrutiny.

Principles of clinical ethics

In clinical ethics, four key principles are frequently used to analyse a problem, and often abbreviated to 'autonomy, beneficence, non-maleficence and justice'.

Respect for persons and their autonomy

This respect is a significant aspect of the relationship between patient and doctor. The patient seeks out a doctor based on a desire to attain freedom from a disability or disease which limits his or her ability to exercise autonomy (the power or right of self-determination). Unless the patient is a child, is unconscious or is mentally incapacitated, it is the patient's choice to seek advice. The physician must therefore respect the patient's autonomy. This includes the patient's right to refuse therapy. The doctor must also actively seek to empower the patient with adequate information.

Truth-telling

Telling the truth is essential to generating and maintaining trust between the doctor and the patient. This includes providing information about the nature of the illness, expected outcome and therapeutic alternatives, and answering questions honestly. The facts should not be given 'brutally' but with due sensitivity to appropriate timing and to the patient's capacity to cope with bad news. However, the clinical uncertainties described earlier in the chapter must also be acknowledged. There are two rare situations where the truth may, at least for a time, be withheld:

- If it will cause real harm to the patient (e.g. a depressed patient likely to commit suicide who has to be told that he or she has cancer). This is sometimes called 'therapeutic privilege', since it should be exercised only in the patient's interests, for serious clinical reasons.
- If the patient makes it clear that he or she does not want to hear the bad news (but always bearing in mind that this may be a stage in the patient's adjustment to the condition).

In no case should false information be given, and the physician should always be prepared to justify any decision to withhold relevant information.

Informed consent

This term describes the participation of patients in decisions about their health care. In order to facilitate this, the clinician must provide the patient with an adequate explanation and details of the relevant risks, benefits and uncertainties of each possible course of action. The amount of information to provide will

vary, depending on the patient's condition and the complexity of the treatment, and on the physician's assessment of the patient's understanding of the situation. Not all options need be explained, but those that a 'prudent patient' would consider significant should be explored – for example, by open questioning (see Box 1.4, p. 4).

From both a legal and an ethical perspective, the patient retains the right to decide what is in his or her best interests. All adults have decision-making capacity if they can understand the relevant information (which may have to be explained in simple terms), consider the implications of the relevant options, and make a communicable decision. If a patient makes choices that seem irrational or are at variance with professional advice, it does not mean that they lack capacity.

When the patient does lack decision-making capacity, the clinician should always act in the best interests of the patient. In an emergency, consent may be presumed, but only for treatment immediately necessary to preserve the patient's life and health, and if there is no clear evidence that this would be against the previous settled wishes of the patient when competent (for example, blood transfusion in the case of an adult Jehovah's Witness). If the patient has a legally entitled surrogate decision-maker, their consent should be sought if possible. It is also good practice to involve close relatives in decision-making but the hierarchy of surrogate decision-makers will depend on local laws and culture.

Confidentiality

Confidentiality in relation to the management of patient-specific information is important in generating and maintaining trust in the doctor–patient relationship. Health-care teams must take precautions to prevent unauthorised access to patient records, and may disclose patient-identifying information only when the patient has given consent or when required by law. When such information is shared with other health-care professionals in order to optimise patient care, this should be done on a strictly 'need-to-know' basis.

Beneficence

This is the principle of doing good, or acting in another person's best interests. In clinical ethics, the term refers to the good of the individual patient. It means considering the patient's view, as well as the medical view, of his or her own best interests. Situations may arise when there is a conflict between what is good for the individual and what is best for society, but the traditional medical approach is that stated in the Declaration of Geneva (World Medical Association): 'The health of my patient will be my first consideration.'

Non-maleficence

This is the principle of doing no harm: in medicine, the traditional 'primum non nocere'. In balancing beneficence and non-maleficence (benefit versus risk), the clinician must share information with the patient, who can then be helped to make an informed decision.

Justice

In the context of clinical ethics, justice relates primarily to the distribution of medical care and the allocation of resources. In order to distribute health resources justly, the concept of utility – 'greatest good for the greatest number' – must be considered. In the case of individual patients, however, justice is also equated with being 'fair' and 'even-handed'. The concept of fair delivery of health care can be viewed from three perspectives:

- Respect for the *needs* of the individual. Health care is delivered first to those who need it most. This perspective is particularly relevant when need must be assessed by some kind of triage.
- Respect for the *rights* of a person. Everyone who needs health care is entitled to a fair share of the resources available. This perspective is particularly relevant when local or global economic, social, educational or other inequalities prevent or reduce equitable access to health care.
- Respect for *merit*. Health care is delivered on the basis of value judgements, according to financial, political, social or other factors relating to the value of the individual to society. For example, many national leaders have their own personal physician and medical teams. The relevance of this perspective to health care is widely disputed, not least because such value judgements are difficult to make in practice and to defend ethically.

Types of ethical problem

When faced with an ethical problem, it is often helpful to characterise it in terms of certain patterns (Fig. 1.5).

A gap or block

The ideal goal is clearly seen but there are major obstacles to achieving it. The obstacles may be economic or social, or in the belief system of the patient. The obvious answer – to bridge the gap or remove the block – may not be possible within the available time frame and resources. A young boy from a poor family in a developing country, who has Wilson's disease and needs a liver transplant, is an example of an economic block. Some problems of this kind cannot be resolved satisfactorily in the clinical context until or unless they are resolved in the economic or political context.

Priority-setting

The right course of action is clear but prioritisation is necessary and the principles to guide that process have to be defined. A decision to allocate the last bed in intensive care to either an 80-year-old with pneumonia or a 20-year-old with advanced lymphoma is an example. While it is not possible to cover all eventualities, guidelines agreed in advance with stakeholders are helpful.

A moral dilemma

Acting in accordance with one ethical principle may conflict with another ethical principle. This can create a moral dilemma – a choice between two alternatives, neither of which is ethically satisfactory. For example, a physician may decide that a particular mode of therapy is best (principle of beneficence), while the patient makes a different choice (principle of respect for autonomy). Consider artificial feeding by a percutaneous endoscopic gastrostomy (PEG; p. 123). The doctor may be reluctant to see the patient die for lack of nutrition and believe that this is the best route for feeding. The patient may, however, refuse the procedure, based on an informed

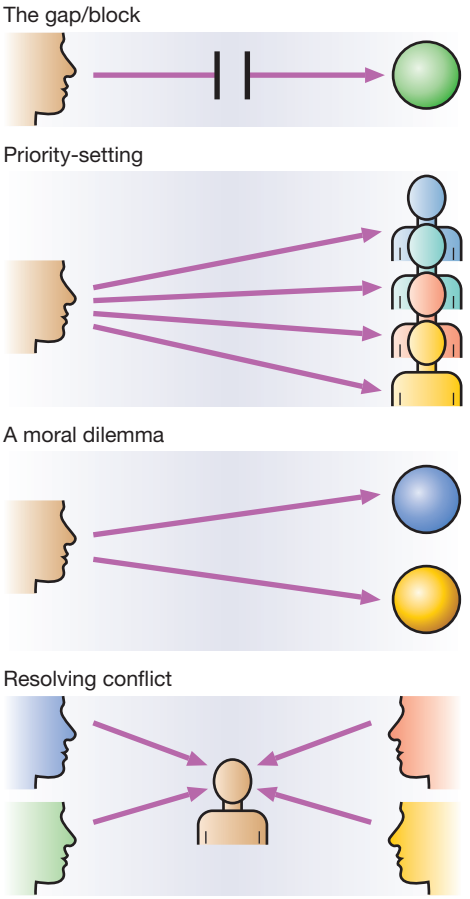

Fig. 1.5 A classification of ethical problems.

assessment of their own quality of life and prospects of recovery. In theory, the dilemma can be resolved only if one of the ethical principles is given priority; ethical analysis (see below) can help to achieve resolution. True moral dilemmas are less common in practice than in theory; apparent dilemmas can often be resolved by good doctor–patient communication.

Resolving conflict

A conflict of opinion may arise between members of the team responsible for care of the patient. For example, doctors in a renal medicine unit providing dialysis therapy (p. 489) may have divergent views on whether this treatment is appropriate for a patient who is elderly with significant comorbidity. Differing views should normally be resolved through discussion; in this example, conflict would usually be resolved in a multidisciplinary team meeting at which discussion of patients approaching end-stage renal failure is routine. However, if this does not work, referral to a decision-making authority allocated in advance (e.g. the clinical director of the service) may be necessary. The challenge then is to ensure consistent and accurate implementation of the decision.

Ethical analysis

Ethical analysis (or moral reasoning) is the process of thinking through ethical problems and reaching a conclusion. It helps the decision-maker to grow personally and professionally, allows communication of the process by which a decision is made, and permits the process to be constructively criticised. When, in everyday practice, time for reflection is limited, knowledge of methods of moral reasoning provides a useful background and aid for decision-making, and is often employed in ways analogous to those of 'the novice–expert shift' (see Box 1.14, p. 14). Some approaches that can be applied are as follows:

- *A principles approach*. This involves analysing an ethical problem in terms of the principles of respect for autonomy, beneficence, non-maleficence and justice. If all of these principles support a particular course of action, then that course of action is probably correct and there may, in fact, no longer be an ethical problem. If, however, different principles suggest different courses of action, this approach has no intrinsic mechanism for deciding which principle has priority. On the other hand, analysing the problem in terms of these principles can help to clarify the nature of the ethical problem and the issues which need to be addressed if the problem is to be resolved.
- *A casuistry (cases) approach*. This uses precedent as a guide to what to do. A case is recalled or imagined which is similar to that under discussion but where the right choice of action/behaviour was obvious. Then the features which make the present case different, if any, are analysed and considered to see if and why they lead to a different conclusion. A variation on this approach, related to virtue ethics, is to imagine what a physician who was particularly skilled or experienced in this type of situation would do, or how a previous patient might have viewed the problem.
- *A perspectives (or narrative) approach*. A perspectives approach involves considering the views of all the stakeholders: the patient, the family or carers, the health-care team, the health service and society. The greater the degree of concordance of these views on a particular outcome, the more likely it is that the decision leading to that outcome is right. A narrative approach is similar but involves listening attentively to the different 'stories' told by the stakeholders about the problem and how they perceive it. Where these stories differ can provide clues to a more nuanced understanding of the problem and how it might be resolved.
- *A counter-argument approach*. A particular course of action is chosen and the best ethical arguments against it are then marshalled and evaluated. This may or may not cause the decision to be reconsidered.
- *Application of rules*. In certain common and clearly defined situations, externally imposed rules (including the law) may require, or guide towards, a specific course of action. This does not obviate the need for ethical analysis. Moreover, any such rules must be reviewed regularly.

While all of these approaches may be useful, it is important to remember that none of them removes the need, on the one hand, for the exercise of judgement and, on the other, for good communication and consensus decision-making. No less important is the

1.11 Ethical analysis: an 'onion-peel' approach

Patient preferences: data gathered from patient and relatives/carers
• What is the quality of life expected after therapy – from the patient's perspective? • If the patient is competent, has he or she been offered options and made choices? • If the patient is not competent, who will make the decisions?
Medical goals: data gathered from literature, guidelines, expert opinion
• What are the prospects of a successful outcome? • What are the best therapeutic options available based on evidence? • Has the therapy been optimised and matched to this individual patient?
Regional issues: data gathered from local sources
• What decisions are most consistent with local laws and with social and cultural values?
Basic ethical principles, type of ethical problem, ethical analysis (see text)
• Consider the basic principles of medical ethics • Consider the type of ethical problem • Choose the ethical analytical approaches to apply to the problem

requirement for all of this to be based on sound and shared information about the clinical and human facts of the case. In this respect, a practical, integrated way of addressing ethical problems is provided by what has been called *an onion-peel approach*, which uses a layered framework to analyse the problem systematically (Box 1.11).

Discussion with colleagues and others is crucial in reaching ethical decisions. Many hospitals have a clinical ethics committee to review difficult decisions. Up-to-date, accurate, valid and reliable data should inform the decision-making progress. Local legal issues must be considered. Once a conclusion has been reached, a strategy to complete the action must be implemented. Post-hoc evaluation of decisions is important, and again is best carried out collectively by an ethics committee or some other means of retrospective review.

A clinical ethics scenario

A 70-year-old man who has chronic obstructive pulmonary disease, hypertension and diabetes mellitus is admitted to hospital with pneumonia. His memory has been deteriorating for 3 years, with a rapid decline in cognition over the last 3 months, and he needs help to carry out activities of daily living. A neurologist has excluded reversible causes of dementia. The patient deteriorates and needs mechanical ventilation. His wife states that he told her (when he was well) that he did not want to be put on 'life support machines' and is therefore opposed to mechanical ventilation. Two of his children fail to confirm this and request active treatment. There is no formal written 'advance directive' on file (pp. 171 and 291). What care should be given?

On the one hand, considered mainly in teleological terms:

The patient is incapable of making an autonomous decision. The closest surrogate indicates that he would have preferred to forego life-sustaining therapy at this stage. (Respect for autonomy might support this.) The consequences of ventilation would probably be to prolong the process of dying (which non-maleficence could argue against) rather than increase his chances of recovery to a good quality of life. Beneficence requires that he receive general care and symptom relief immediately. An appropriate action therefore is not to ventilate the patient but to continue basic medical (fluids, oxygen and antibiotics) and nursing care in a general ward setting in order to optimise patient comfort.

On the other hand, considered in deontological as well as teleological terms:

The present illness is due to a potentially reversible infection. The patient's real preference is uncertain and his family, who have difficulty in looking after him, have expressed differing views. In terms of the duty of a doctor to make the patient's health the first consideration, and of the patient's right to appropriate health care regardless of his age or mental condition, it would therefore be appropriate to institute all possible care, including ventilation on an intensive care unit.

In practice:

The physician responsible for the patient's care should consider the different courses of action suggested, but not determined, by these ethical analyses, explain the reasons for and against each course of action to the patient's family and, if one of them is the patient's legal surrogate, help that person come to a decision. Where there is no legal surrogate, the physician will have to reach a judgement about what is in the patient's best interests, recognising that, while judgement is always fallible, whatever decision is made must be defensible if challenged on ethical or legal grounds. Decisions that are reached on the basis of ethical and moral reasoning will be relatively easy to defend.

In this case, further discussion of the relevant issues with the relatives and other members of the health-care team led to concordance. The patient was treated by artificial ventilation in the intensive care unit for 3 days. He made a good recovery and appeared grateful for the care he had received.

Medical law

The law impinges on medical practice in many ways. Although a description of specific laws in different countries is beyond the scope of this book, it is important for doctors to be familiar with local legislation. Some of the ethical principles described above are captured in legislation, for example, in relation to informed consent (p. 10) and confidentiality (p. 11). Other laws enforce standard requirements for formal procedures, such as death certification. In many countries, regulatory authorities with statutory powers – for example, to license doctors to practise – also impose standards. The distinction and overlap between these domains are illustrated in Box 1.12.

1.12 Some definitions in ethics, law and regulation of medical practice

	Definition	In practice
Ethics	The science of morality; a branch of philosophy concerned with human character and conduct	Morally, what may be the best thing for me to do in this situation?
Law	Rules of action established by authority (normally, a community or state)	What must I do in this situation to avoid breaking the law?
Negligence	Omission of duty and such care for the interests of others as the law may require	What would any 'ordinarily competent' doctor do in this situation?
(Practice) guidance	Direction from another person or body	What do a group of experts say that I should do, supported by the best available evidence (e.g. guidelines, protocols)?
(Clinical) governance	Control, autonomy	What will I and the members of my medical team do, with due regard to ethics, law and practice guidelines?

A high-profile area of overlap between medicine and the law occurs in legal action (litigation) related to processes of care. The latter frequently involves the concept of negligence. In the UK, the 'Bolam test' is often used to define whether medical care is or is not negligent. Care is measured against what any 'ordinarily competent' (or sometimes 'reasonable') doctor would have done in the same situation. In addition to this test, it must also be established that:

- there was a *duty of care* between the doctor and patient (this is usually straightforward)
- there was a *causal link* between any breach of duty and harm to the patient
- the harm was not too *remote* from the episode of care.

PERSONAL AND PROFESSIONAL DEVELOPMENT

Good doctors never stop learning, and continue to develop their knowledge, skills and attributes throughout their working lives, to the benefit of their patients and themselves. Many also participate actively in improving medical knowledge and practice through research. These activities have become an essential component of clinical governance, which is a mechanism for ensuring high standards of clinical care (Box 1.13). Personal and professional development (PPD) requires a reflective and self-directed approach to the study and practice of medicine (Fig. 1.6), and will maximise both lifelong effectiveness and personal satisfaction. Linked to this is the concept of the novice–expert shift (Box 1.14).

PPD begins in the first days at medical school and continues through postgraduate training and subsequent professional practice. Maintaining competence and expertise requires continuous professional development (CPD). In the UK, this is formally regulated by professional bodies such as the Royal Colleges, and is linked to processes of appraisal (Box 1.15) and re-accreditation for established practitioners.

To support this process, outcomes and competences for PPD are being defined at all levels of medical training, including undergraduate and postgraduate study. These sit alongside and complement curricula that focus on discipline-based knowledge and skills. As adult learners, doctors are expected to reflect on their own practice and identify their own particular learning or developmental needs. This recognises that doctors will have different learning needs throughout their career, which will be affected by their current clinical practice, their future career plans and any areas of educational need that have become apparent through the appraisal process.

1.13 Key components in clinical governance

- Continuing education
- Clinical audit
- Clinical effectiveness
- Risk management
- Research and development
- Openness

1.14 The novice–expert shift

- **Novices** use pre-determined methods which they learn
- **Advanced beginners** recognise that these methods are not effective in all circumstances and can adapt them
- **Competent professionals** are able to make conscious, independent choices and can manage and regulate their own practice
- **Proficient professionals** make use of intuition based on experience, and integrate multiple aspects of practice into a holistic model
- **Experts** function largely through 'unconscious competence' and are inseparable from the tasks they undertake

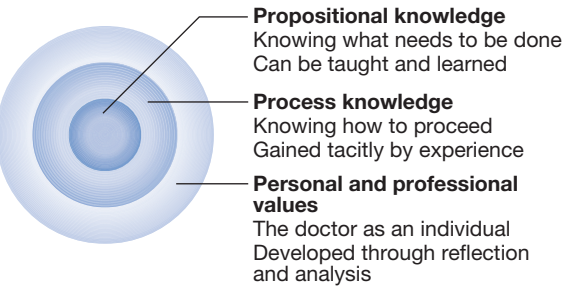

Fig. 1.6 The personal and professional development of a doctor.

1.15 Some techniques used in the appraisal process

- Formal, structured assessment (e.g. postgraduate examinations)
- 360-degree assessment (surveying colleagues from medicine and other disciplines who work alongside the practitioner)
- Educational supervision and mentoring (a specific colleague has nominated responsibility to guide, and also assess, the practitioner)
- Logbooks (records of work undertaken and outcomes)
- Portfolio-based assessment (the practitioner accumulates a record of educational and clinical experiences, together with evidence of reflective practice)

Each doctor has a duty to ensure that their clinical knowledge and skills are up to date and comparable with their peers. Clinical audit is one method of assessing practice in this context.

Clinical audit

Clinical audit is the process by which the clinical practice of a doctor or medical team and the outcomes of that practice are evaluated against an agreed standard. Where practice fails to meet the standard, changes to practice are implemented; after a period, practice can be re-evaluated to identify any improvement. The continuing evaluation, implementation of change and re-evaluation process is known as the audit loop or cycle (Fig. 1.7). The standard against which practice is measured is usually an externally agreed one, rather than a local one. It is important to know that clinical care is comparable to that delivered elsewhere. For this reason, national standards are the norm in most countries, often set alongside national guidelines which signpost the practice necessary to achieve them. Clinical audit may be conducted by the doctor or team themselves, or by an external body. Outcome measures may include success rates or complication rates of clinical procedures such as surgical operations; process variables such as waiting times for clinical care; or the perspective of patients and relatives. In the UK, all practising clinicians are now expected to participate in audit, and it is an integral part of procedures for appraisal, revalidation and relicensing of doctors.

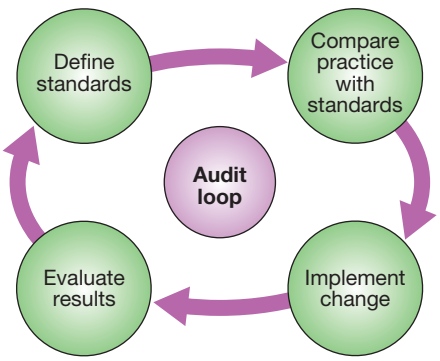

Fig. 1.7 The clinical audit loop.

COMPLEMENTARY AND ALTERNATIVE MEDICINE

Complementary and alternative medicine (CAM) refers to a group of medical and health-care systems, practices and products that are not considered to be part of conventional medicine; as such, the relevant principles and skills are not included in the curricula of conventional medical education programmes. CAM covers an enormous and ever-changing range of activities, from well-established physical therapies such as osteopathy to spiritual measures such as prayer specifically for health. Proponents suggest that CAM focuses on the whole person: their lifestyle, environment, diet, and mental, emotional and spiritual health, as well as physical complaints.

'Complementary medicine' is the term used to describe the use of these treatments in conjunction with conventional medicine (e.g. acupuncture to reduce pain after surgery). 'Alternative medicine' describes their use in place of conventional medicine (e.g. reflexology instead of anti-inflammatory drugs for arthritis). Clearly, most forms of treatment can be used in either way, so the term CAM is often used generically. 'Integrative medicine' describes the use of conventional therapy in combination with one or more complementary therapies.

A variety of different taxonomies are used for CAM therapies. The National Center for Complementary and Alternative Medicine in the USA uses the following classification:

- *Alternative medical systems*. These have their own constructs of theory and practice, often based on ancient historical beliefs. Examples are homeopathy, naturopathy, traditional Chinese medicine and Ayurveda.
- *Mind–body interactions*. These rely on the mind's capacity to influence physical function. Examples are meditation, biofeedback, prayer for healing, mental healing, music therapy and dance.
- *Biologically based therapies*. These involve the use or regulation of an extraneous agent or preparation. Examples include herbal medicine, dietary supplementation and nutritional medicine.
- *Manipulative and body-based methods*. These are based on manipulation or movement of parts of the body. They include osteopathy, chiropractic, reflexology and massage.
- *Energy therapies*. These involve use of energy fields. Examples include qigong, reiki and therapeutic touch.

Some forms of CAM are embedded in the cultural norms of particular social and ethnic groups, e.g. traditional Chinese medicine. In Western society, the use of CAM is extensive. For example, in 2007 in the USA, 38% of the adult population had used some form of CAM in the previous year (males 33.5%, females 42.8%); 12% of children had also used CAM. The most common medical conditions involved were back pain, neck pain, other joint pain/arthritis, anxiety, raised cholesterol, head or chest 'colds', headache, insomnia, stress and depression, and gastrointestinal symptoms.

The popularity of CAM may reflect a lack of confidence in conventional medicine, particularly a belief that

it will not help the condition or may cause harm. CAM is often used by cancer patients who have disease which is unresponsive to conventional medicines. In addition, it may reflect the increasing ease of access to information and therapies via the Internet. CAM is often perceived to be completely safe; patients may therefore be willing to experiment with it as a 'no-lose' measure. Many forms of CAM are inherently pleasurable, regardless of any therapeutic benefit.

Safety

Not all CAM therapies are safe; some are toxic in their own right (e.g. dietary supplements containing ephedrine alkaloids, now banned in the USA) and others are harmful if used in combination with conventional treatment (e.g. garlic supplements that interfere with the action of anti-HIV chemotherapy). Others have been associated with rare but serious side-effects, which can be life-threatening (e.g. bowel perforation from coffee enemas, hyponatraemia from noni juice).

There is also a potential for harm when alternative medicine is used to treat serious or life-threatening medical conditions, if the resultant delay in seeking conventional treatment compromises clinical outcome.

On balance, however, the relative safety of most CAM therapies can be regarded as a positive feature; homeopathy is an example.

Evidence

In an era where EBM is the norm, practitioners and advocates of CAM are increasingly challenged to justify these treatments through independent, well-conducted, randomised controlled clinical trials. In some cases, this may be difficult (e.g. the placebo arm of a double-blind trial of acupuncture). In addition, it can be argued that different types and standards of evidence, focusing on patient satisfaction and subjective benefit rather than measurable clinical outcomes, may be more appropriate for CAM. The literature in this area is growing rapidly but, at present, only a minority of CAM therapies are supported by any evidence that would be acceptable for conventional medicine. These are primarily the 'big five' CAM therapies: osteopathy, chiropractic, acupuncture, homeopathy and herbal medicine. Moreover, where such positive evidence does exist, it is often outweighed by negative studies, and limited to a small subset of the clinical conditions for which the treatment is used.

Regulation

Many CAM therapies have professional regulatory frameworks in place and others are following suit. Nevertheless, for many CAM therapies, there is still no established structure of training, certification and accreditation, and practice is effectively open to all. Set against the demanding training and life-long continuous professional development that pertain to conventional medicine, this constitutes an important barrier to integrative medicine.

Integrated health care

There is a considerable impetus behind moves to integrate CAM with conventional medicine and health care at the level of resource allocation, service design, clinical practice, education and research. Almost 50% of general practices in the UK and an increasing number of hospitals offer some form of access to CAM. In many parts of Asia in particular, this kind of medical pluralism is the norm, and patients do not necessarily make a distinction between different systems of health care. Historically, in Western societies, patients using both types of therapy have often experienced conflicting advice and value judgements, poor or absent communication between practitioners, and even hostility or ridicule. They often revert to secrecy, an inherently undesirable and potentially dangerous outcome. Integrated health care aims to understand and remove the barriers that create such dilemmas for patients. It aims to let them exercise their choice of treatment in an open environment characterised by good communication, respect, and due consideration of autonomy, efficacy and risk.

Managing the use of medicines 31

Prescribing in practice 33
Decision-making in prescribing 33
Prescribing in special circumstances 36
Writing prescriptions 37
Monitoring drug therapy 39

Prescribing medicines is a major tool used by most doctors to restore or preserve the health of their patients. Medicines contain drugs (the specific chemical substances with pharmacological effects), either alone or in combination, in a formulation mixed with other ingredients. The beneficial effects of medicines must be weighed against their cost and the risks of adverse drug reactions and interactions, often caused by injudicious prescribing decisions and by prescribing errors. The modern prescriber must meet the challenges posed by an increasing number of drugs and formulations available and of indications for prescribing them, and the greater complexity of treatment regimens followed by individual patients ('polypharmacy', a particular challenge in the ageing population). The purpose of this chapter is to elaborate on the principles and practice that underpin good prescribing (Box 2.1).

2.1 Steps in good prescribing

- Make a diagnosis
- Consider factors influencing the patient's responses to therapy (age, concomitant drug therapy, renal and liver function etc.)*
- Establish the therapeutic goal*
- Choose the therapeutic approach*
- Choose the drug and its formulation (the 'medicine')
- Choose the dose, route and frequency
- Choose the duration of therapy
- Write an unambiguous prescription (or 'medication order')
- Inform the patient about the treatment and its likely effects
- Monitor treatment effects, both beneficial and harmful
- Review/alter the prescription

*These steps in particular take the patient's views into consideration to establish a therapeutic partnership.

PRINCIPLES OF CLINICAL PHARMACOLOGY

Prescribers need to understand what the drug does to the body (pharmacodynamics) and what the body does to the drug (pharmacokinetics) (Fig. 2.1). Although this chapter is focused on the most common drugs, which are synthetic small molecules, the same principles apply to the increasingly numerous 'biological' therapies (sometimes abbreviated to 'biologics') now in use, which include peptides, proteins, enzymes and monoclonal antibodies (p. 74).

Pharmacodynamics

Drug targets and mechanisms of action

Modern drugs are usually discovered by screening compounds for activity either to stimulate or to block the function of a specific molecular target, which is predicted to have a beneficial effect in a particular disease (Box 2.2). Other drugs have useful but less selective chemical properties, such as chelators (e.g. for treatment of iron or copper overload), osmotic agents (used as diuretics in cerebral oedema) or general anaesthetics

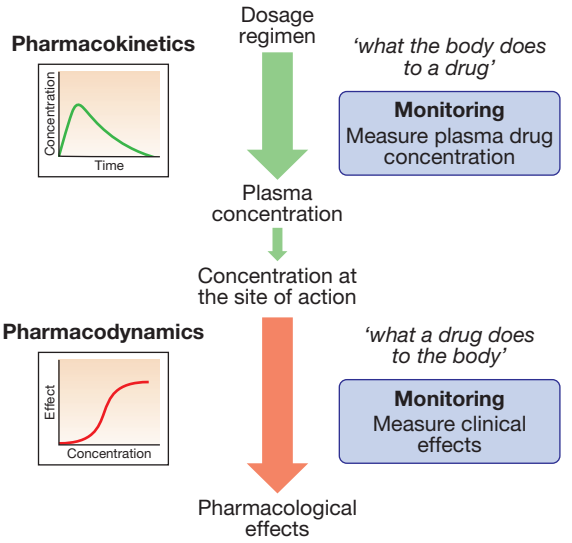

Fig. 2.1 Pharmacokinetics and pharmacodynamics.

(that alter the biophysical properties of lipid membranes). The following characteristics of the interaction of drugs with receptors illustrate some of the important determinants of the effects of drugs:

- *Affinity* describes the propensity for a drug to bind to a receptor and is related to the 'molecular fit' and the strength of the chemical bond. Some drug–receptor interactions are *irreversible*, either because the affinity is so strong or because the drug modifies the structure of its molecular target.
- *Selectivity* describes the propensity for a drug to bind to one target rather than another. Selectivity is a relative term, not to be confused with absolute specificity. It is common for drugs targeted at a particular subtype of receptor to exhibit some effect at other subtypes. For example, β-adrenoceptors can be subtyped on the basis of their responsiveness to the endogenous agonist noradrenaline (norepinephrine): the concentration of noradrenaline required to cause bronchodilatation (via β_2-adrenoceptors) is ten times higher than that required to cause tachycardia (via β_1-adrenoceptors). 'Cardioselective' β-blockers have anti-anginal effects on the heart (β_1) but may still cause bronchospasm in the lung (β_2) and are contraindicated for asthmatic patients.
- *Agonists* bind to a receptor to produce a conformational change that is coupled to a biological response. As agonist concentration increases, so does the proportion of receptors occupied, and hence the biological effect. *Partial agonists* activate the receptor, but cannot produce a maximal signalling effect equivalent to that of a full agonist even when all available receptors are occupied.
- *Antagonists* bind to a receptor but do not produce the conformational change that initiates an intracellular signal. A *competitive antagonist* competes with endogenous ligands to occupy receptor binding sites, with the resulting antagonism depending on the relative affinities and concentrations of drug and ligand. *Non-competitive*

2.2 Examples of target molecules for drugs

Drug target	Description	Examples
Receptors		
Channel-linked receptors	Ligand binding controls a linked ion channel, known as 'ligand-gated' (in contrast to 'voltage-gated' channels that respond to changes in membrane potential)	Nicotinic acetylcholine receptor γ-aminobutyric acid (GABA) receptor Sulphonylurea receptor
G-protein-coupled receptors (GPCRs)	Ligand binding affects one of a family of 'G-proteins' that mediate signal transduction either by activating intracellular enzymes (such as adenylate or guanylate cyclase, producing cyclic AMP or GMP, respectively) or by controlling ion channels	Muscarinic acetylcholine receptor β-adrenoceptors Dopamine receptors Serotonin receptors Opioid receptors
Kinase-linked receptors	Ligand binding activates an intracellular protein kinase that triggers a cascade of phosphorylation reactions	Insulin receptor Cytokine receptors
Transcription factor receptors	Intracellular and also known as 'nuclear receptors'; ligand binding promotes or inhibits gene transcription and hence synthesis of new proteins	Steroid receptors Thyroid hormone receptors Vitamin D receptors Retinoid receptors PPARγ and α receptors
Other targets		
Voltage-gated ion channels	Mediate electrical signalling in excitable tissues (muscle and nervous system)	Na^+ channels Ca^{2+} channels
Enzymes	Catalyse biochemical reactions. Drugs interfere with binding of substrate to the active site or of co-factors	Cyclo-oxygenase Angiotensin converting enzyme (ACE) Xanthine oxidase
Transporter proteins	Carry ions or molecules across cell membranes	Serotonin re-uptake transporter Na^+/K^+ ATPase

(AMP = adenosine monophosphate; ATPase = adenosine triphosphatase; GMP = guanosine monophosphate; PPAR = peroxisome proliferator-activated receptor)

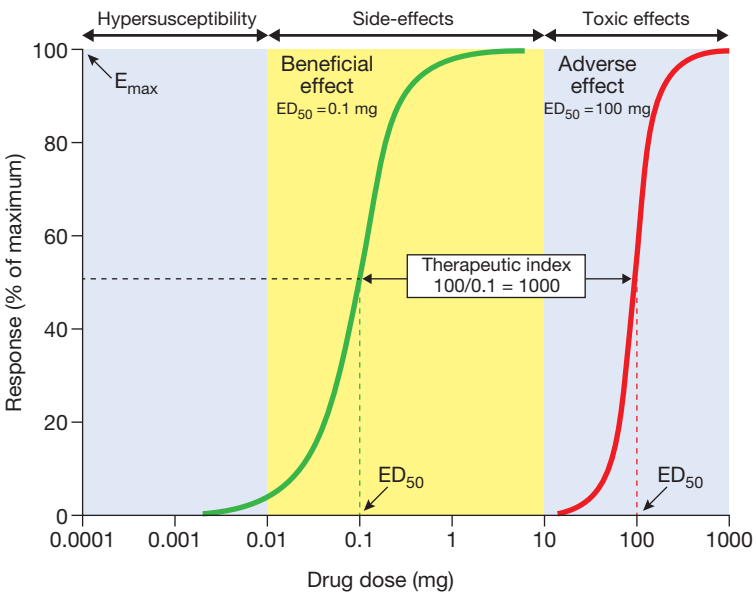

Fig. 2.2 Dose–response curve. The green curve represents the beneficial effect of the drug. The maximum response on the curve is the E_{max} and the dose (or concentration) producing half this value ($E_{max}/2$) is the ED_{50} (or EC_{50}). The red curve illustrates the dose–response relationship for the most important adverse effect of this drug. This occurs at much higher doses; the ratio between the ED_{50} for the adverse effect and that for the beneficial effect is the 'therapeutic index', which indicates how much margin there is for prescribers when choosing a dose that will provide beneficial effects without also causing this adverse effect. Adverse effects that occur at doses above the therapeutic range (yellow area) are normally called 'toxic effects', while those occurring within the therapeutic range are 'side-effects' and those below it are 'hyper-susceptibility effects'.

antagonists inhibit the effect of an agonist by mechanisms other than direct competition for receptor binding with the agonist (e.g. by affecting post-receptor signalling).

Dose–response relationships

Plotting the logarithm of drug dose against drug response typically produces a sigmoidal dose–response curve (Fig. 2.2). Progressive increases in drug dose (which for most drugs is proportional to the plasma drug concentration) produce increasing response, but only within a relatively narrow range of dose; further increases in dose beyond this range produce little extra effect. The following characteristics of the drug response are useful in comparing different drugs:

- *Efficacy* describes the extent to which a drug can produce a target-specific response when all available receptors or binding sites are occupied

(i.e. E_{max} on the dose–response curve). A full agonist can produce the maximum response of which the receptor is capable, while a partial agonist at the same receptor will have lower efficacy. *Therapeutic efficacy* describes the effect of the drug on a desired biological endpoint, and can be used to compare drugs that act via different pharmacological mechanisms (e.g. loop diuretics induce a greater diuresis than thiazide diuretics and therefore have greater therapeutic efficacy).

- *Potency* describes the amount of drug required for a given response. More potent drugs produce biological effects at lower doses, so they have a lower ED_{50}. A less potent drug can still have an equivalent efficacy if it is given in higher doses.

The dose–response relationship varies between patients because of variations in the many determinants of pharmacokinetics and pharmacodynamics. In clinical practice, the prescriber is unable to construct a dose–response curve for each individual patient. Therefore, most drugs are licensed for use within a recommended range of doses that is expected to reach close to the top of the dose–response curve for most patients. However, it is sometimes possible to achieve the desired therapeutic efficacy at doses towards the lower end of, or even below, the recommended range.

Therapeutic index

The adverse effects of drugs are often dose-related in a similar way to the beneficial effects, although the dose–response curve for these adverse effects is normally shifted to the right (see Fig. 2.2). The ratio of the ED_{50} for therapeutic efficacy and for a major adverse effect is known as the 'therapeutic index'. In reality, drugs have multiple potential adverse effects but the concept of therapeutic index is usually reserved for those requiring dose reduction or discontinuation. For most drugs, the therapeutic index is greater than 100 but there are some notable exceptions with therapeutic indices less than 10 (e.g. digoxin, warfarin, insulin, phenytoin, opioids). The doses of such drugs have to be titrated carefully for individual patients to maximise benefits but avoid adverse effects.

Desensitisation and withdrawal effects

Desensitisation refers to the common situation in which the biological response to a drug diminishes when it is given continuously or repeatedly. It may be possible to restore the response by increasing the dose of the drug but, in some cases, the tissues may become completely refractory to its effect.

- *Tachyphylaxis* describes desensitisation that occurs very rapidly, sometimes with the initial dose. This rapid loss of response implies depletion of chemicals that may be necessary for the pharmacological actions of the drug (e.g. a stored neurotransmitter released from a nerve terminal) or receptor phosphorylation.
- *Tolerance* describes a more gradual loss of response to a drug that occurs over days or weeks. This slower change implies changes in receptor numbers or the development of counter-regulatory physiological changes that offset the actions of the drug (e.g. accumulation of salt and water in response to vasodilator therapy).
- *Drug resistance* is a term normally reserved for describing the loss of effectiveness of an antimicrobial (p. 151) or cancer chemotherapy drug.
- In addition to these pharmacodynamic causes of desensitisation, reduced response may be the consequence of lower plasma and tissue drug concentrations as a result of altered *pharmacokinetics* (see below).

2.3 Examples of drugs associated with withdrawal effects

Drug	Symptoms	Signs	Treatment
Alcohol	Anxiety, panic, paranoid delusions, visual and auditory hallucinations	Agitation, restlessness, confusion, tremor, tachycardia, ataxia, disorientation, seizures	Treat immediate withdrawal syndrome with benzodiazepines
Barbiturates, benzodiazepines	Similar to alcohol	Similar to alcohol	Transfer to long-acting benzodiazepine then gradually reduce dosage
Corticosteroids	Weakness, fatigue, decreased appetite, weight loss, nausea, vomiting, diarrhoea, abdominal pain	Hypotension, hypoglycaemia	Prolonged therapy suppresses the hypothalamic–pituitary–adrenal axis and causes adrenal insufficiency requiring corticosteroid replacement. Withdrawal should be gradual after prolonged therapy (p. 776)
Opioids	Rhinorrhoea, sneezing, yawning, lacrimation, abdominal and leg cramping, nausea, vomiting, diarrhoea	Dilated pupils	Transfer addicts to long-acting agonist methadone
Selective serotonin re-uptake inhibitors (SSRIs)	Dizziness, sweating, nausea, insomnia, tremor, confusion, nightmares	Tremor	Reduce SSRIs slowly to avoid withdrawal effects

When drugs induce chemical, hormonal and physiological changes that offset their actions, discontinuation may allow these changes to cause 'rebound' withdrawal effects (Box 2.3).

Pharmacokinetics

Understanding 'what the body does to the drug' (Fig. 2.3) is extremely important for prescribers because this forms the basis on which the optimal route of administration and dose regimen are chosen and explains the majority of inter-individual variation in the response to drug therapy.

Drug absorption and routes of administration

Absorption is the process by which drug molecules gain access to the blood stream. The rate and extent of drug absorption depend on the route of administration (see Fig. 2.3).

Enteral administration

These routes involve administration via the gastrointestinal tract:

- *Oral*. This is the commonest route of administration because it is simple, convenient and readily used by patients to self-administer their medicines. Absorption after an oral dose is a complex process that depends on the drug being swallowed, surviving exposure to gastric acid, avoiding unacceptable food binding, being absorbed across the small bowel mucosa into the portal venous system, and surviving metabolism by gut wall or liver enzymes ('first-pass metabolism'). As a consequence, absorption is frequently incomplete following oral administration. The term 'bioavailability' describes the proportion of the dose that reaches the systemic circulation intact.
- *Buccal, intranasal and sublingual (SL)*. These routes have the advantage of enabling rapid absorption into the systemic circulation without the uncertainties associated with oral administration (e.g. organic nitrates for angina pectoris, triptans for migraine, opioid analgesics).
- *Rectal (PR)*. The rectal mucosa is occasionally used as a site of drug administration when the oral route is compromised because of nausea and vomiting or unconsciousness (e.g. diazepam in status epilepticus).

Parenteral administration

These routes avoid absorption via the gastrointestinal tract and first-pass metabolism in the liver:

- *Intravenous (IV)*. The IV route enables all of a dose to enter the systemic circulation reliably, without any concerns about absorption or first-pass metabolism (i.e. the dose is 100% bioavailable), and rapidly achieve a high plasma concentration. It is ideal for very ill patients when a rapid, certain effect is critical to outcome (e.g. benzylpenicillin for meningococcal meningitis).
- *Intramuscular (IM)*. IM administration is easier to achieve than the IV route (e.g. adrenaline (epinephrine) for acute anaphylaxis) but absorption is less predictable and depends on muscle blood flow.
- *Subcutaneous (SC)*. The SC route is ideal for drugs that have to be administered parenterally because of low oral bioavailability, are absorbed well from subcutaneous fat, and might ideally be injected by patients themselves (e.g. insulin, heparin).
- *Transdermal*. A transdermal patch can enable a drug to be absorbed through the skin and into the circulation (e.g. oestrogens, testosterone, nicotine, nitrates).

Other routes of administration

- *Topical* application of a drug involves direct administration to the site of action (e.g. skin, eye, ear). This has the advantage of achieving sufficient concentration at this site while minimising systemic exposure and the risk of adverse effects elsewhere.
- *Inhaled (INH)* administration allows drugs to be delivered directly to a target in the respiratory tree, usually the small airways (e.g. salbutamol,

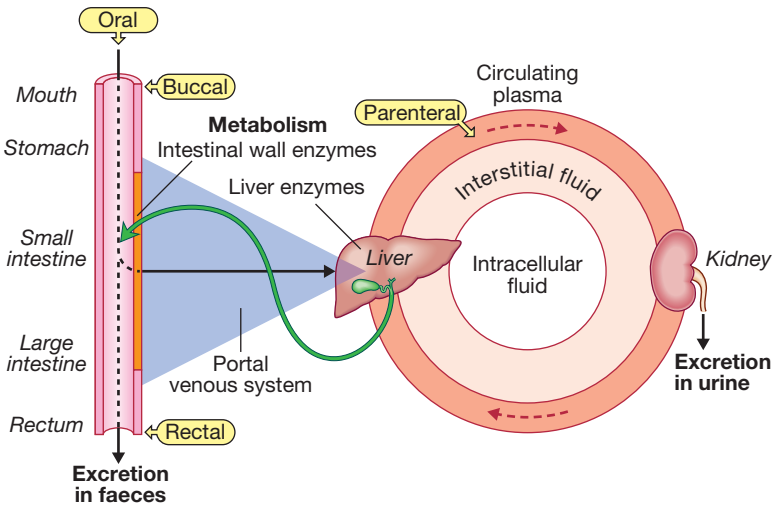

Fig. 2.3 Pharmacokinetics summary. Most drugs are taken orally, are absorbed from the intestinal lumen and enter the portal venous system to be conveyed to the liver, where they may be subject to first-pass metabolism and/or excretion in bile. Active drugs then enter the systemic circulation, from which they may diffuse (or sometimes be actively transported) in and out of the interstitial and intracellular fluid compartments. Drug that remains in circulating plasma is subject to liver metabolism and renal excretion. Drugs excreted in bile may be reabsorbed, creating an enterohepatic circulation. First-pass metabolism in liver is avoided if drugs are administered via the buccal or rectal mucosa, or parenterally (e.g. by intravenous injection).

beclometasone). However, a significant proportion of the inhaled dose may be absorbed from the lung or is swallowed and can reach the systemic circulation. The most common mode of delivery is the metered-dose inhaler but its success depends on some degree of manual dexterity and timing (see Fig. 19.23, p. 670). Patients who find these difficult may use a 'spacer' device to improve drug delivery. A special mode of inhaled delivery is via a nebulised solution created by using pressurised oxygen or air to break up solutions and suspensions into small aerosol droplets that can be directly inhaled from the mouthpiece of the device.

Drug distribution

Distribution is the process by which drug molecules transfer into and out of the blood stream. This is influenced by the drug's molecular size and lipid solubility, the extent to which it binds to proteins in plasma, its susceptibility to drug transporters expressed on cell surfaces, and its binding to its molecular target and to other cellular proteins (which can be irreversible). Most drugs diffuse passively across capillary walls down a concentration gradient into the interstitial fluid until the concentration of free drug molecules in the interstitial fluid is equal to that in the plasma. As drug molecules in the blood are removed by metabolism or excretion, the plasma concentration falls and drug molecules diffuse back from the tissue compartment into the blood, and eventually all will be eliminated. Note that this reverse movement of drug away from the tissues will be prevented if further drug doses are administered and absorbed into the plasma.

Volume of distribution

The apparent volume of distribution (V_d) is the volume into which a drug appears to have distributed following intravenous injection. It is calculated from the equation

$$V_d = D/C_o$$

where D is the amount of drug given and C_0 is the initial plasma concentration (Fig. 2.4A). Drugs that are highly bound to plasma proteins may have a V_d below 10 L (e.g. warfarin, aspirin), while those that diffuse into the interstitial fluid but do not enter cells because they have low lipid solubility may have a V_d between 10 and 30 L (e.g. gentamicin, amoxicillin). It is an 'apparent' volume because those drugs that are lipid-soluble and highly tissue-bound may have a V_d of greater than 100 L (e.g. digoxin, amitriptyline). Drugs with a larger V_d are eliminated more slowly from the body.

Drug elimination

Drug metabolism

Metabolism is the process by which drugs are chemically altered from a lipid-soluble form suitable for absorption and distribution to a more water-soluble form that is necessary for excretion. Some drugs, known as 'pro-drugs', are inactive in the form in which they are administered, but are converted to an active metabolite in vivo.

Phase I metabolism involves oxidation, reduction or hydrolysis to make drug molecules suitable for phase II reactions or for excretion. Oxidation is much the commonest form of phase I reaction and chiefly involves members of the cytochrome P450 family of membrane-bound enzymes in the endoplasmic reticulum of hepatocytes.

Phase II metabolism involves combining phase I metabolites with an endogenous substrate to form an inactive conjugate that is much more water-soluble. Reactions include glucuronidation, sulphation, acetylation or methylation, and conjugation with glutathione. This is necessary to enable renal excretion because lipid-soluble metabolites will simply diffuse back into the body after glomerular filtration (p. 430).

Drug excretion

Excretion is the process by which drugs and their metabolites are removed from the body.

Renal excretion is the usual route of elimination for drugs or their metabolites that are of low molecular weight and sufficiently water-soluble to avoid reabsorption from the renal tubule. Drugs bound to plasma proteins are not filtered by the glomeruli. The pH of the urine is more acidic than that of plasma, so that some drugs (e.g. salicylates) become un-ionised and tend to be reabsorbed. Alkalination of the urine can hasten excretion (e.g. after a salicylate overdose). For some drugs, active secretion into the proximal tubule lumen, rather than glomerular filtration, is the predominant mechanism of excretion (e.g. methotrexate, penicillin).

Faecal excretion is the predominant route of elimination for drugs with high molecular weight, including those that are excreted in the bile after conjugation with glucuronide in the liver, and any drugs that are not absorbed after enteral administration. Molecules of drug or metabolite that are excreted in the bile enter the small intestine, where they may, if they are sufficiently lipid-soluble, be reabsorbed through the gut wall and return to the liver via the portal vein (see Fig. 2.3). This recycling between the liver, bile, gut and portal vein is known as 'enterohepatic circulation' and can significantly prolong the residence of drugs in the body.

Elimination kinetics

The net removal of drug from the circulation results from a combination of drug metabolism and excretion, and is usually described as 'clearance', i.e. the volume of plasma that is completely cleared of drug per unit time.

For most drugs, elimination is a high-capacity process that does not become saturated, even at high dosage. The rate of elimination is therefore directly proportional to the drug concentration because of the 'law of mass action', whereby higher drug concentrations will drive faster metabolic reactions and support higher renal filtration rates. This results in 'first-order' kinetics, when a constant fraction of the drug remaining in the circulation is eliminated in a given time and the decline in concentration over time is exponential (see Fig. 2.4A). This elimination can be described by the drug's half-life ($t_{1/2}$), i.e. the time taken for the plasma drug concentration to halve, which remains constant throughout the period of drug elimination. The significance of this phenomenon for prescribers is that the effect of increasing doses on plasma concentration is predictable – a doubled dose leads to a doubled concentration at all time points.

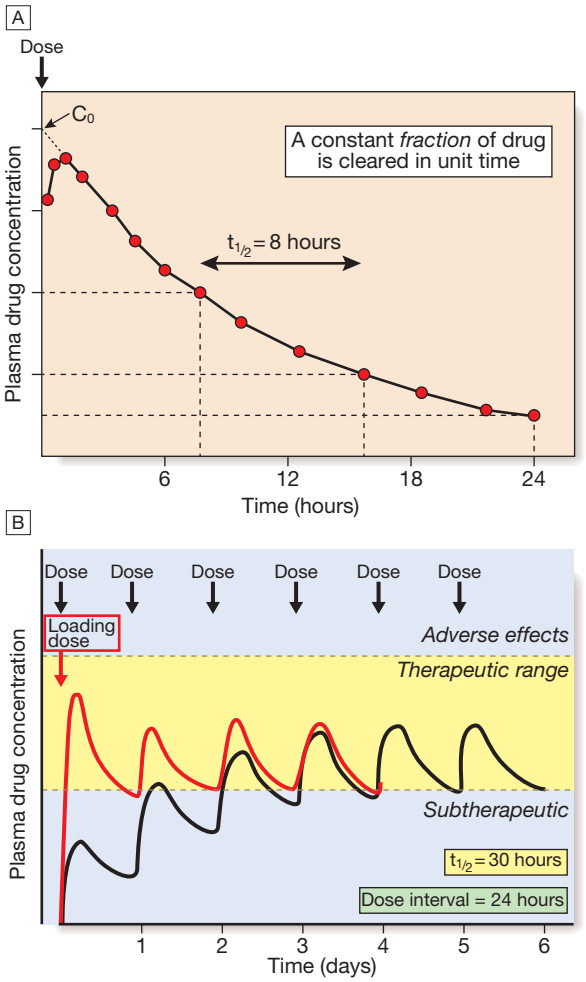

Fig. 2.4 Drug concentrations in plasma following single and multiple drug dosing. **A** In this example of first-order kinetics following a single intravenous dose, the time period required for the plasma drug concentration to halve (half-life, $t_{1/2}$) remains constant throughout the elimination process. **B** After multiple dosing, the plasma drug concentration rises if each dose is administered before the previous dose has been entirely cleared. In this example, the drug's half-life is 30 hours, so that with daily dosing the peak, average and trough concentrations steadily increase as drug accumulates in the body (black line). Steady state is reached after approximately 5 half-lives, when the rate of elimination (the product of concentration and clearance) is equal to the rate of drug absorption (the product of rate of administration and bioavailability). The long half-life in this example means that it takes 6 days for steady state to be achieved and, for most of the first 3 days of treatment, plasma drug concentrations are below the therapeutic range (yellow-shaded area). This problem can be overcome if a larger loading dose (red line) is used to achieve steady state drug concentrations more rapidly.

For a few drugs in common use (e.g. phenytoin, alcohol), elimination capacity is exceeded (saturated) within the usual dose range. This is called 'zero-order' kinetics. Its significance for prescribers is that, if the rate of administration exceeds the maximum rate of elimination, the drug will accumulate progressively, leading to serious toxicity.

Repeated dose regimens

The goal of therapy is usually to maintain drug concentrations within the therapeutic range (see Fig. 2.2) over several days (e.g. antibiotics) or even for months or years (e.g. antihypertensives, lipid-lowering drugs, thyroid hormone replacement therapy). This goal is rarely achieved with single doses, so prescribers have to plan a regimen of repeated doses. This involves choosing the size of each individual dose and the frequency of dose administration.

As illustrated in Figure 2.4B, the time taken to reach drug concentrations within the therapeutic range depends on the half-life of the drug. Typically, with doses administered regularly, it takes approximately 5 half-lives to reach a 'steady state' in which the rate of drug elimination is equal to the rate of drug administration. This applies when starting new drugs and when adjusting doses of current drugs. With appropriate dose selection, steady state drug concentrations will be maintained within the therapeutic range. This is important for prescribers because it means that the effects of a new prescription, or dose titration, for a drug with a long half-life (e.g. digoxin – 36 hours) may not be known for a few days. In contrast, drugs with a very short half-life (e.g. dobutamine – 2 minutes) have to be given continuously by infusion but reach a new steady state within minutes.

For drugs with a long half-life, if it is unacceptable to wait for 5 half-lives until concentrations within the therapeutic range are maintained, then an initial 'loading dose' can be given that is much larger than the maintenance dose, and equivalent to the amount of drug required in the body at steady state. This achieves a peak plasma concentration close to the plateau concentration, which can then be maintained by successive maintenance doses.

'Steady state' actually involves fluctuations in drug concentrations, with peaks just after administration followed by troughs just prior to the next administration. The manufacturers of medicines recommend dosing regimens that predict that, for most patients, these oscillations result in troughs within the therapeutic range and peaks that are not high enough to cause adverse effects. The optimal dose interval is a compromise between convenience for the patient and a constant level of drug exposure. More frequent administration (e.g. 25 mg 4 times daily) achieves a smoother plasma concentration profile than 100 mg once daily but is much more difficult for patients to sustain. A solution to this need for compromise in dosing frequency for drugs with half-lives of less than 24 hours is the use of 'modified-release' formulations. These allow drugs to be absorbed more slowly from the gastrointestinal tract and reduce the oscillation in plasma drug concentration profile, which is especially important for drugs with a low therapeutic index (e.g. levodopa).

Inter-individual variation in drug responses

Prescribers have numerous sources of guidance about how to use drugs appropriately (e.g. dose, route, frequency, duration) for many conditions. However, this advice is based on average dose–response data derived from observations in many individuals. When applying this information to an individual patient, prescribers

2.4 Patient-specific factors that influence pharmacokinetics

Age
• Drug metabolism is low in the fetus and newborn, may be enhanced in young children, and becomes less effective with advancing age • Drug excretion falls with the age-related decline in renal function
Sex
• Women have a greater proportion of body fat than men, increasing volume of distribution and half-life of lipid-soluble drugs
Body weight
• Obesity increases volume of distribution and half-life of lipid-soluble drugs • Patients with higher lean body mass have larger body compartments into which drugs are distributed and may require higher doses
Liver function
• Metabolism of most drugs depends on several cytochrome P450 enzymes that are impaired in patients with advanced liver disease • Hypoalbuminaemia influences the distribution of drugs that are highly protein-bound
Kidney function
• Renal disease and the decline in renal function with ageing may lead to drug accumulation
Gastrointestinal function
• Small intestinal absorption of oral drugs may be delayed by reduced gastric motility • Absorptive capacity of the intestinal mucosa may be reduced in disease (e.g. Crohn's disease, coeliac disease) or after surgical resection
Food
• Food in the stomach delays gastric emptying and reduces the rate (but not usually the extent) of drug absorption • Some food constituents bind to certain drugs and prevent their absorption
Smoking
• Tar in tobacco stimulates the oxidation of certain drugs
Alcohol
• Regular alcohol consumption stimulates liver enzyme synthesis, while binge drinking may temporarily inhibit drug metabolism
Drugs
• Drug–drug interactions cause marked variation in pharmacokinetics (see Box 2.11, p. 28)

must take account of inter-individual variability in response. Some of this variability is predictable and good prescribers are able to anticipate it and adjust their prescriptions accordingly to maximise the chances of benefit and minimise harm. Inter-individual variation in responses also mandates that effects of treatment should be monitored (p. 39).

Some inter-individual variation in drug response is accounted for by differences in pharmacodynamics. For example, the beneficial natriuresis produced by the loop diuretic furosemide is often significantly reduced at a given dose in patients with renal impairment, while confusion caused by opioid analgesics is more likely in the elderly. However, differences in pharmacokinetics more commonly account for different drug responses. Examples of factors influencing the absorption, metabolism and excretion of drugs are shown in Box 2.4.

It is hoped that a significant proportion of the inter-individual variation in drug responses can be explained by studying genetic differences in single genes ('pharmacogenetics') (Box 2.5) or the effects of multiple gene variants ('pharmacogenomics'). The aim is to identify those patients most likely to benefit from specific treatments and those most susceptible to adverse effects. In this way, it may be possible to select drugs and dose regimens for individual patients to maximise the benefit:hazard ratio ('personalised medicine').

ADVERSE OUTCOMES OF DRUG THERAPY

The decision to prescribe a drug always involves a judgement of the balance between therapeutic benefits and risk of an adverse outcome. Both prescribers and patients tend to be more focused on the former but a truly informed decision requires consideration of both.

Adverse drug reactions

Some important definitions for the adverse effects of drugs are:

- *Adverse event.* A harmful event that occurs while a patient is taking a drug, irrespective of whether the drug is suspected of being the cause.
- *Adverse drug reaction (ADR).* An unwanted or harmful reaction that is experienced following the administration of a drug or combination of drugs under normal conditions of use and is suspected to be related to the drug. An ADR will usually require the drug to be discontinued or the dose reduced.
- *Side-effect.* Any effect caused by a drug other than the intended therapeutic effect, whether beneficial, neutral or harmful. The term 'side-effect' is often used interchangeably with 'ADR', although the former usually implies an effect that is less harmful, is predictable and may not require discontinuation of therapy (e.g. ankle oedema with vasodilators).
- *Drug toxicity.* Adverse effects of a drug that occur because the dose or plasma concentration has risen above the therapeutic range, either unintentionally or intentionally (drug overdose, see Fig. 2.2, p. 19).
- *Drug abuse.* The misuse of recreational or therapeutic drugs that may lead to addiction or dependence, serious physiological injury (such as liver damage), psychological harm (abnormal behaviour patterns, hallucinations, memory loss) or death (p. 240).

Prevalence of ADRs

ADRs are a common cause of illness, accounting in the United Kingdom (UK) for approximately 3% of consultations in primary care and 7% of emergency

2.5 Examples of pharmacogenetic variations that influence drug response

Genetic variant	Drug affected	Clinical outcome
Pharmacokinetic		
Aldehyde dehydrogenase-2 deficiency	Ethanol	Elevated blood acetaldehyde causes facial flushing and increased heart rate in ~50% of Japanese, Chinese and other Asian populations
Acetylation	Isoniazid, hydralazine, procainamide	Increased responses in slow acetylators, up to 50% of some populations
Oxidation (CYP2D6)	Nortriptyline Codeine	Increased risk of toxicity in poor metabolisers Reduced responses with slower conversion of codeine to more active morphine in poor metabolisers, 10% of European populations Increased risk of toxicity in ultra-fast metabolisers, 3% of Europeans but 40% of North Africans
Oxidation (CYP2C18)	Proguanil	Reduced efficacy with slower conversion to active cycloguanil in poor metabolisers
Oxidation (CYP2C9)	Warfarin	Polymorphisms known to influence dosages
Oxidation (CYP2C19)	Clopidogrel	Reduced enzymatic activation results in reduced antiplatelet effect
Sulphoxidation	Penicillamine	Increased risk of toxicity in poor metabolisers
HLA-B*1502	Carbamazepine	Increased risk of serious dermatological reactions (e.g. Stevens–Johnson syndrome) for 1 in 2000 in Caucasian populations (much higher in some Asian countries)
Pseudocholinesterase deficiency	Suxamethonium (succinylcholine)	Decreased drug inactivation leads to prolonged paralysis and sometimes persistent apnoea requiring mechanical ventilation until the drug can be eliminated by alternate pathways in 1 in 1500 people
Pharmacodynamic		
Glucose-6-phosphate dehydrogenase (G6PD) deficiency	Oxidant drugs including antimalarials (e.g. chloroquine, primaquine)	Risk of haemolysis in G6PD deficiency
Acute intermittent porphyria	Enzyme-inducing drugs	Increased risk of an acute attack
SLC01B1 polymorphism	Statins	Increased risk of rhabdomyolysis
HLA-B*5701 polymorphism	Abacavir	Increased risk of skin hypersensitivity reactions
HLA-B*5801 polymorphism	Allopurinol	Increased risk of rashes in Han Chinese
HLA-B*1502 polymorphism	Carbamazepine	Increased risk of skin hypersensitivity reactions in Han Chinese

(HLA = human leucocyte antigen)

admissions to hospital, and affecting around 15% of hospital inpatients. Many 'disease' presentations are eventually attributed to ADRs, emphasising the importance of always taking a careful drug history (Box 2.6). Factors accounting for the rising prevalence of ADRs are the increasing age of patients, polypharmacy (higher risk of drug interactions), increasing availability of over-the-counter medicines, increase in use of herbal or traditional medicines, and increase in medicines available via the Internet. Risk factors for ADRs are shown in Box 2.7.

ADRs are important because they reduce quality of life for patients, reduce adherence to and therefore efficacy of beneficial treatments, cause diagnostic confusion, undermine the confidence of patients in their health-care professional(s), and consume health-care resources.

Retrospective analysis of ADRs has shown that more than half could have been avoided if the prescriber had taken more care in anticipating the potential hazards of drug therapy. Each year in the UK, non-steroidal anti-inflammatory drug (NSAID) use alone accounts for 65 000 emergency admissions, 12 000 gastrointestinal bleeding episodes and 2000 deaths. In many cases, the patients were at increased risk due to their age, interacting drugs (e.g. aspirin, warfarin) or a past history of peptic ulcer disease. Drugs that commonly cause ADRs are listed in Box 2.8.

Prescribers and their patients ideally want to know the frequency with which ADRs occur for a specific drug. Although this may be well characterised for more common ADRs observed in clinical trials, it is less clear for rarely reported ADRs when the total numbers of reactions and patients exposed are not known. The words used to describe frequency can be misinterpreted by patients, but widely accepted meanings include: *very common* (10% or more), *common* (1–10%), *uncommon* (0.1–1%), *rare* (0.01–0.1%) and *very rare* (0.01% or less).

Classification of ADRs

ADRs have traditionally been classified into two major groups:

- *Type A ('augmented') ADRs*. These are predictable from the known pharmacodynamic effects of the drug, and are dose-dependent, common (detected early in drug development) and usually mild.

2.6 How to take a drug history

Information from the patient (or carer)

Use language that patients will understand (e.g. 'medicines' rather than 'drugs', which may be mistaken for drugs of abuse) while gathering the following information:

- Current prescribed drugs, including formulations (e.g. modified-release tablets), doses, routes of administration, frequency and timing, duration of treatment
- Other medications that are often forgotten (e.g. over-the-counter drugs, herbal remedies, vitamins)
- Drugs that have been taken in the recent past and reasons for stopping them
- Previous drug hypersensitivity reactions, their nature and time course (e.g. rash, anaphylaxis)
- Previous ADRs, their nature and time course (e.g. muscle aches with simvastatin)
- Adherence to therapy (e.g. 'are you taking your medication regularly?')

Information from the general practitioner (GP) medical records and/or pharmacist

- Up-to-date list of medications
- Previous ADRs
- Last order dates for each medication

Inspection of medicines

- Drugs and their containers (e.g. blister packs, bottles, vials) should be inspected for name, dosage, and the number of dosage forms taken since dispensed

(ADR = adverse drug reaction)

2.7 Risk factors for ADRs

Patient factors

- Elderly age (e.g. low physiological reserve)
- Gender (e.g. ACE inhibitor-induced cough in women)
- Polypharmacy (e.g. drug interactions)
- Genetic predisposition (see Box 2.5)
- Hypersensitivity/allergy (e.g. β-lactam antibiotics)
- Diseases altering pharmacokinetics (e.g. hepatic or renal impairment) or pharmacodynamic responses (e.g. bladder instability)
- Adherence problems (e.g. cognitive impairment)

Drug factors

- Steep dose–response curve (e.g. insulin)
- Low therapeutic index (e.g. digoxin, cytotoxic drugs)

Prescriber factors

- Inadequate understanding of principles of clinical pharmacology
- Inadequate knowledge of the prescribed drug
- Inadequate instructions and warnings provided to patients
- Inadequate monitoring arrangements planned

Examples include constipation caused by opioids, hypotension caused by antihypertensives and dehydration caused by diuretics.

- *Type B ('bizarre') ADRs*. These are not predictable, are not obviously dose-dependent in the therapeutic range, and are rare (remaining undiscovered until the drug is marketed) and often severe. Patients who experience type B reactions are generally 'hyper-susceptible' because of unpredictable immunological or genetic factors (e.g. anaphylaxis caused by penicillin, peripheral neuropathy caused by isoniazid in poor acetylators).

2.8 Drugs that are common causes of ADRs

Drug or drug class	Common ADRs
ACE inhibitors (e.g. lisinopril)	Renal impairment Hyperkalaemia
Antibiotics (e.g. amoxicillin)	Nausea Diarrhoea
Anticoagulants (e.g. warfarin, heparin)	Bleeding
Antipsychotics (e.g. haloperidol)	Falls Sedation Confusion
Aspirin	Gastrotoxicity (dyspepsia, gastrointestinal bleeding)
Benzodiazepines (e.g. diazepam)	Drowsiness Falls
β-blockers (e.g. atenolol)	Cold peripheries Bradycardia
Calcium channel blockers (e.g. amlodipine)	Ankle oedema
Digoxin	Nausea and anorexia Bradycardia
Diuretics (e.g. furosemide, bendroflumethiazide)	Dehydration Electrolyte disturbance (hypokalaemia, hyponatraemia) Hypotension Renal impairment
Insulin	Hypoglycaemia
NSAIDs (e.g. ibuprofen)	Gastrotoxicity (dyspepsia, gastrointestinal bleeding) Renal impairment
Opioid analgesics (e.g. morphine)	Nausea and vomiting Confusion Constipation

(ACE = angiotensin-converting enzyme; NSAID = non-steroidal anti-inflammatory drug)

This simple classification has shortcomings and a more detailed classification based on dose (see Fig. 2.2, p. 19), timing and susceptibility (DoTS) is now used by those analysing ADRs in greater depth (Box 2.9). The AB classification can be extended as a reminder of some other types of ADR:

- *Type C ('chronic/continuous') ADRs*. These occur only after prolonged continuous exposure to a drug. Examples include osteoporosis caused by corticosteroids, retinopathy caused by chloroquine, and tardive dyskinesia caused by phenothiazines.
- *Type D ('delayed') ADRs*. These are delayed until long after drug exposure, making diagnosis difficult. Examples include malignancies that may emerge after immunosuppressive treatment post transplantation (e.g. azathioprine, tacrolimus) and vaginal cancer occurring many years after exposure to diethylstilboestrol.

2.9 DoTS classification of ADRs

Category	Example
Dose	
Below therapeutic dose	Anaphylaxis with penicillin
In the therapeutic dose range	Nausea with morphine
At high doses	Hepatotoxicity with paracetamol
Timing	
With the first dose	Anaphylaxis with penicillin
Early stages of treatment	Hyponatraemia with diuretics
On stopping treatment	Benzodiazepine withdrawal syndrome
Significantly delayed	Clear cell cancer with diethylstilboestrol
Susceptibility	See patient factors in Box 2.7

(INR = international normalised ratio)

- *Type E ('end of treatment') ADRs*. These occur after abrupt drug withdrawal (see Box 2.3, p. 20).

A teratogen is a drug with the potential to affect the development of the fetus in the first 10 weeks of intrauterine life (e.g. phenytoin, warfarin). The thalidomide disaster in the early 1960s highlighted the risk of teratogenicity and led to mandatory testing of all new drugs. Congenital defects in a live infant or aborted fetus should lead to the suspicion of an ADR and a careful exploration of drug exposures (including self-medication and herbal remedies).

Detecting ADRs – pharmacovigilance

Type A ADRs become apparent early in the development of a new drug. However, by the time a new drug is licensed and launched on to a possible worldwide market, hundreds rather than thousands of patients may have been exposed to it, so that rarer but potentially serious type B ADRs may remain undiscovered. Pharmacovigilance is the process of detecting ('signal generation') and evaluating ADRs in order to help prescribers and patients to be better informed about the risks of drug therapy. Drug regulatory agencies may respond to this information by placing restrictions on the licensed indications, reducing the recommended dose range, adding special warnings and precautions for prescribers in the product literature, writing to all health-care professionals, or withdrawing the product from the market.

Voluntary reporting systems allow health-care professionals and patients to report suspected ADRs to the regulatory authorities. A good example is the 'Yellow Card' scheme that was set up in the UK in response to the thalidomide tragedy. Reports are analysed to assess the likelihood that they represent a true ADR (Box 2.10). Although voluntary reporting is a continuously operating and effective early warning system for previously unrecognised rare ADRs, its weaknesses include low reporting rates (only 3% of all ADRs and 10% of serious ADRs are ever reported), an inability to quantify risk (because the ratio of ADRs to prescriptions is unknown), and the influence of prescriber awareness on likelihood of reporting (reporting rates rise rapidly following publicity about potential ADRs).

More systematic approaches to collecting information on ADRs include 'prescription event monitoring', in which a sample of prescribers of a particular drug are issued with questionnaires concerning the clinical outcome for their patients, and the collection of population statistics. Many health-care systems routinely collect patient identifiable data on prescriptions (a surrogate marker of exposure to a drug), health-care events (e.g. hospitalisation, operations, new clinical diagnoses) and other clinical data (e.g. haematology, biochemistry). As these records are linked, with appropriate safeguards for confidentiality and data protection, they are providing a much more powerful mechanism for assessing both the harms and benefits of drugs.

All prescribers will inevitably see patients experiencing ADRs caused by prescriptions written by themselves or their colleagues. It is important that these are recognised early. In addition to the features in Box 2.10, features that should raise suspicion of an ADR and the need to respond (by drug withdrawal, dosage reduction or reporting to the regulatory authorities) include:

- concern expressed by a patient that a drug has harmed him/her
- abnormal clinical measurements (e.g. blood pressure, temperature, pulse, blood glucose and

2.10 TREND analysis of suspected ADRs

Factor	Key question	Comment
***T*emporal relationship**	What is the time interval between the start of drug therapy and the reaction?	Most ADRs occur soon after starting treatment and within hours in the case of anaphylactic reactions
***Re*-challenge**	What happens when the patient is re-challenged with the drug?	Re-challenge is rarely possible because of the need to avoid exposing patients to unnecessary risk
***E*xclusion**	Have concomitant drugs and other non-drug causes been excluded?	ADR is a diagnosis of exclusion following clinical assessment and relevant investigations for non-drug causes
***N*ovelty**	Has the reaction been reported before?	The suspected ADR may already be recognised and mentioned in the SPC approved by the regulatory authorities
***De*-challenge**	Does the reaction improve when the drug is withdrawn or the dose is reduced?	Most, but not all, ADRs improve on drug withdrawal, although recovery may be slow

(SPC = Summary of Product Characteristics)

weight) or laboratory results (e.g. abnormal liver or renal function, low haemoglobin white cell count) while on drug therapy
- new therapy started which could be in response to an ADR (e.g. omeprazole, allopurinol, naloxone)
- the presence of risk factors for ADRs (see Box 2.7).

Drug interactions

A drug interaction has occurred when the administration of one drug increases or decreases the beneficial or adverse responses to another drug. Although the number of potential interacting drug combinations is very large, only a small number are common in clinical practice. Important drug interactions are most likely to occur when the affected drug has a low therapeutic index, steep dose–response curve, high first-pass or saturable metabolism, or single mechanism of elimination.

Mechanisms of drug interactions

Pharmacodynamic interactions occur when two drugs produce additive, synergistic or antagonistic effects at the same drug target (e.g. receptor, enzyme) or physiological system (e.g. electrolyte excretion, heart rate). These are the most common interactions in clinical practice and some important examples are given in Box 2.11.

Pharmacokinetic interactions occur when the administration of a second drug alters the concentration of the first at its site of action. There are numerous potential mechanisms:
- *Absorption interactions.* Drugs that either delay (e.g. anticholinergic drugs) or enhance (e.g. prokinetic drugs) gastric emptying influence the rate of rise in plasma concentration of other drugs but not the total amount of drug absorbed. Drugs that bind to form insoluble complexes or chelates (e.g. aluminium-containing antacids binding with ciprofloxacin) can reduce drug absorption.
- *Distribution interactions.* Co-administration of drugs that compete for protein binding in plasma (e.g. phenytoin and diazepam) can increase the unbound drug concentration, but the effect is usually short-lived due to increased elimination and hence restoration of the pre-interaction equilibrium.
- *Metabolism interactions.* Many drugs rely on metabolism by different isoenzymes of cytochrome P450 (CYP) in the liver. CYP enzyme inducers (e.g. phenytoin, rifampicin) generally reduce plasma concentrations of other drugs, although they may enhance activation of prodrugs. CYP enzyme inhibitors (e.g. clarithromycin, cimetidine, grapefruit

2.11 Common drug interactions

Mechanism	Object drug	Precipitant drug	Result
Pharmaceutical*			
Chemical reaction	Sodium bicarbonate	Calcium gluconate	Precipitation of insoluble calcium carbonate
Pharmacokinetic			
Reduced absorption	Tetracyclines	Calcium, aluminium, and magnesium salts	Reduced tetracycline absorption
Reduced protein binding	Phenytoin	Aspirin	Increased unbound and reduced total phenytoin plasma concentration
Reduced metabolism			
CYP3A4	Terfenadine	Grapefruit juice	Cardiac arrhythmias because of prolonged QT interval (p. 570)
	Warfarin	Clarithromycin	Enhanced anticoagulation
CYP2C19	Phenytoin	Omeprazole	Phenytoin toxicity
CYP2D6	Clozapine	Paroxetine	Clozapine toxicity
Xanthine oxidase	Azathioprine	Allopurinol	Azathioprine toxicity
Monoamine oxidase	Catecholamines	Monoamine oxidase inhibitors	Hypertensive crisis due to monoamine toxicity
Increased metabolism (enzyme induction)	Ciclosporin	St John's wort	Loss of immunosuppression
Reduced renal elimination	Lithium	Diuretics	Lithium toxicity
	Methotrexate	NSAIDs	Methotrexate toxicity
Pharmacodynamic			
Direct antagonism at same receptor	Opiates	Naloxone	Reversal of opiate effects used therapeutically
	Salbutamol	Atenolol	Inhibits bronchodilator effect
Direct potentiation in same organ system	Benzodiazepines	Alcohol	Increased sedation
	ACE inhibitors	NSAIDs	Increased risk of renal impairment
Indirect potentiation	Digoxin	Diuretics	Digoxin toxicity enhanced because of hypokalaemia
	Warfarin	Aspirin, NSAIDs	Increased risk of bleeding because of gastrotoxicity and antiplatelet effects

*Pharmaceutical interactions are related to the formulation of the drugs and occur before drug absorption.

juice) have the opposite effect. Enzyme induction effects usually take a few days to manifest because of the need to synthesise new CYP enzyme, in contrast with the rapid effects of enzyme inhibition.

- *Excretion interactions*. These primarily affect renal excretion. For example, drug-induced reduction in glomerular filtration rate (e.g. diuretic-induced dehydration, ACE inhibitors, NSAIDs) can reduce the clearance and increase the plasma concentration of many drugs, including some with a low therapeutic index (e.g. digoxin, lithium, aminoglycoside antibiotics). Less commonly, interactions may be due to competition for a common tubular organic anion transporter (e.g. methotrexate excretion may be inhibited by competition with NSAIDs).

Avoiding drug interactions

Drug interactions are increasing as patients are prescribed more medicines (polypharmacy). Prescribers can avoid the adverse consequences of drug–drug interactions by taking a careful drug history (see Box 2.6) before prescribing additional drugs, only prescribing for clear indications, and taking special care when prescribing drugs with a narrow therapeutic index (e.g. warfarin). When prescribing an interacting drug is unavoidable, good prescribers will seek further information and anticipate the potential risk. This will allow them to provide special warnings for the patient and arrange for monitoring, either of the clinical effects (e.g. coagulation tests for warfarin) or of plasma concentration (e.g. digoxin).

Medication errors

A medication error is any *preventable* event that may lead to inappropriate medication use or patient harm while the medication is in the control of the health-care professional or patient. Errors may occur in prescribing, dispensing, preparing solutions, administration or monitoring. Many ADRs are considered in retrospect to have been 'avoidable' with more care or forethought; in other words, an adverse event considered by one prescriber to be an unfortunate ADR might be considered by another to be a prescribing error.

Medication errors are very common. Several thousand medication orders are dispensed and administered each day in a medium-sized hospital. Recent UK studies suggest that 7–9% of hospital prescriptions contain an error, and most are written by junior doctors. Common prescribing errors in hospitals include omission of medicines (especially failure to prescribe regular medicines at the point of admission or discharge, i.e. 'medicines reconciliation'), dosing errors, unintentional prescribing and poor use of documentation (Box 2.12).

Most prescription errors result from a combination of failures by the individual prescriber and the health-service systems in which they work (Box 2.13). Health-care organisations increasingly encourage reporting of errors within a 'no blame culture' so that they can be subject to 'root cause analysis' using human error theory (Fig. 2.5). Prevention is targeted at the factors in Box 2.13, and can be supported by prescribers communicating and cross-checking with colleagues (e.g. when calculating doses adjusted for body weight, or planning appropriate monitoring after drug administration), and by health-care systems providing clinical pharmacist support (e.g. for checking the patient's previous medications and current prescriptions) and electronic prescribing (which avoids errors due to illegibility or serious dosing mistakes, and may be combined with a clinical decision support system to take account of patient characteristics and drug history and provide warnings of potential contraindications and drug interactions).

2.12 Hospital prescribing errors

Error type	Approximate % of total
Omission on admission	30
Underdose	11
Overdose	8
Strength/dose missing	7
Omission on discharge	6
Administration times incorrect/missing	6
Duplication	6
Product or formulation not specified	4
Incorrect formulation	4
No maximum dose	4
Unintentional prescribing	3
No signature	2
Clinical contraindication	1
Incorrect route	1
No indication	1
IV instructions incorrect/missing	1
Drug not prescribed but indicated	1
Drug continued for longer than needed	1
Route of administration missing	1
Start date incorrect/missing	1
Risk of drug interaction	< 0.5
Controlled drug requirements incorrect/missing	< 0.5
Daily dose divided incorrectly	< 0.5
Significant allergy	< 0.5
Drug continued in spite of adverse effects	< 0.5
Premature discontinuation	< 0.5
Failure to respond to out-of-range drug level	< 0.5

Responding when an error is discovered

All prescribers will make errors. When they do, their first duty is to protect the patient's safety. This will involve a clinical review and taking any steps that will reduce harm (e.g. remedial treatment, monitoring, recording the event in the notes, informing colleagues). Patients should be informed if they have been exposed to potential harm. For errors that do not reach the patient, it is the prescriber's duty to report them, so that

2.13 Causes of prescribing errors

Systems factors

- Working hours of prescribers (and others)
- Patient throughput
- Professional support and supervision by colleagues
- Availability of information (medical records)
- Design of prescription forms
- Distractions
- Decision support available
- Checking routines (e.g. clinical pharmacy)
- Reporting and reviewing of incidents

Prescriber factors

Knowledge

- Clinical pharmacology principles
- Drugs in common use
- Therapeutic problems commonly encountered
- Knowledge of workplace systems

Skills

- Taking a good drug history
- Obtaining information to support prescribing
- Communicating with patients
- Numeracy and calculations
- Prescription writing

Attitudes

- Coping with risk and uncertainty
- Monitoring of prescribing
- Checking routines

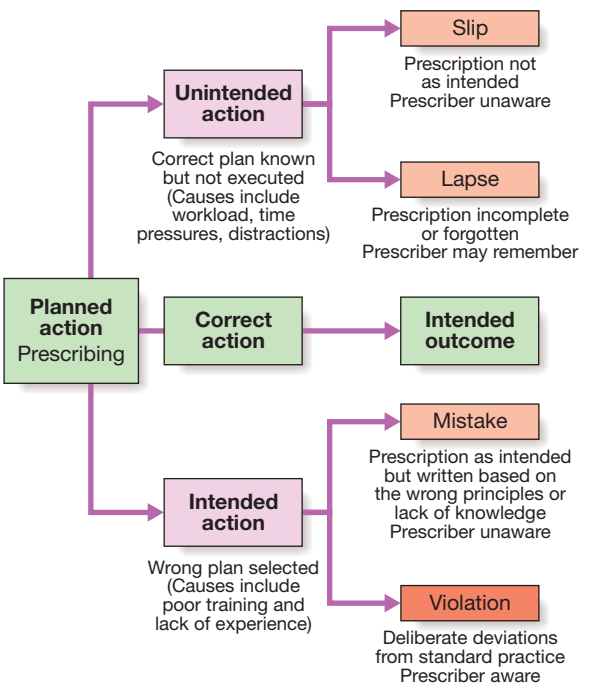

Fig. 2.5 Human error theory. Unintended errors may occur because the prescriber fails to complete the prescription correctly (a slip) (e.g. writes the dose in 'mg' not 'micrograms') or forgets part of the action that is important for success (a lapse) (e.g. forgets to co-prescribe folic acid with methotrexate); prevention requires the system to provide appropriate checking routines. Intended errors occur when the prescriber acts incorrectly due to lack of knowledge (a mistake) (e.g. prescribes atenolol for a patient with known severe asthma because of ignorance about the contraindication); prevention must focus on training the prescriber.

others can learn from the experience, and take the opportunity to reflect on how a similar incident might be avoided in the future.

DRUG REGULATION AND MANAGEMENT

Given the powerful beneficial and potentially adverse effects of drugs, the production and use of medicines are strictly regulated (e.g. by the Food and Drug Administration in the United States (US), Medicines and Healthcare Products Regulatory Agency in the UK, and Central Drugs Standard Control Organisation in India). Regulators are responsible for licensing medicines, monitoring their safety (pharmacovigilance, p. 27), approving clinical trials, and inspecting and maintaining standards of drug development and manufacture.

In addition, because of the high costs of drugs and of their adverse effects, health-care services must prioritise their use in light of the evidence of their benefit and harm, a process referred to as 'medicines management'.

Drug development and marketing

Naturally occurring products have been used to treat illnesses for thousands of years and some remain in common use today. Examples include morphine from the opium poppy (*Papaver somniferum*), digitalis from the foxglove (*Digitalis purpurea*), curare from the bark of a South American tree, and quinine from another bark (*Cinchona* species). Although plants and animals remain a source of discovery, the majority of new drugs come from drug discovery programmes that aim to identify

2.14 Clinical development of new drugs

Phase I

- Healthy volunteers (20–80). These involve initial single-dose, 'first-into-man' studies, followed by repeated-dose studies. They aim to establish the basic pharmacokinetic and pharmacodynamic properties, and short-term safety. Duration: 6–12 months

Phase II

- Patients (100–200). These investigate clinical effectiveness ('proof of concept'), safety and dose–response relationship, often with a surrogate clinical endpoint, in the target patient group to determine the optimal dosing regimen for larger confirmatory studies. Duration: 1–2 years

Phase III

- Patients (100s–1000s). These are large, expensive clinical trials that confirm safety and efficacy in the target patient population, using relevant clinical endpoints. They may be placebo-controlled studies or comparisons with other active compounds. Duration: 1–2 years

Phase IV

- Patients (100s–1000s). These are undertaken after the medicine has been marketed for its first indication to evaluate new indications, new doses or formulations, long-term safety or cost-effectiveness

2.15 Novel therapeutic alternatives to conventional small-molecule drugs

Approaches	Therapeutic indications	Challenges
Monoclonal antibodies: targeting of receptors or other molecules with relatively specific antibodies	Cancer Chronic inflammatory diseases (e.g. rheumatoid arthritis, inflammatory bowel disease)	Selectivity of action Complex manufacturing process
Small interfering RNA (siRNA): inhibits gene expression	Macular degeneration	Delivery to target
Gene therapy: delivery of modified genes that supplement or alter host DNA	Cystic fibrosis Cancer Cardiovascular disease	Delivery to target Adverse effects of delivery vector (e.g. virus)
Stem cell therapy: stem cells differentiate and replace damaged host cells	Parkinson's disease Spinal cord injury Ischaemic heart disease	Delivery to target Immunological compatibility Long-term effects unknown

small-molecule compounds with specific interactions with a molecular target that will induce a predicted biological effect.

The usual pathway for development of these small molecules includes: identifying a plausible molecular target by investigating pathways in disease; screening a large library of compounds for those that interact with the molecular target in vitro; conducting extensive medicinal chemistry to optimise the properties of lead compounds; testing efficacy and toxicity of these compounds in vitro and in animals; and undertaking a clinical development programme (Box 2.14). This process typically takes longer than 10 years and may cost up to $1 billion. Manufacturers have a defined period of exclusive marketing of the drug while it remains protected by an original patent, typically 10–15 years, during which time they must recoup the costs of developing the drug. Meanwhile, competitor companies will often produce similar 'me too' drugs of the same class. Once the drug's patent has expired, 'generic' drug manufacturers may step in to produce cheaper formulations.

The number of new drugs produced by the pharmaceutical industry has declined in recent years. The traditional approach of targeting membrane-bound receptors and enzymes with small molecules (see Box 2.2) is now giving way to new targets such as complex second messenger systems, cytokines, nucleic acids and cellular networks. These require novel therapeutic agents which present new challenges for 'translational medicine', the discipline of converting scientific discoveries into a useful medicine with a well-defined benefit–risk profile (Box 2.15).

Licensing new medicines

New drugs are given a 'market authorisation' based on the evidence of quality, safety and efficacy presented by the manufacturer. The regulator will not only approve the drug but will also take great care to ensure that the accompanying information reflects the evidence that has been presented. The summary of product characteristics (SPC), or 'label', provides detailed information about indications, dosage, adverse effects, warnings, monitoring etc. If approved, drugs can be made available with different levels of restriction:

- *Controlled drug (CD)*. These drugs are subject to strict legal controls on supply and possession, usually due to their abuse potential (e.g. opioid analgesics).
- *Prescription-only medicine (PoM)*. These are only available from a pharmacist and can only be supplied if prescribed by an appropriate practitioner.
- *Pharmacy (P)*. These are only available from a pharmacist but can be supplied without a prescription.
- *General sales list (GSL)*. These medicines may be bought 'over the counter' (OTC) from any shop and without a prescription.

Drug marketing

The marketing activities of the pharmaceutical industry are well resourced and are important in the process of recouping the massive costs of drug development. In some countries, such as the US, it is possible to promote a new drug by direct-to-consumer advertising, although this is illegal in the countries of the European Union. A major focus is on promotion to prescribers via educational events, sponsorship of meetings, adverts in journals, involvement with opinion leaders, and direct contact by company representatives. Such largesse has the potential to cause significant conflicts of interest, and might tempt prescribers to favour one drug over another, even in the face of evidence on effectiveness or cost-effectiveness.

Managing the use of medicines

Many medicines meet the three key regulatory requirements of quality, safety and efficacy. Although prescribers are legally entitled to prescribe any of them, it is desirable to limit the choice so that treatments for specific diseases can be focused on the most effective and cost-effective options, prescribers (and patients) gain familiarity with a smaller number of medicines, and pharmacies can concentrate stocks on them.

The process of ensuring optimal use of available medicines is known as 'medicines management' or 'quality use of medicines'. It involves careful evaluation of the evidence of benefit and harm from using the medicine, an assessment of cost-effectiveness, and support for processes to implement the resulting recommendations.

These activities usually involve both national and local organisations.

Evaluating evidence

The principles of evidence-based medicine are described on page 8. Drugs are often evaluated in high-quality randomised controlled trials, the results of which can be considered by systematic review (Fig. 2.6). Ideally, data are available not only for comparison with placebo but also in 'head-to-head' comparison with alternative therapies. However, trials are conducted in selected patient populations and are not representative of every clinical scenario, so extrapolation to individual patients is not always straightforward.

Clinical trials typically report the percentage reduction in risk of a primary outcome, such as a stroke. However, if the absolute risk of stroke for a given patient is low, then even an apparently substantial percentage reduction in risk may not be worthwhile. As an aid to interpreting the results of clinical trials, it is often helpful to consider the number needed to treat (NNT). For example, in a systematic review of warfarin therapy to prevent stroke in patients with atrial fibrillation, strokes occurred in 133 of 1450 patients given placebo and in 53 of 1450 patients given warfarin. This represents a relative risk of 0.40, i.e. a 60% reduction. It equates to an NNT of 18, i.e. 18 patients would need to be treated for 1 year to prevent 1 stroke; NNT is calculated as the inverse of the difference in absolute rate of stroke = 1/[(133/1450) − (53/1450)]. However, if the absolute risk of stroke were halved, the relative risk reduction with warfarin would still be 60%, but the NNT would increase to 1/[(67/1450) − (27/1450)] = 36, i.e. 36 patients would need to be treated for 1 year to prevent 1 stroke, with a consequent increase in cost and risk of adverse effects compared with benefit. NNT can usefully be applied to assess both benefit (NNT_B) and harm (NNT_H).

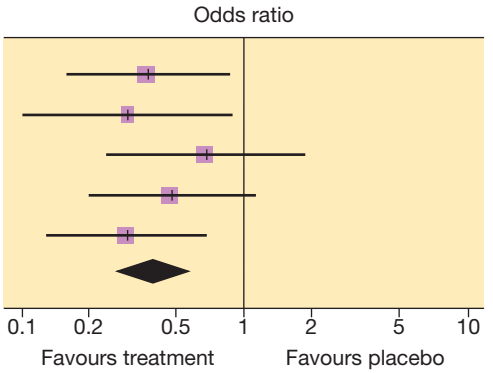

Fig. 2.6 Systematic review of the evidence from randomised controlled clinical trials. This forest plot shows the effect of warfarin compared with placebo on likelihood of stroke in patients with atrial fibrillation in five randomised controlled trials that passed the quality criteria required for inclusion in a meta-analysis. For each trial, the purple box is proportionate to the number of participants. The tick marks show the mean odds ratio, and the black lines indicate its 95% confidence intervals. Note that not all the trials showed statistically significant effects (i.e. the confidence intervals cross 1.0). However, the meta-analysis, represented by the black diamond, confirms a highly significant statistical benefit. The overall odds ratio is approximately 0.4, indicating a mean 60% risk reduction with warfarin treatment in patients with the characteristics of the participants in these trials.

Evaluating cost-effectiveness

New drugs often represent an incremental improvement over the current standard of care but are usually more expensive. The principles for evaluating and comparing cost-effectiveness of treatment are described on page 9. A major challenge is to compare the value of interventions for different clinical outcomes. One method is to calculate the quality-adjusted life years (QALYs) gained if the new drug is used rather than standard treatment. This analysis involves estimating the 'utility' of various health states between 1 (perfect health) and 0 (dead). If the additional costs and any savings are known, then it is possible to derive the incremental cost-effectiveness ratio (ICER) in terms of cost/QALY. These principles are exemplified in Box 2.16. However, there are inherent weaknesses in this kind of analysis: it usually depends on modelling future outcomes well beyond the duration of the clinical trial data that are available; it assumes that QALYs gained at all ages are of equivalent value; and the appropriate standard care against which the new drug should be compared is often uncertain.

These pharmacoeconomic assessments are challenging and resource-intensive, and are undertaken at national level in most countries: for example in the UK by the National Institute for Health and Clinical Excellence (NICE).

Implementing recommendations

Many recommendations about drug therapy are included in clinical guidelines written by an expert group after systematic review of the evidence. As described on page 8, these provide recommendations rather than obligations for prescribers, and are helpful in promoting more consistent and higher-quality

2.16 Cost-effectiveness analysis

A clinical trial lasting 2 years compares two interventions for the treatment of colon cancer:

- Treatment A: standard treatment, cost £1000/year, oral therapy
- Treatment B: new treatment, cost £6000/year, monthly IV infusions often followed by a week of nausea.

The new treatment (B) significantly increases the average time to progression (18 months versus 12 months) and reduces overall mortality (40% versus 60%). The health economist models the survival curves from the trial in order to undertake a cost–utility analysis and concludes that:

- Intervention A: allows a patient to live for 2 extra years at a utility 0.7 = 1.4 QALYs (cost £2000)
- Intervention B: allows a patient to live for 3 extra years at a utility 0.6 = 1.8 QALYs (cost £18 000).

The health economists conclude that Treatment B provides an extra 0.4 QALYs at an extra cost of £16 000, meaning that the ICER = £40 000/QALY. They recommend that the new treatment should not be funded on the basis that their threshold for cost acceptability is £30 000/QALY.

(ICER = incremental cost-effectiveness ratio; QALY = quality-adjusted life year)

prescribing. However, guidelines are often written without concern for cost-effectiveness, and may be limited by the quality of available evidence. Guidelines cannot anticipate the extent of the variation between individual patients who may, for example, have unexpected contraindications to recommended drugs or choose different priorities for treatment. However, when deviating from respected national guidance, prescribers should be able to justify their practice.

Additional recommendations for prescribing are often implemented locally or imposed by bodies responsible for paying for health care. Most health-care units have a drug and therapeutics committee (or equivalent) comprised of senior and junior medical staff, pharmacists and nurses, as well as managers (because of the implications of the committee's work for governance and resources). This group typically develops local prescribing policy and guidelines, maintains a local drug formulary and evaluates requests to use new drugs. The local formulary contains a more limited list than any national formulary (e.g. *British National Formulary*) because the latter lists all licensed medicines that can be prescribed legally, while the former contains only those which the health-care organisation has approved for local use. The local committee may also be involved, with local specialists, in providing explicit protocols for management of clinical scenarios (p. 9).

PRESCRIBING IN PRACTICE

Decision-making in prescribing

Prescribing should be based on a rational approach to a series of challenges (see Box 2.1, p. 18).

Making a diagnosis

Ideally, prescribing should be based on a confirmed diagnosis but, in reality, many prescriptions are based on the balance of probability, taking into account the differential diagnosis (e.g. proton pump inhibitors for post-prandial retrosternal discomfort).

Establishing the therapeutic goal

The goals of treatment are usually clear, particularly when relieving symptoms (e.g. pain, nausea, constipation). Sometimes the goal is less obvious to the patient, especially when aiming to prevent future events (e.g. ACE inhibitors to prevent hospitalisation and extend life in chronic heart failure). Prescribers should be clear about the therapeutic goal against which they will judge success or failure of treatment. It is also important to establish that the value placed on this goal by the prescriber is shared by the patient.

Choosing the therapeutic approach

For many clinical problems, drug therapy is not absolutely mandated. Having taken the potential benefits and harms into account, prescribers must consider whether drug therapy is in the patient's interest and is preferred to no treatment or one of a range of alternatives (e.g. physiotherapy, psychotherapy, surgery). Assessing the balance of benefit and harm is often complicated and depends on various features associated with the patient, disease and drug (Box 2.17).

2.17 Factors to consider when balancing benefits and harms of drug therapy

- Seriousness of the disease or symptom
- Efficacy of the drug
- Seriousness of potential adverse effects
- Likelihood of adverse effects
- Efficacy of alternative drugs or non-drug therapies
- Safety of alternative drugs or non-drug therapies

Choosing a drug

For most common clinical indications (e.g. type 2 diabetes, depression), more than one drug is available, often from more than one drug class. Although prescribers often have guidance about which represents the rational choice for the average patient, they still need to consider whether this is the optimal choice for the individual patient. Certain factors may influence the choice of drug:

Absorption. Patients may find some formulations easier to swallow than others or may be vomiting and require a drug available for parenteral administration.

Distribution. Distribution of a drug to a particular tissue sometimes dictates choice (e.g. tetracyclines and rifampicin are concentrated in the bile, and lincomycin and clindamycin in bones).

Metabolism. Drugs that are extensively metabolised should be avoided in severe liver disease (e.g. opioid analgesics).

Excretion. Drugs that depend on renal excretion for elimination (e.g. digoxin, aminoglycoside antibiotics) should be avoided in patients with impaired renal function if suitable alternatives exist.

Efficacy. Prescribers normally choose drugs with the greatest efficacy in achieving the goals of therapy (e.g. proton pump inhibitors rather than histamine$_2$ receptor antagonists). However, it may be appropriate to compromise on efficacy if other drugs are more convenient, safer to use or less expensive.

Avoiding adverse effects. Prescribers should be wary of choosing drugs that are more likely to cause adverse effects (e.g. cephalosporins rather than alternatives for patients allergic to penicillin) or worsen coexisting conditions (e.g. β-blockers as treatment for angina in patients with asthma).

Features of the disease. This is most obvious when choosing antibiotic therapy, which should be based on the known or suspected sensitivity of the infective organism (p. 149).

Severity of disease. The choice of drug should be appropriate to disease severity (e.g. paracetamol for mild pain, morphine for severe pain).

Coexisting diseases may be either an indication or a contraindication to therapy. Hypertensive patients might be prescribed a β-blocker if they also have left ventricular impairment but not if they have asthma.

Avoiding adverse drug interactions. Prescribers should avoid giving combinations of drugs that might interact, either directly or indirectly (see Box 2.11).

Patient adherence to therapy. Prescribers should choose drugs with a simple dosing schedule or easier administration (e.g. the ACE inhibitor enalapril once daily rather than captopril 3 times daily for hypertension).

Cost. Prescribers should choose the cheaper drug if two drugs are of equal efficacy and safety. Even if cost is not

a concern for the individual patient, it is important to remember that unnecessary expenditure will ultimately limit choices for other prescribers and patients. Sometimes a more costly drug may be appropriate (e.g. if it yields improved adherence).

Genetic factors. There are already a small number of examples where genotype influences the choice of drug therapy (see Box 2.5).

Choosing a dosage regimen

Prescribers have to choose a dose, route and frequency of administration (dosage regimen) to achieve a steady-state drug concentration that provides sufficient exposure of the target tissue without producing toxic effects. Manufacturers draw up dosage recommendations based on average observations in many patients but the optimal regimen that will maximise the benefit/harm ratio for an individual patient is never certain. Rational prescribing involves treating each prescription as an experiment and gathering sufficient information to amend it if necessary. There are some general principles that should be followed:

Dose titration. Prescribers should generally start with a low dose and titrate this slowly upwards as necessary. This cautious approach is particularly important if the patient is likely to be more sensitive to adverse pharmacodynamic effects (e.g. confusion or postural hypotension in the elderly) or have altered pharmacokinetic handling (e.g. renal or hepatic impairment), and when using drugs with a low therapeutic index (e.g. benzodiazepines, lithium, digoxin). However, there are some exceptions. Some drugs must achieve therapeutic concentration quickly because of the clinical circumstance (e.g. antibiotics, glucocorticoids, carbimazole). When early effect is important but there may be a delay in achieving steady state because of a drug's long half-life (e.g. digoxin, warfarin, amiodarone), an initial loading dose is given prior to establishing the appropriate maintenance dose (see Fig. 2.4, p. 23).

If adverse effects occur, the dose should be reduced or an alternative drug prescribed; in some cases, a lower dose may suffice if it can be combined with another synergistic drug (e.g. the immunosuppressant azathioprine reduces glucocorticoid requirements in patients with inflammatory disease). It is important to remember that the shape of the dose–response curve (see Fig. 2.2, p. 19) means that higher doses may produce little added therapeutic effect and might increase the chances of toxicity.

Route. There are many reasons for choosing a particular route of administration (Box 2.18).

Frequency. Frequency of doses is usually dictated by a manufacturer's recommendation. Less frequent doses are more convenient for patients but result in greater fluctuation between peaks and troughs in drug concentration (see Fig. 2.4, p. 23). This is relevant if the peaks are associated with adverse effects (e.g. dizziness with antihypertensives) or the troughs are associated with troublesome loss of effect (e.g. anti-Parkinsonian drugs). These problems can be tackled either by splitting the dose or by employing a modified-release formulation, if available.

Timing. For many drugs the time of administration is unimportant. However, there are occasionally pharmacokinetic or therapeutic reasons for giving drugs at particular times (Box 2.19).

2.18 Factors influencing the route of drug administration

Reason	Example
Only one route possible	Dobutamine (IV) Gliclazide (oral)
Patient adherence	Phenothiazines and thioxanthenes (2 weekly IM depot injections rather than daily tablets in schizophrenia)
Poor absorption	Furosemide (IV rather than oral, in severe heart failure)
Rapid action	Haloperidol (IM rather than oral, in acute behavioural disturbance)
Vomiting	Phenothiazines (PR or buccal rather than oral, in nausea)
Avoiding first-pass metabolism	Glyceryl trinitrate (SL, in angina pectoris)
Certainty of effect	Amoxicillin (IV rather than oral, in acute chest infection)
Direct access to the site of action (avoiding unnecessary systemic exposure)	Bronchodilators (INH rather than oral, in asthma) Local application of drugs to skin, eyes etc.
Ease of access	Diazepam (PR, if IV access is difficult in status epilepticus) Adrenaline (epinephrine) (IM, if IV access is difficult in acute anaphylaxis)
Comfort	Morphine (SC rather than IV in terminal care)

(IM = intramuscular; INH = by inhalation; IV = intravenous; PR = per rectum; SC = subcutaneous; SL = sublingual)

Formulation. For some drugs there is a choice of formulation, some for use by different routes. Some are easier to ingest, particularly by children (e.g. elixirs). The formulation is important when writing repeat prescriptions for drugs with a low therapeutic index that come in different formulations (e.g. lithium, phenytoin, theophylline). Even if the prescribed dose remains constant, another formulation may differ in its absorption and bioavailability, and hence plasma drug concentration. These are examples of the small number of drugs that should be prescribed by specific brand name rather than 'generic' International Non-proprietary Name (INN).

Duration. Some drugs require a single dose (e.g. thrombolysis post myocardial infarction), while for others the duration of the course of treatment is certain at the outset (e.g. antibiotics). For most, the duration will be largely at the prescriber's discretion and will depend on response and disease progression (e.g. analgesics, antidepressants). For many, the treatment will be long-term (e.g. insulin, antihypertensives, levothyroxine).

Involving the patient

Patients should, whenever possible, be engaged in making choices about drug therapy. Their beliefs and

2.19 Factors influencing the timing of drug therapy

Drug	Recommended timing	Reasons
Diuretics (e.g. furosemide)	Once in the morning	Night-time diuresis undesirable
Statins (e.g. simvastatin)	Once at night	HMG CoA reductase activity is greater at night
Antidepressants (e.g. amitriptyline)	Once at night	Allows adverse effects to occur during sleep
Salbutamol	Before exercise	Reduces symptoms in exercise-induced asthma
Glyceryl trinitrate **Paracetamol**	When required	Relief of acute symptoms only
Regular nitrate therapy (e.g. isosorbide mononitrate)	Eccentric dosing regimen (e.g. twice daily at 8 a.m. and 2 p.m.)	Reduces development of nitrate tolerance by allowing drug-free period each night
Aspirin	With food	Minimises gastrotoxic effects
Alendronate	Once in the morning before breakfast, sitting upright	Minimises risk of oesophageal irritation
Tetracyclines	2 hours before or after food or antacids	Divalent and trivalent cations chelate tetracyclines, preventing absorption
Hypnotics (e.g. temazepam)	Once at night	Maximises therapeutic effect and minimises daytime sedation
Antihypertensive drugs (e.g. amlodipine)	Once in the morning	Blood pressure is higher during the daytime

(HMG CoA = 3-hydroxy-3-methylglutaryl-coenzyme A)

2.20 What patients need to know about their medicines*

Knowledge	Comment
The reason for taking the medicine **How the medicine works**	Reinforces the goals of therapy
How to take the medicine	May be important for the effectiveness (e.g. inhaled salbutamol in asthma) and safety (e.g. alendronate for osteoporosis) of treatment
What benefits to expect	May help to support adherence or prompt review because of treatment failure
What adverse effects might occur	Discuss common and mild effects that may be transient and might not require discontinuation Mention rare but serious effects that might influence the patient's consent
Precautions that improve safety	Explain symptoms to report that might allow serious adverse effects to be averted, monitoring that will be required and potentially important drug–drug interactions
When to return for review	This will be important to enable monitoring

*Many medicines are provided with patient information leaflets, which the patient should be encouraged to read.

expectations affect the goals of therapy and help in judging the acceptable benefit/harm balance when selecting treatments. Very often, patients may wish to defer to the professional expertise of the prescriber. Nevertheless, they play key roles in adherence to therapy and in monitoring treatment, not least by providing early warning of adverse events. It is important that they are provided with the necessary information to understand the choice that has been made, what to expect from the treatment, and any measurements that must be undertaken (Box 2.20).

A major drive to include patients has been the recognition that up to half of the drug doses for chronic preventative therapy are not taken. This is often termed 'non-compliance' but is more appropriately called 'non-adherence', to reflect a less paternalistic view of the doctor–patient relationship; it may or may not be intentional. Non-adherence to the dose regimen reduces the likelihood of benefits to the patient and can be costly in terms of wasted medicines and unnecessary health-care episodes. An important reason may be a failure of concordance with the prescriber about the goals of treatment. A more open and shared decision-making process might resolve any misunderstandings at the outset and foster improved adherence as well as improved satisfaction with health-care services and confidence in prescribers.

Writing the prescription

The culmination of the planning described above is writing an accurate and legible prescription so that the drug will be dispensed and administered as planned (see 'Writing prescriptions' below).

Monitoring treatment effects

Rational prescribing involves monitoring for the beneficial and adverse effects of treatment so that the balance remains in favour of a positive outcome (see 'Monitoring drug therapy' below).

Stopping drug therapy

It is also important to review long-term treatment at regular intervals to assess whether continued treatment is required. Elderly patients are keen to reduce their medication burden and are often prepared to compromise on the original goals of long-term preventative therapy to achieve this.

Prescribing in special circumstances

Prescribing for patients with renal disease

Patients with renal impairment are readily identified by having a low estimated glomerular filtration rate (eGFR < 60 mL/min) based on their serum creatinine, age, sex and ethnic group (p. 466). This group includes a large proportion of elderly patients. If a drug (or its active metabolites) is eliminated predominantly by the kidneys, it will tend to accumulate and so the maintenance dose must be reduced. For some drugs, renal impairment makes patients more sensitive to their adverse pharmacodynamic effects. Examples of drugs that require extra caution in patients with renal disease are listed in Box 2.21.

2.21 Some drugs that require extra caution in patients with renal or hepatic disease

Kidney disease	Liver disease
Pharmacodynamic effects enhanced	
ACE inhibitors and ARBs (renal impairment, hyperkalaemia) Metformin (lactic acidosis) Spironolactone (hyperkalaemia) NSAIDs (impaired renal function) Sulphonylureas (hypoglycaemia) Insulin (hypoglycaemia)	Warfarin (increased anticoagulation because of reduced clotting factor synthesis) Metformin (lactic acidosis) Chloramphenicol (bone marrow suppression) NSAIDs (gastrointestinal bleeding, fluid retention) Sulphonylureas (hypoglycaemia) Benzodiazepines (coma)
Pharmacokinetic handling altered (reduced clearance)	
Aminoglycosides (e.g. gentamicin) Vancomycin Digoxin Lithium Other antibiotics (e.g. ciprofloxacin) Atenolol Allopurinol Cephalosporins Methotrexate Opioids (e.g. morphine)	Phenytoin Rifampicin Propranolol Warfarin Diazepam Lidocaine Opioids (e.g. morphine)

(ARB = angiotensin receptor blocker)

Prescribing for patients with hepatic disease

The liver has a large capacity for drug metabolism and hepatic insufficiency has to be advanced before drug dosages need to be modified. Patients who may have impaired metabolism include those with jaundice, ascites, hypoalbuminaemia, malnutrition or encephalopathy. Hepatic drug clearance may also be reduced in acute hepatitis, in hepatic congestion due to cardiac failure, and if there is intrahepatic arteriovenous shunting (for example, in hepatic cirrhosis). There are no good tests of hepatic drug-metabolising capacity or of biliary excretion, so dosage should be guided by the therapeutic response and careful monitoring for adverse effects. The presence of liver disease also increases the susceptibility to adverse pharmacological effects of drugs. Some drugs that require extra caution in patients with hepatic disease are listed in Box 2.21.

Prescribing for elderly patients

See Box 2.22.

2.22 Prescribing in old age

- **Reduced drug elimination**: partly due to impaired renal function.
- **Increased sensitivity to drug effects**: notably in the brain (leading to sedation or delirium) and as a result of comorbidities.
- **More drug interactions**: largely as a result of polypharmacy.
- **Lower starting doses and slower dose titration**: often required, with careful monitoring of drug effects.
- **Drug adherence**: may be poor because of cognitive impairment, difficulty swallowing (dry mouth) and complex polypharmacy regimens. Supplying medicines in pill organisers (e.g. dosette boxes or calendar blister packs), providing automatic reminders, and regularly reviewing and simplifying the drug regimen can help.
- **Some drugs that require extra caution, and their mechanisms**:
  - Digoxin: increased sensitivity of Na^+/K^+ pump; hypokalaemia due to diuretics; renal impairment favours accumulation → increased risk of toxicity
  - Antihypertensive drugs: reduced baroreceptor function → increased risk of postural hypotension
  - Antidepressants, hypnotics, sedatives, tranquillisers: increased sensitivity of the brain; reduced metabolism → increased risk of toxicity
  - Warfarin: increased tendency to falls and injury and to bleeding from intra- and extracranial sites; increased sensitivity to inhibition of clotting factor synthesis → increased risk of bleeding
  - Clomethiazole, lidocaine, nifedipine, phenobarbital, propranolol, theophylline: metabolism reduced → increased risk of toxicity
  - NSAIDs: poor renal function → increased risk of renal impairment; susceptibility to gastrotoxicity → increased risk of upper gastrointestinal bleeding.

Prescribing for women who are pregnant or breastfeeding

Prescribing in pregnancy should be avoided if possible to minimise the risk of adverse effects in the fetus.

2.23 Prescribing in pregnancy

- **Teratogenesis**: a potential risk, especially when drugs are taken between 2 and 8 weeks of gestation. Common teratogens include retinoids (e.g. isotretinoin), cytotoxic drugs, ACE inhibitors, corticosteroids, antiepileptics and warfarin. If there is inadvertent exposure, then the timing of conception should be established, counselling given and investigations undertaken for fetal abnormalities.
- **Adverse fetal effects in late gestation**: for example, tetracyclines stain growing teeth and bones; sulphonamides displace fetal bilirubin from plasma proteins, potentially causing kernicterus; opioids given during delivery suppress the neonate's respiration.
- **Altered maternal pharmacokinetics**: extracellular fluid volume and V_d increase. Plasma albumin falls but other binding globulins (e.g. for thyroid and steroid hormones) increase. Glomerular filtration increases by approximately 70%, enhancing renal clearance. Placental metabolism contributes to increased clearance, e.g. of thyroxine and corticosteroids.
- **In practice**:
  Avoid any drugs unless the benefit to the mother greatly outweighs the risk to the fetus
  Use drugs for which there is some record of safety
  Use the lowest dose for the shortest time possible
  Choose the least harmful drug if alternatives are available

However, drug therapy in pregnancy may be required either for a pre-existing problem (e.g. epilepsy, asthma, hypothyroidism) or for problems that arise during pregnancy (e.g. morning sickness, anaemia, prevention of neural tube defects, gestational diabetes, hypertension). About 35% of women take drug therapy at least once during pregnancy and 6% take drug therapy during the first trimester (excluding iron, folic acid and vitamins). The most commonly used drugs are simple analgesics, antibacterial drugs and antacids. Some considerations when prescribing in pregnancy are listed in Box 2.23.

Drugs that are excreted in breast milk may cause adverse effects in the baby. Prescribers should always consult the summary of product characteristics for each drug or a reliable formulary when treating a pregnant woman or breastfeeding mother.

Writing prescriptions

A prescription is a means by which a prescriber communicates the intended plan of treatment to the pharmacist who dispenses a medicine and to a nurse or patient who administers it. It should be precise, accurate, clear and legible. The two main kinds of prescription are those written, dispensed and administered in hospital and those written in primary care (in the UK by a GP), dispensed at a community pharmacy and self-administered by the patient. The information supplied must include:

- the date
- identification of the patient
- the name of the drug
- the formulation
- the dose
- the frequency of administration
- the route and method of administration
- the amount to be supplied (primary care only)
- instructions for labelling (primary care only)
- the prescriber's signature.

Prescribing in hospital

Although GP prescribing is increasingly electronic, most hospital prescribing continues to be based around the prescription and administration record (the 'drug chart'). A variety of charts is in use and prescribers must familiarise themselves with the local version. Most contain the following sections:

- *Basic patient information*. Will usually include name, age, date of birth, hospital number and address. These details are often 'filled in' using a sticky addressograph label, but this increases the risk of serious error.
- *Previous adverse reactions/allergies*. Communicates important patient safety information based on a careful drug history and/or the medical record.
- *Other medicines charts*. Notes any other hospital prescription documents that contain current prescriptions being received by the patient (e.g. anticoagulants, insulin, oxygen, fluids).
- *Once-only medications*. For prescribing medicines to be used infrequently, such as single-dose prophylactic antibiotics and other pre-operative medications.
- *Regular medications*. For prescribing medicines to be taken for a number of days or continuously, such as a course of antibiotics, antihypertensive drugs etc.
- *'As required' medications*. For prescribing for symptomatic relief, usually to be administered at the discretion of the nursing staff (e.g. antiemetics, analgesics).

Prescribers should be aware of the risks of prescription error (Box 2.24 and Box 2.13, p. 30), ensure they have considered the rational basis for their prescribing decision described above, and then follow the rules in Box 2.25 in order to write the prescription. It is a basic principle that a prescription will be followed by a judgement as to its success or failure and appropriate changes made, often by discontinuing one prescription and writing another.

Hospital discharge ('to take out') medicines

Most patients will be prescribed a short course of their medicines at discharge. This prescription is particularly important because it usually informs future therapy at the point of transfer of prescribing responsibility to primary care. Great care is required to ensure that this list is accurate and that any hospital medicines to be stopped are not included or are identified as of specified short duration. It is also important that any significant ADRs experienced in hospital are recorded and that any specific monitoring or review is identified.

Prescribing in primary care

Most of the considerations above are equally applicable to primary care (GP) prescriptions. In many health-care systems, community prescribing is electronic, making issues of legibility irrelevant and often providing basic decision support to limit the range of doses that can be written and highlight potential drug interactions.

2.24 High-risk prescribing moments

- Trying to amend an active prescription (e.g. altering the dose/timing) – *always avoid and start again*
- Writing up drugs in the immediate presence of more than one prescription chart or set of notes – *avoid*
- Allowing one's attention to be diverted in the middle of completing a prescription – *avoid*
- Prescribing 'high risk' drugs (e.g. anticoagulants, opioids, insulin, sedatives) – *ask for help if necessary*
- Prescribing parenteral drugs – *take care*
- Rushing prescribing (e.g. in the midst of a busy ward round) – *avoid*
- Prescribing unfamiliar drugs – *consult the formulary and ask for help if necessary*
- Transcribing multiple prescriptions from an expired chart to a new one – *take care*
- Writing prescriptions based on information from another source such as a referral letter (the list may contain errors and some of the medicines may be the cause of the patient's illness) – *review the justification for each as if it is a new prescription*
- Writing up 'to take out' drugs (because these will become the patient's regular medication for the immediate future) – *take care and seek advice if necessary*
- Calculating drug doses – *ask a colleague to perform an independent calculation*
- Prescribing sound-alike or look-alike drugs (e.g. chlorphenamine and chlorpromazine) – *take care*

2.25 How to write a drug prescription

- **Write** in block capitals, legibly, with black ballpoint pen. Do not amend what is already written: if a mistake is made, then start again
- Ensure there is clear and unambiguous labelling to **identify the patient.** Write the patient's name, hospital number and date of birth (with age if under 12 years) on every sheet. The patient's weight and height may be required to calculate safe doses for many drugs with narrow therapeutic indices
- Check the **drug sensitivities/allergies** box and obtain further details of the drug history if there are any doubts
- Use the generic **International Non-proprietary Name (INN)** rather than brand name (e.g. write 'SIMVASTATIN', not 'ZOCOR®'). The only exceptions are when variation occurs in the properties of alternative branded formulations (e.g. modified-release preparations of drugs such as lithium, theophylline, phenytoin and nifedipine) or when the drug is a combination product with no generic name (e.g. Kliovance®). Do not use abbreviations, e.g. write 'ISOSORBIDE MONONITRATE' not 'ISMN'
- Write the **drug dose.** The only acceptable abbreviations are 'g' and 'mg'. 'Units' (e.g. of insulin or heparin) and 'micrograms' must always be written in full, never as 'U' or 'μg' (nor 'mcg', nor 'ug'). Avoid decimal points (i.e. 500 mg not 0·5 g) or, if unavoidable, put a '0' in front of it (e.g. '0·5 micrograms' not '·5 micrograms'). Do not use a decimal point for round numbers (e.g. '7 mg' not '7·0 mg'). For liquid preparations write the dose in mg; 'mL' can only be written for a combination product (e.g. Gaviscon® liquid) or if the strength is not expressed in weight (e.g. adrenaline (epinephrine) 1 in 1000). Use numbers/figures (e.g. 1 or 'one') to denote use of a sachet/enema but avoid prescribing numbers of tablets without specifying their strength. Always include the dose of inhaled drugs in addition to stating numbers of 'puffs', as strengths can vary. For some drugs a maximum dose may need to be stated (e.g. colchicine in gout)
- Write the **route and method of administration.** Widely accepted abbreviations are: intravenous – 'IV'; intramuscular – 'IM'; subcutaneous – 'SC'; sublingual – 'SL'; per rectum – 'PR'; per vaginam – 'PV'; nasogastric – 'NG'; inhaled – 'INH'; and topical – 'TOP'. 'ORAL' is preferred to per oram – 'PO'. Never abbreviate 'INTRATHECAL'. Care should be taken in specifying 'RIGHT' or 'LEFT' for eye and ear drops. It may be necessary to specify the method of giving a medicine intravenously (e.g. as a single undiluted bolus injection, or as an infusion in a specified volume of saline over a specified time)
- Indicate the **frequency and timing of administration** clearly. For example: furosemide 40 mg once daily; amoxicillin 250 mg 3 times daily. Widely accepted Latin abbreviations for dose frequency are: once daily – 'OD'; twice daily – 'BD'; 3 times daily – 'TDS'; 4 times daily – 'QDS'; as required – 'PRN'; in the morning – 'OM' (omni mane); at night – 'ON' (omni nocte); and immediately – 'stat'. Alternatives are, for example, 6-hourly and 8-hourly, but these are less precise. The hospital chart usually requires specific times to be identified for regular medicines that coincide with nursing drug rounds. If treatment is for a known time period, cross off subsequent days when the medicine is not required. Similarly, if a drug is not to be given every day, cross off the days when it is not required. For **'as required' medicines** describe the indication, frequency, minimal time interval between doses, and maximum dose in any 24-hour period
- Use the space provided for **added information,** e.g. whether a medicine should be taken with food, type of inhaler device used, and anything else that the drug dispenser should know. State here the times for peak/trough plasma levels for drugs requiring therapeutic monitoring
- **Sign and print your name** clearly so that you can be identified by colleagues. The prescription should be dated
- **Discontinue** a prescription by drawing a vertical line at the point of discontinuation, horizontal lines through the remaining days on the chart, and diagonal lines through the drug details and administration boxes. Sign and date this action and consider writing a supplementary note to explain it (e.g. describing any adverse effect)

Important additional issues more relevant to GP prescribing are:

- *Formulation*. The prescription needs to carry information about the formulation for the dispensing pharmacist (e.g. tablets or oral suspension).
- *Amount to be supplied*. In the hospital the pharmacist will organise this. Elsewhere it must be specified either as the precise number of tablets or as the duration of treatment. Creams and ointments should be specified in grams and lotions in mL.
- *Controlled drugs*. Prescriptions for 'controlled' drugs (e.g. opioid analgesics, with potential for drug abuse) are subject to additional legal requirements. In the UK they must contain the address of the patient and prescriber (not necessary on most hospital forms), the form and the strength of the preparation, and the total quantity of the preparation/number of dose units in both words and figures.
- *'Repeat prescriptions'*. A large proportion of GP prescribing involves 'repeat prescriptions' for chronic medication. These are often generated automatically, although the prescriber remains responsible for regular review and for ensuring that the benefit to harm ratio remains favourable.

Monitoring drug therapy

Prescribers should measure the effects of the drug, both beneficial and harmful, to inform decisions about dose titration (up or down), discontinuation or substitution of treatment. Monitoring can be achieved subjectively by asking the patient about symptoms or more objectively by measuring a clinical effect. Alternatively, if the pharmacodynamic effects of the drug are difficult to assess, then the plasma drug concentration may be measured on the basis that it will be closely related to the effect of the drug (see Fig. 2.2, p. 19).

Clinical and surrogate endpoints

Ideally, clinical endpoints are measured directly and the drug dosage titrated to achieve the therapeutic goal and avoid toxicity (e.g. control of ventricular rate in a patient with atrial fibrillation). Sometimes this is impractical because the clinical endpoint is a future event (e.g. prevention of myocardial infarction by statins or resolution of a chest infection with antibiotics); in these circumstances it may be possible to select a 'surrogate' endpoint that will predict success or failure. This may be an intermediate step in the pathophysiological process (e.g. serum cholesterol as a surrogate for risk of myocardial infarction) or a measurement which follows the pathophysiology even if it is not a key factor in its progression (e.g. serum C-reactive protein as a surrogate for resolution of inflammation in chest infection). Such surrogates are sometimes termed 'biomarkers'.

Plasma drug concentration

The following criteria must be met to justify routine monitoring by plasma drug concentration:

- Clinical endpoints and other pharmacodynamic (surrogate) effects are difficult to monitor.
- The relationship between plasma concentration and clinical effects is predictable.
- The therapeutic index is low. For drugs with a high therapeutic index any variability in plasma concentrations is likely to be irrelevant clinically.

Some examples of drugs that fulfil these criteria are listed in Box 2.26.

Measurement of plasma concentration may be useful in planning adjustments of drug dose and frequency of administration; to explain an inadequate therapeutic

2.26 Drugs commonly monitored by plasma drug concentration

Drug	Half-life (hrs)*	Comment
Digoxin	36	Steady state takes several days to achieve. Samples should be taken 6 hrs post dose. Measurement is useful to confirm the clinical impression of toxicity or non-adherence but clinical effectiveness is better assessed by ventricular heart rate. Risk of toxicity increases progressively at concentrations > 1.5 μg/L, and is likely at concentrations > 3.0 μg/L (toxicity is more likely in the presence of hypokalaemia)
Gentamicin	2	Measure pre-dose trough concentration (should be < 1 μg/mL) to ensure that accumulation (and the risk of nephrotoxicity and ototoxicity) is avoided; see p. 156
Levothyroxine	> 120	Steady state may take up to 6 wks to achieve (p. 743)
Lithium	24	Steady state takes several days to achieve. Samples should be taken 12 hrs post dose. Target range 0.4–1 mmol/L
Phenytoin	24	Measure pre-dose trough concentration (should be 10–20 mg/L) to ensure that accumulation is avoided. Good correlation between concentration and toxicity. Concentration may be misleading in the presence of hypoalbuminaemia
Theophylline (oral)	6	Steady state takes 2–3 days to achieve. Samples should be taken 6 hrs post dose. Target concentration is 10–20 mg/L but its relationship with bronchodilator effect and adverse effects is variable
Vancomycin	6	Measure pre-dose trough concentration (should be 10–15 mg/L) to ensure clinical efficacy and that accumulation and the risk of nephrotoxicity is avoided

*Half-lives vary considerably with different formulations and between patients.

response (by identifying subtherapeutic concentration or incomplete adherence); to establish whether a suspected ADR is likely to be caused by the drug; and to assess and avoid potential drug interactions.

Timing of samples in relation to doses

The concentration of drug rises and falls during the dosage interval (see Fig. 2.4B, p. 23). Measurements made during the initial absorption and distribution phases are unpredictable because of the rapidly changing concentration, so samples are usually taken at the end of the dosage interval (a 'trough' or 'pre-dose' concentration). This measurement is normally made in steady state, which usually takes five half-lives to achieve after the drug is introduced or the dose changed (unless a loading dose has been given).

Interpreting the result

A target range is provided for many drugs, based on average thresholds for therapeutic benefit and toxicity. Inter-individual variability means that these can only be used as a guide. For instance, a patient who describes symptoms that could be consistent with toxicity but has a drug concentration in the top half of the target range should still be suspected of suffering toxic effects. Another important consideration is that some drugs are heavily protein-bound (e.g. phenytoin) but only the unbound drug is pharmacologically active. Therefore, patients with hypoalbuminaemia may have a therapeutic or even toxic concentration of unbound drug, despite a low 'total' concentration.

Almost all diseases have a genetic component. In children and young adults in particular, many of the disorders causing long-term morbidity and mortality are genetically determined. The molecular basis of most Mendelian (or 'single-gene') diseases has now been determined, and our understanding of the abnormalities in cell function responsible for the clinical presentation is improving. It has also become clear that variants in many genes contribute to the pathogenesis of several common diseases such as asthma, rheumatoid arthritis and osteoporosis. In this chapter, we review key principles of cell biology, cellular signalling and molecular genetics, with emphasis on the diagnosis and assessment of patients with genetic diseases.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Cell and molecular biology

All human cell types are derived from a single totipotent stem cell, the zygote (the fertilised ovum). During development, organs and tissues are formed by the integration of four closely regulated cellular processes: cell division, migration, differentiation and programmed cell death. In many adult tissues such as skin, liver and the intestine, these processes continue throughout life, mediated by populations of stem cells that are responsible for tissue maintenance and repair. Cell biology is the study of these processes and of intracellular compartments, called organelles, which maintain cellular homeostasis. Dysfunction of any of these processes may lead to disease.

DNA, chromosomes and chromatin

The nucleus is a membrane-bound compartment found in all cells except erythrocytes and platelets. The human nucleus contains 46 chromosomes, each a single linear molecule of deoxyribonucleic acid (DNA) complexed with proteins to form chromatin. The basic protein unit of chromatin is the nucleosome, comprising 147 base pairs (bp) of DNA wound round a core of four different histone proteins. The vast majority of chromosomal DNA is double-stranded, with the exception of the ends of chromosomes, where 'knotted' domains of single-stranded DNA, called telomeres, are found. Telomeres prevent degradation and accidental fusion of chromosomal DNA.

The genome comprises approximately 3.1 billion bp of DNA. Humans are diploid organisms, meaning that each nucleus contains two copies of the genome, visible microscopically as 22 identical chromosomal pairs – the autosomes – named 1 to 22 in descending size order (see Fig. 3.11, p. 57), and two sex chromosomes (XX in females and XY in males). Each DNA strand consists of a linear sequence of four bases – guanine (G), cytosine (C), adenine (A) and thymine (T) – covalently linked by phosphate bonds. The sequence of one strand of double-stranded DNA determines the sequence of the opposite strand because the helix is held together by hydrogen bonds between adenine and thymine or guanine and cytosine nucleotides.

Genes and transcription

Genes are functional elements on the chromosome that are capable of transmitting information from the DNA template via the production of messenger ribonucleic acid (mRNA) to the production of proteins. The human genome contains an estimated 21 500 genes, although many of these are inactive or silenced in different cell types. For example, although the gene for parathyroid hormone (PTH) is present in every cell, activation of gene expression and production of PTH mRNA is virtually restricted to the parathyroid glands. Genes that are active in different cells undergo transcription, which requires binding of an enzyme called RNA polymerase II to a segment of DNA at the start of the gene termed the promoter. Once bound, RNA polymerase II moves along one strand of DNA, producing an RNA molecule that is complementary to the DNA template. A DNA sequence close to the end of the gene, called the polyadenylation signal, acts as a signal for termination of the RNA transcript (Fig. 3.1). The activity of RNA polymerase II is regulated by transcription factors. These proteins bind to specific DNA sequences at the promoter, or to enhancer elements that may be many thousands of base pairs away from the promoter. A loop in the chromosomal DNA brings the enhancer close to the promoter, enabling the bound proteins to interact.

The human genome encodes approximately 1200 different transcription factors, and mutations in many of these can cause genetic diseases (Fig. 3.2). Mutation of the transcription factor binding sites within promoters or enhancers also causes genetic disease. For example, the blood disorder alpha-thalassaemia can result from loss of an enhancer located more than 100 000 bp from the alpha-globin gene promoter, leading to greatly reduced transcription. Similarly, variation in the promoter of the gene encoding intestinal lactase determines whether or not this is 'shut off' in adulthood, producing lactose intolerance.

The accessibility of promoters to RNA polymerase II depends on the structural configuration of chromatin. Transcriptionally active regions have decondensed (or 'open') chromatin (euchromatin). Conversely, transcriptionally silent regions are associated with densely packed chromatin called heterochromatin. Chemical modification of both the DNA and core histone proteins allows heterochromatic regions to be distinguished from open chromatin. DNA can be modified by addition of a methyl group to cytosine molecules (methylation). In promoter regions, this silences transcription, since methyl cytosines are usually not available for transcription factor binding or RNA transcription. The core histones can also be modified via methylation, phosphorylation, acetylation or sumoylation at specific amino acid residues in a pattern that reflects the functional state of the chromatin; this is called the histone code – reflecting an emerging understanding of the 'rules' by which specific modifications mark transcriptionally activating (trimethylation of lysine 4 on histone H3; acetylation of many histone residues) or silencing (methylation of lysine 9 on histone H4; deacetylation of many histone residues) effects. Such DNA and protein modifications are termed epigenetic, as they do not alter the primary sequence of the DNA code but have biological significance in chromosomal function. Abnormal epigenetic changes are increasingly recognised as

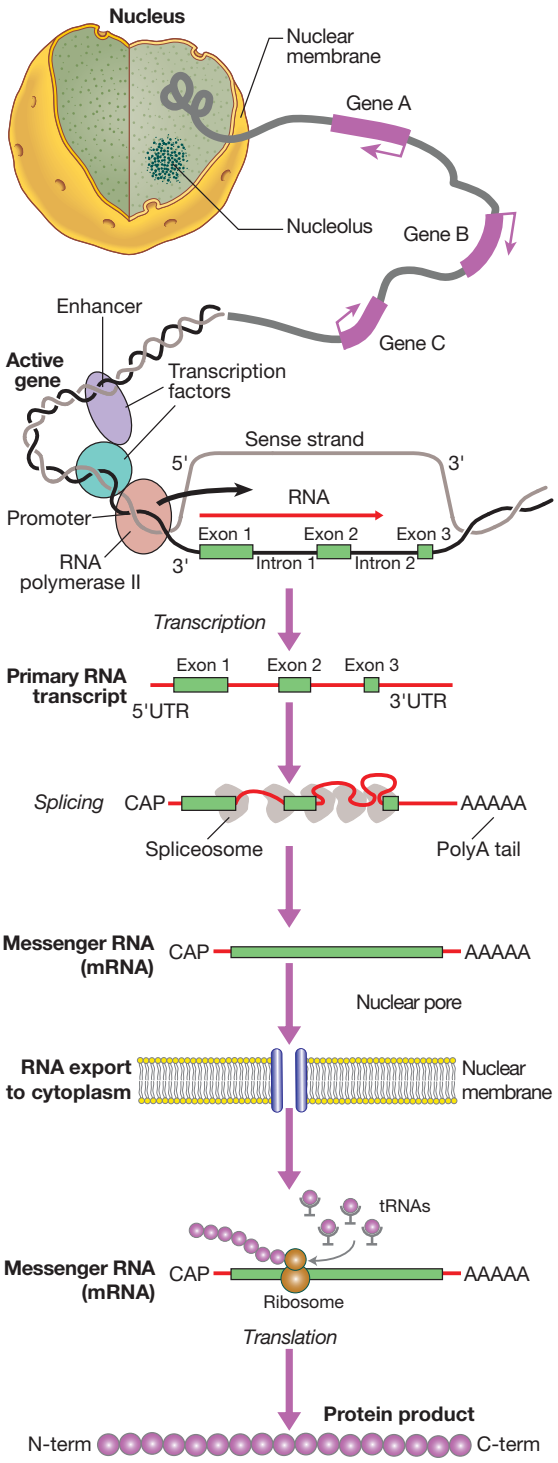

Fig. 3.1 RNA synthesis and its translation into protein. Gene transcription involves binding of RNA polymerase II to the promoter of genes being transcribed with other proteins (transcription factors) that regulate the transcription rate. The primary RNA transcript is a copy of the whole gene and includes both introns and exons, but the introns are removed within the nucleus by splicing and the exons are joined to form the messenger RNA (mRNA). Prior to export from the nucleus, a methylated guanosine nucleotide is added to the 5′ end of the RNA ('cap') and a string of adenine nucleotides is added to the 3′ ('poly A tail'). This protects the RNA from degradation and facilitates transport into the cytoplasm. In the cytoplasm, the mRNA binds to ribosomes and forms a template for protein production.

important events in the progression of cancer, allowing expression of genes which are normally silenced during development to support cancer cell de-differentiation (see Box 3.3, p. 54). They also afford therapeutic targets. For instance, the histone deacetylase inhibitor vorinostat has been successfully used to treat cutaneous T-cell lymphoma, due to the re-expression of genes that had previously been silenced in the tumour. These genes encode transcription factors which promote T-cell cell differentiation as opposed to proliferation, thereby causing tumour regression.

RNA splicing, editing and degradation

Transcription produces an RNA molecule that is a copy of the whole gene, termed the primary or nascent transcript. RNA differs from DNA in three main ways:

- RNA is single-stranded.
- The sugar residue within the nucleotide is ribose, rather than deoxyribose.
- Uracil (U) is used in place of thymine (T).

The nascent RNA molecule then undergoes splicing, to generate the shorter, 'mature' mRNA molecule, which provides the template for protein production. Splicing removes the regions of the nascent RNA molecule that are not required to make protein (intronic regions), and retains and rejoins those segments that are necessary for protein production (exonic regions). Splicing is a highly regulated process that is carried out by a multimeric protein complex called the spliceosome. Following splicing, the mRNA molecule is exported from the nucleus and used as a template for protein synthesis. It should be noted that many genes produce more than one form of mRNA (and thus protein) by a process termed alternative splicing. Different proteins from the same gene can have entirely distinct functions. For example, in thyroid C cells the calcitonin gene produces mRNA encoding the osteoclast inhibitor calcitonin (p. 738), but in neurons the same gene produces an mRNA with a different complement of exons via alternative splicing, which encodes the neurotransmitter calcitonin-gene-related peptide.

The portion of the mRNA molecule that directs synthesis of a protein product is called the open reading frame (ORF). This comprises a contiguous series of three sequential bases (codons), which specify that a particular amino acid should be incorporated into the protein. There are 64 different codons; 61 of these specify incorporation of one of the 20 amino acids, whereas the remaining three codons – UAA, UAG and UGA (stop codons) – cause termination of the growing polypeptide chain. In humans, most ORF start with the amino acid methionine, which is specified by the codon AUG. All mRNA molecules have domains before and after the ORF called the 5′ untranslated region (5′UTR) and 3′UTR, respectively. The start of the 5′UTR contains a cap structure that protects mRNA from enzymatic degradation, and other elements within the 5′UTR are required for efficient translation. The 3′UTR also contains elements that regulate efficiency of translation and mRNA stability, including a stretch of adenine bases known as a polyA tail.

However, there are approximately 4500 genes in humans in which the transcribed RNA molecules do not code for proteins. There are various categories of

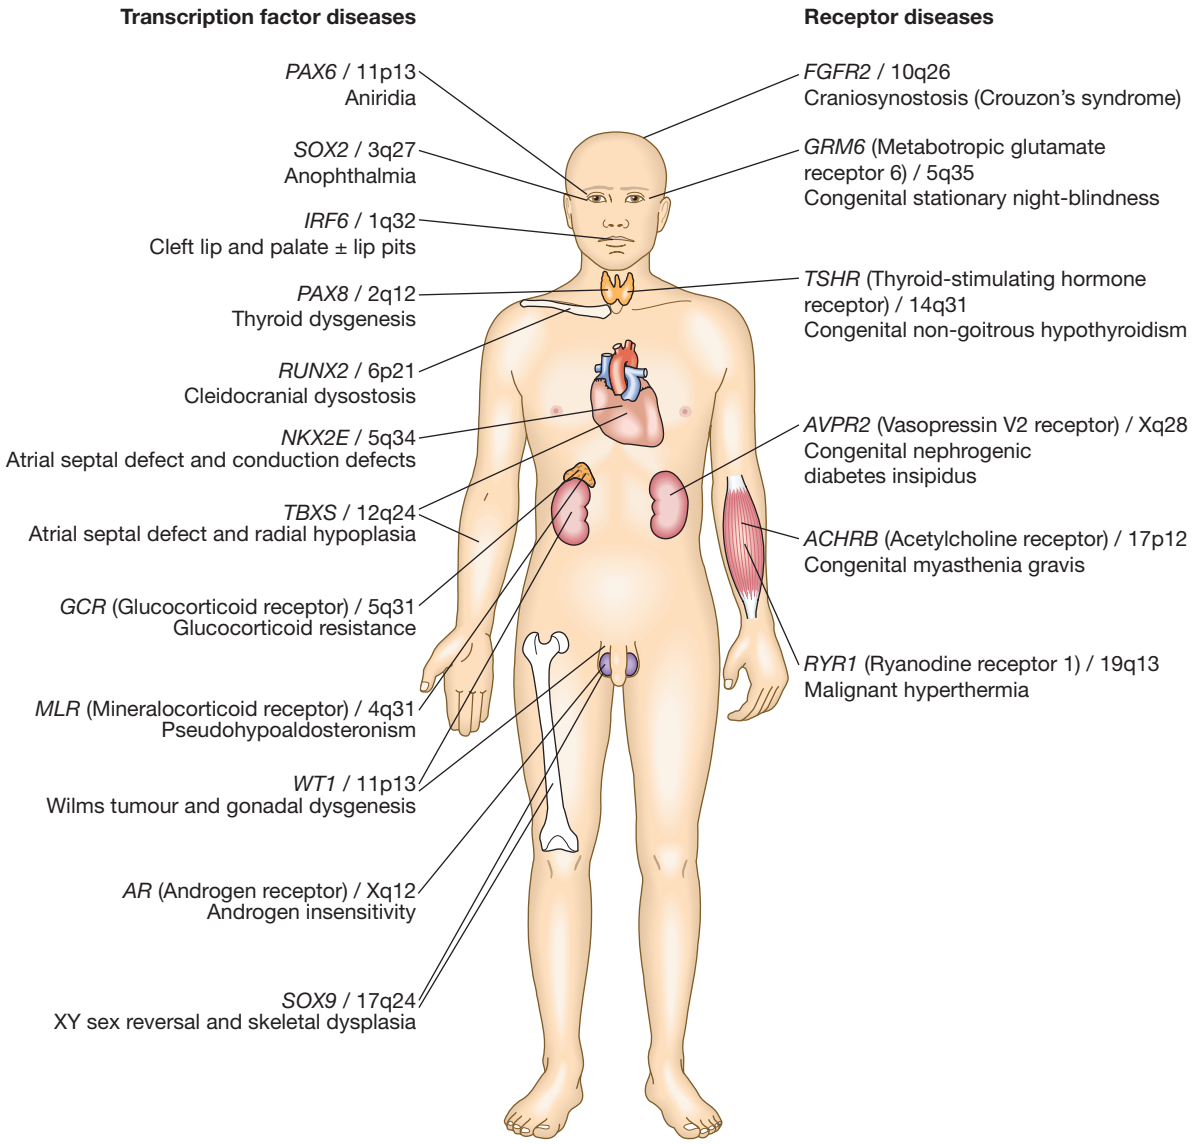

Fig. 3.2 Examples of genetic diseases caused by mutations in genes encoding either transcription factors or receptors.

non-coding RNA (ncRNA), including transfer RNA (tRNA), ribosomal RNA (rRNA), ribozymes and microRNA (miRNA). There are more than 1000 miRNAs that bind to various target mRNAs, typically in the 3'UTR, to affect mRNA stability. This usually results in enhanced degradation of the target mRNA, leading to translational gene silencing. Together, miRNAs affect over half of all human genes and have important roles in normal development, cancer and common degenerative disorders. This is the subject of considerable research interest at present.

Translation and protein production

Following splicing and export from the nucleus, mRNAs associate with ribosomes, which are the sites of protein production (see Fig. 3.1). Each ribosome consists of two subunits (40S and 60S), which comprise non-coding rRNA molecules complexed with proteins. During translation, tRNA binds to the ribosome. The tRNAs deliver amino acids to the ribosome so that the newly synthesised protein can be assembled in a stepwise fashion. Individual tRNA molecules bind a specific amino acid and 'read' the mRNA ORF via an 'anticodon' of three nucleotides that is complementary to the codon in mRNA. A proportion of ribosomes are bound to the membrane of the endoplasmic reticulum (ER), a complex tubular structure that surrounds the nucleus. Proteins synthesised on these ribosomes are translocated into the lumen of the ER, where they undergo folding and processing. From here the protein may be transferred to the Golgi apparatus, where it undergoes post-translational modifications, such as glycosylation (covalent attachment of sugar moieties), to form the mature protein that can be exported into the cytoplasm or packaged into vesicles for secretion. The clinical importance of post-translational modification of proteins is shown by the severe developmental, neurological, haemostatic and soft-tissue abnormalities that occur in patients with mutations of the enzymes that catalyse the addition of chains of sugar moieties to proteins. An example is phosphomannose isomerase deficiency, in

which there is a defect in the conversion of fructose-6-phosphate to mannose-6-phosphate. This results in a defect in supply of D-mannose derivatives for glycosylation of a variety of proteins, resulting in a multi-system disorder characterised by protein-losing enteropathy, hepatic fibrosis, coagulopathy and hypoglycaemia. Post-translational modifications can also be disrupted by the synthesis of proteins with abnormal amino acid sequences. For example, the most common mutation in cystic fibrosis (ΔF508) results in an abnormal protein that cannot be exported from the ER and Golgi.

Mitochondria and energy production

The mitochondrion is the main site of energy production within the cell. Mitochondria arose during evolution via the symbiotic association with an intracellular bacterium. They have a distinctive structure with functionally distinct inner and outer membranes. Mitochondria produce energy in the form of adenosine triphosphate (ATP). ATP is mostly derived from the metabolism of glucose and fat (Fig. 3.3). Glucose cannot

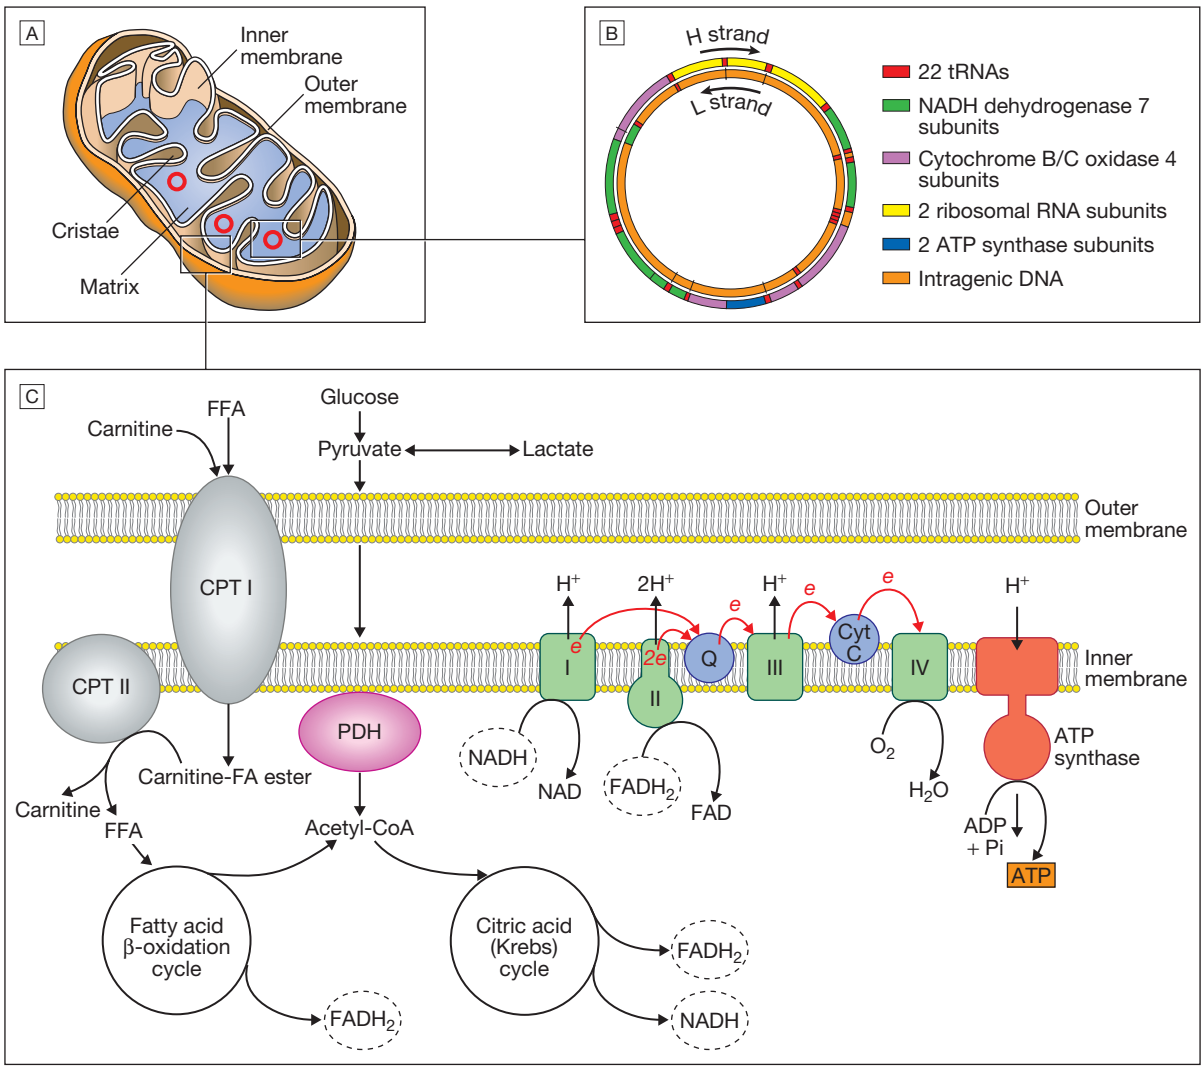

Fig. 3.3 Mitochondria. A Mitochondrial structure. There is a smooth outer membrane surrounding a convoluted inner membrane, which has inward projections called cristae. The membranes create two compartments: the inter-membrane compartment, which plays a crucial role in the electron transport chain, and the inner compartment (or matrix), which contains mitochondrial DNA and the enzymes responsible for the citric acid (Krebs) cycle and the fatty acid β-oxidation cycle. B Mitochondrial DNA. The mitochondrion contains several copies of a circular double-stranded DNA molecule, which has a non-coding region, and a coding region which encodes the genes responsible for energy production, mitochondrial tRNA molecules and mitochondrial rRNA molecules. ATP = adenosine triphosphate; NADH = nicotinamide adenine dinucleotide. C Mitochondrial energy production. Fatty acids enter the mitochondrion conjugated to carnitine by carnitine-palmityl transferase type 1 (CPT I) and, once inside the matrix, are unconjugated by CPT II to release free fatty acids (FFA). These are broken down by the β-oxidation cycle to produce acetyl-CoA. Pyruvate can enter the mitochondrion directly and is metabolised by pyruvate dehydrogenase (PDH) to produce acetyl-CoA. The acetyl-CoA enters the Krebs cycle, leading to the production of NADH and flavine adenine dinucleotide (reduced form) ($FADH_2$), which are used by proteins in the electron transport chain to generate a hydrogen ion gradient across the inter-membrane compartment. Reduction of NADH and $FADH_2$ by proteins I and II respectively releases electrons (e), and the energy released is used to pump protons into the inter-membrane compartment. As these electrons are exchanged between proteins in the chain, more protons are pumped across the membrane, until the electrons reach complex IV (cytochrome oxidase), which uses the energy to reduce oxygen to water. The hydrogen ion gradient is used to produce ATP by the enzyme ATP synthase, which consists of a proton channel and catalytic sites for the synthesis of ATP from ADP. When the channel opens, hydrogen ions enter the matrix down the concentration gradient, and energy is released that is used to make ATP.

enter mitochondria directly but is first metabolised to pyruvate via glycolysis. Pyruvate is then imported into the mitochondrion and metabolised to acetyl-coenzyme A (CoA). Fatty acids are transported into the mitochondria following conjugation with carnitine and are sequentially catabolised by a process called β-oxidation to produce acetyl-CoA. The acetyl-CoA from both pyruvate and fatty acid oxidation is used in the citric acid (Krebs) cycle – a series of enzymatic reactions that produces CO_2, NADH and $FADH_2$. Both NADH and $FADH_2$ then donate electrons to the respiratory chain. Here these electrons are transferred via a complex series of reactions resulting in the formation of a proton gradient across the inner mitochondrial membrane. The gradient is used by an inner mitochondrial membrane protein, ATP synthase, to produce ATP, which is then transported to other parts of the cell. Dephosphorylation of ATP is used to produce the energy required for many cellular processes.

Each mitochondrion contains 2–10 copies of a 16 kilobase (kB) double-stranded circular DNA molecule (mtRNA). mtDNA contains 13 protein-coding genes, all involved in the respiratory chain, and the ncRNA genes required for protein synthesis within the mitochondria (see Fig. 3.3). The mutational rate of mtDNA is relatively high due to the lack of protection by chromatin. Several mtDNA diseases characterised by defects in ATP production have been described. mtDNA diseases are inherited exclusively via the maternal line (see Fig. 3.7, p. 51). This unusual inheritance pattern exists because all mtDNA in an individual is derived from that person's mother via the egg cell, as sperm contribute no mitochondria to the zygote. Mitochondria are most numerous in cells with high metabolic demands, such as muscle, retina and the basal ganglia, and these tissues tend to be the ones most severely affected in mitochondrial diseases (Box 3.1). There are many other mitochondrial diseases that are caused by mutations in nuclear genes, which encode proteins that are then imported into the mitochondrion and are critical for energy production: for example, Leigh's syndrome and complex I deficiency.

Protein degradation

The cell uses several different systems to degrade proteins and other molecules that are damaged, are potentially toxic or have simply served their purpose. The proteasome is the main site of protein degradation within the cell. The first step in proteasomal degradation is ubiquitination – the covalent attachment of a protein called ubiquitin as a side chain to the target protein. Ubiquitination is carried out by a large group of enzymes called E3 ligases, whose function is to recognise specific proteins that should be targeted for degradation by the proteasome. The E3 ligases ubiquitinate their target protein, which is then transported to a large multiprotein complex called the 26S proteasome, where it is degraded. There is mounting evidence that defects in the proteasome contribute to the pathogenesis of many diseases, particularly degenerative diseases of the nervous system like Parkinson's disease and some types of dementia that are characterised by formation of abnormal protein aggregates (inclusion bodies) within neurons. At least one inherited disease, termed Angelman's syndrome, is due to a mutation affecting the UBE3 E3 ligase.

Proteins with complex post-translational modifications are degraded in membrane-bound structures called lysosomes, which have an acidic pH and contain proteolytic enzymes that degrade proteins. There are many inherited defects in lysosomal enzymes that result in failure to degrade intracellular toxic substances. For instance, in Gaucher's disease, mutations of the gene encoding lysosomal (acid) β-glucosidase lead to undigested lipid accumulating in macrophages, producing hepatosplenomegaly and, if severe, deposition in the brain and mental retardation.

Lysosomes are also crucial for the process of autophagy, a process of self-cannibalisation that allows the cell to adapt to periods of starvation by recycling cellular components. Autophagy is triggered by metabolic stress and begins with the formation of a membrane-bound vesicle called the autophagosome, which contains targeted cellular components such as long-lived proteins

3.1 The structure of the respiratory chain complexes and the diseases associated with their dysfunction

Complex	Enzyme	nDNA subunits[1]	mtDNA subunits[2]	Diseases
I	NADH dehydrogenase	38	7	MELAS, bilateral striatal necrosis, LHON, myopathy and exercise intolerance, Parkinsonism, Leigh's disease, exercise myoglobinuria, leucodystrophy/myoclonic epilepsy
II	Succinate dehydrogenase	4	0	Phaeochromocytoma
III	Cytochrome bc_1 complex	10	1	Parkinsonism/MELAS, cardiomyopathy, myopathy, exercise myoglobinuria
IV	Cytochrome c oxidase	10	3	Sideroblastic anaemia, myoclonic ataxia, deafness, myopathy, MELAS, mitochondrial encephalomyopathy, motor neuron disease-like, exercise myoglobinuria
V	ATP synthase	14	2	Leigh's disease, NARP, bilateral striatal necrosis

[1]nDNA subunits
[2]mtDNA subunits = number of different protein subunits in each complex that are encoded in the nDNA and mtDNA respectively.
(LHON = Leber hereditary optic neuropathy; MELAS = myopathy, encephalopathy, lactic acidosis and stroke-like episodes; MERRF = myoclonic epilepsy and ragged red fibres; mtDNA = mitochondrial DNA; NARP = neuropathy, ataxia and retinitis pigmentosa; nDNA = nuclear DNA)

and organelles. The autophagosome then fuses with the lysosome to start the degradation and recycling process. Mutations in proteins that are crucial for formation of the autophagosome lead to neurodegenerative diseases in humans, such as juvenile neuronal ceroid lipofuscinosis (Batten's disease), caused by autosomal recessive mutations in *CLN3*.

Peroxisomes are small, single membrane-bound cytoplasmic organelles containing many different oxidative enzymes such as catalase. Peroxisomes degrade hydrogen peroxide, bile acids and amino acids. However, the β-oxidation of very long-chain fatty acids appears to be their most important function, since mutations in the peroxisomal β-oxidation enzymes (or the proteins that import these enzymes into the peroxisome) result in the same severe congenital disorder as mutations that cause complete failure of peroxisomal biogenesis. This group of disorders is called Zellweger's syndrome (cerebrohepatorenal syndrome) and is characterised by severe developmental delay, seizures, hepatomegaly and renal cysts; the biochemical diagnosis is made on the basis of elevated plasma levels of very long-chain fatty acids.

The cell membrane and cytoskeleton

The cell membrane is a phospholipid bilayer, with hydrophilic surfaces and a hydrophobic core (Fig. 3.4). The cell membrane is, however, much more than a simple wall. Cholesterol-rich 'rafts' float within the membrane, and proteins are anchored to them via the post-translational addition of complex lipid moieties. The membrane also hosts a series of transmembrane proteins that function as receptors, pores, ion channels, pumps and associated energy suppliers. These proteins allow the cell to monitor the extracellular milieu, import crucial molecules for function, and exclude or exchange unwanted substances. Many protein–protein interactions within the cell membrane are highly dynamic, and individual peptides will associate and disassociate to effect specific roles.

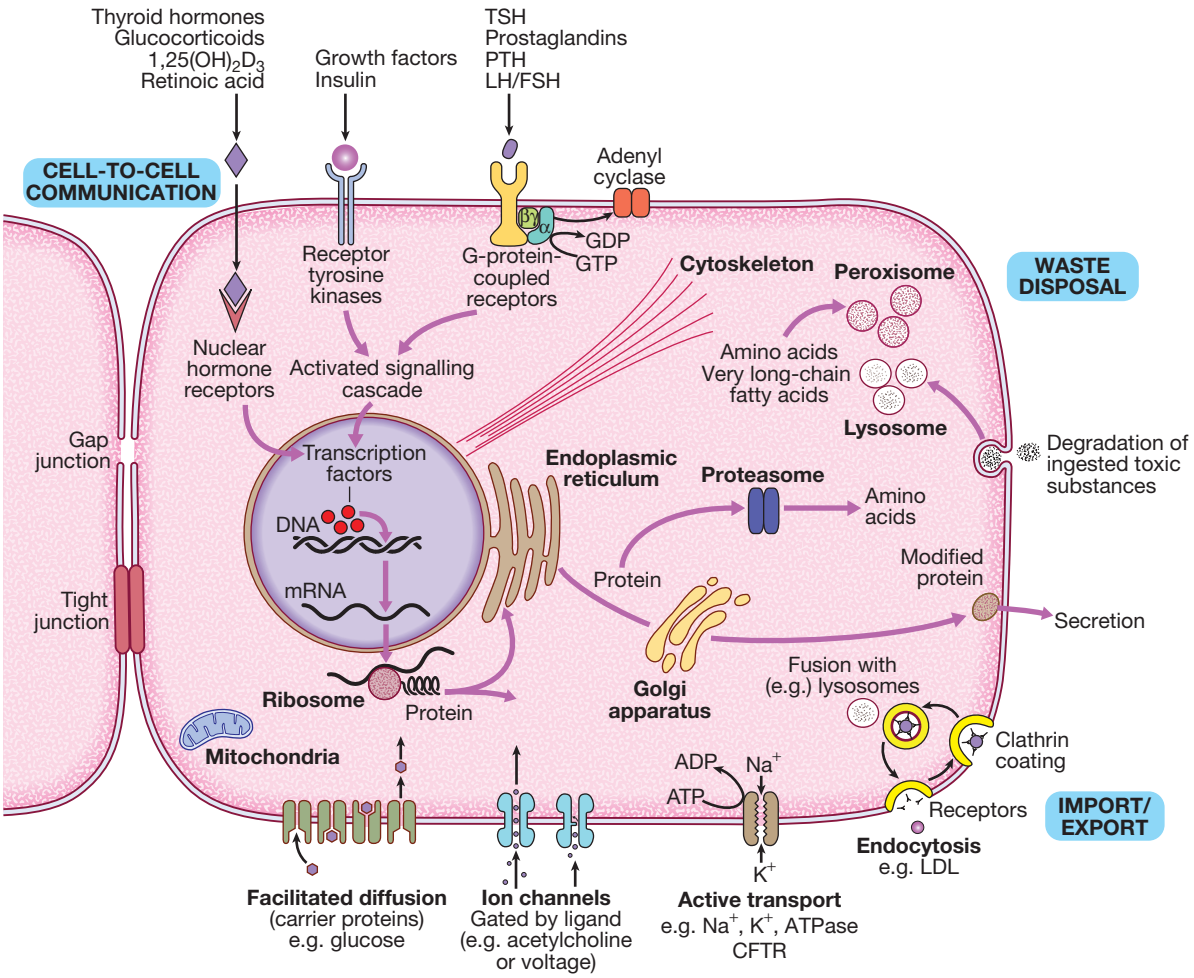

Fig. 3.4 An archetypal human cell. The basic cell components required for function within a tissue: (1) cell-to-cell communication taking place via gap junctions and the various types of receptor that receive signals from the extracellular environment and transduce these into intracellular messengers; (2) the nucleus containing the chromosomal DNA; (3) intracellular organelles, including the mechanisms for proteins and lipid catabolism; (4) the cellular mechanisms for import and export of molecules across the cell membrane. (ABC = ATP-binding cassette transporters; ATP = adenosine triphosphate: cAMP = cyclic adenosine monophosphate; CFTR = cystic fibrosis transmembrane regulator; CREB = cAMP response element-binding protein; GDP/GTP = guanine diphosphate/triphosphate; LDL = low-density lipoproteins; LH/FSH = luteinising hormone/follicle-stimulating hormone; PTH = parathyroid hormone; TSH = thyroid-stimulating hormone)

The cell membrane is permeable to hydrophobic substances, such as anaesthetic gases. Water is able to pass through the membrane via a pore formed by aquaporin proteins; mutations of an aquaporin gene cause congenital nephrogenic diabetes insipidus (p. 794). Most other molecules must be actively transported using either channels or pumps. Channels are responsible for the transport of ions and other small molecules across the cell membrane. They open and close in a highly regulated manner. The cystic fibrosis transmembrane conductance regulator (CFTR) is an example of an ion channel that is responsible for transport of chloride ions across epithelial cell membranes. Mutation of the CFTR chloride channel, highly expressed in the lung and gut, leads to defective chloride transport, producing cystic fibrosis. Pumps are highly specific for their substrate and often use energy (ATP) to drive transport against a concentration gradient.

Endocytosis is a cellular process that allows internalisation of larger complexes and molecules by invagination of plasma membrane to create intracellular vesicles. This process is typically mediated by specific binding of the particle to surface receptors. An important example is the binding of low-density lipoprotein (LDL) cholesterol-rich particles to the LDL receptor (LDLR) in a specialised region of the membrane called a clathrin pit. In some cases of familial hypercholesterolaemia (p. 453), LDLR mutations cause failure of this binding and thus reduce cellular uptake of LDL. Other LDLR mutations change a specific tyrosine in the intracellular tail of the receptor, preventing LDLR from concentrating in clathrin-coated pits and hence impairing uptake of LDL, even though LDLR bound to LDL is present elsewhere in the cell membrane.

The shape and structure of the cell are maintained by the cytoskeleton, which consists of a series of proteins which form microfilaments (actin), microtubules (tubulins) and intermediate filaments (keratins, desmin, vimentin, laminins) that facilitate cellular movement and provide pathways for intracellular transport. Dysfunction of the cytoskeleton may result in a variety of human disorders. For instance, some keratin genes encode intermediate filaments in epithelia. In epidermolysis bullosa simplex (p. 1292), mutations in keratin genes (*KRT5*, *KRT14*) lead to cell fragility, producing the characteristic blistering on mild trauma.

Receptors, cellular communication and intracellular signalling

Several mechanisms exist that allow cells to communicate with one another. Direct communication between adjacent cells occurs through gap junctions. These are pores formed by the interaction of 'hemichannels' in the membrane of adjacent cells. Many diseases are due to mutations in gap junction proteins, including the most common form of autosomal recessive hearing loss (*GJB2*) and the X-linked form of Charcot–Marie–Tooth disease (*GJB1*).

Communication between cells that are not directly in contact with each other occurs through hormones, cytokines and growth factors, which bind to and activate receptors on the target cell. Receptors then bind to various other proteins within the cell termed signalling molecules, which directly or indirectly activate gene expression to produce a cellular response.

There are many different signalling pathways; for example, in nuclear steroid hormone signalling, the ligands (steroid hormones or thyroid hormone) bind to their cognate receptor in the cytoplasm of target cells and the receptor/ligand complex then enters the nucleus, where it acts as a transcription factor to regulate the expression of target genes (Box 3.2). However, the most diverse and abundant types of receptor are located at the cell surface, and these activate gene expression and cellular responses indirectly. Activation of a cell surface receptor by its ligand results in a series of intracellular events, involving a cascade of phosphorylation of specific residues in target proteins by an important group of enzymes called kinases. This cascade typically culminates in phosphorylation and activation of transcription factors, which bind DNA and modulate gene expression.

Figure 3.5 depicts some of the signalling molecules downstream of the tumour necrosis factor (TNF) receptor. On activation of the receptor by the ligand (in this case, TNF), other molecules, including TNF-receptor-associated proteins (TRAFs), are recruited to the intracellular domain of the receptor. These regulate the activity of a kinase termed IKKγ, which in turn regulates activity of two further kinases termed IKKα and IKKβ. These regulate degradation of an inhibitory protein called IκB, which normally binds to the effector protein NFκB, holding it in the cytoplasm. On receptor activation, a signal is transmitted through TRAFs and the IKK proteins to cause phosphorylation and

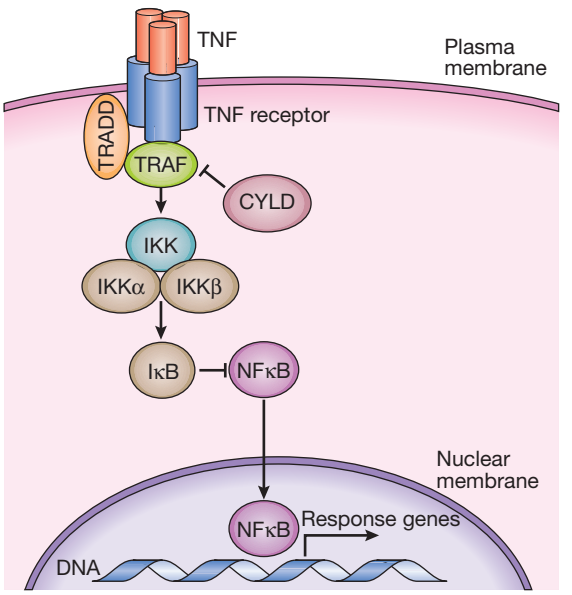

Fig. 3.5 The tumour necrosis factor (TNF) signalling pathway. TNF binds to its receptor, forming a trimeric complex in the cell membrane. Various receptor-associated factors are attracted to the intracellular domain of the receptor, including TNF-receptor-associated protein 6 (TRAF6) and tumour necrosis factor receptor type 1-associated death domain protein (TRADD). These proteins modulate activity of downstream signalling proteins, the most important of which are IKKγ (which in turn modulates activity of IKKα and IKKβ). These proteins cause phosphorylation of IκB, which is targeted for degradation by the proteasome, releasing NFκB, which translocates to the nucleus to activate gene expression. The signalling pathway is further regulated in a negative manner by cylindromatosis (CYLD), which de-ubiquitinates TRAF6, thereby impairing its ability to activate downstream signalling.

3.2 Examples of molecules involved in specific signalling cascades

Receptor	Receptor type	Ligands	Signal transduction	Clinical significance
TNFR1	TNF receptor superfamily	TNF	TRAF2/5, TRADD, IKK, IκB, NFκB, CYLD, RANK	Mediator of inflammatory diseases and immune responses
RANK	TNF receptor superfamily	RANKL	TRAF6, IKK, IκB, NFκB	Regulates bone resorption
Insulin receptor	Receptor tyrosine kinase	Insulin	IRS1, PI3K, PIP3, PKB, PDK1, mTORC2, GSK3	Regulation of energy homeostasis and glucose metabolism
Erythropoietin receptor	Receptor tyrosine kinase	Erythropoietin	JAK2, STAT5, c-Jun, c-Fos, Src PI3K, PIP3, PDK1, PKB	Regulates erythropoiesis
THRα and THRβ	Nuclear receptor superfamily	T3	Ligand/receptor complex	Regulates differentiation and function of many cells and tissues
ERα and ERβ	Nuclear receptor superfamily	Oestrogen	Ligand/receptor complex	Important for fertility, reproduction and bone health
GnRHR	GPCR	GnRH	G_q/G11, PLCbetal, PLA(2), PLD, PKC, MAPK	Regulates fertility
PTHR1	GPCR	PTH, PTHLP	Gs, adenyl cyclase, cAMP, PKA, CREB, G_q/G11, PLC, DAG, IP3, PKC, Ca^{++}	Regulates calcium homeostasis and bone turnover

(cAMP = cyclic adenosine monophosphate; CREB = Ca^{++} intracellular calcium; CYLD = cylindromatosis; DAG = diacylglycerol; ER = (o)estrogen receptor; GnRHR = gonadotrophin releasing hormone receptor; GPCR = G protein-coupled receptor; Gq/G11/Gs = guanine nucleotide binding proteins; GSK3 = glycogen synthetase kinase 3; IκB = inhibitor of kappa B; IKK = I kappa B kinase; IP3 = D-myo-inositol-1,4,5-trisphosphate; IRS1 = insulin receptor substrate 1; JAK2 = Janus activated kinase 2; MAPK = mitogen-activated kinase; mTOR = mammalian target of rapamycin; NFκB = nuclear factor kappa B; PDK1 = phosphoinosotide-dependent kinase 1; PIP3 = phosphoinosotol triphosphate; PI3K = phosphoinosotol 3 kinase; PKA/PKB/PKC = protein kinase A/B/C; PLA/PLC/PLD = phospholipase A/C/D; PTHR1 = parathyroid hormone receptor 1; PTHLP = parathyroid hormone-like protein; RANK = receptor activator of nuclear factor kappa B; STAT5 = signal transducer and activator of transcription; TNF = tumour necrosis factor; TNFR1 = TNF receptor 1; TRAF = TNF receptor-associated factors; TRADD = tumour necrosis factor receptor type 1-associated death domain protein; TRH = thyrotrophin releasing hormone)

degradation of IκB, allowing NFκB to translocate to the nucleus and activate gene expression. The system also has negative regulators, including the cylindromatosis (CYLD) enzyme, which regulates the activity of TRAFs by de-ubiquitination. Other transmembrane receptors can be grouped into:

- ion channel-linked receptors (glutamate and the nicotinic acetylcholine receptor)
- G protein-coupled receptors (GnRH, rhodopsin, olfactory receptors, parathyroid hormone receptor)
- receptors with kinase activity (insulin receptor, erythropoietin receptor, growth factor receptors)
- receptors which have no kinase activity, but interact with kinases via their intracellular domain when activated by ligand (TNF receptor) (see Figure 3.5 and Box 3.2).

Many receptors can signal only when they assemble as a multimeric complex. Mutations which interfere with assembly of the functional receptor multimer can result in disease. For example, mutations of the insulin receptor that inhibit dimerisation lead to childhood insulin resistance and growth failure. Conversely, some fibroblast growth factor receptor 2 (*FGFR2*) gene mutations cause dimerisation in the absence of ligand binding, leading to bone overgrowth and an autosomal dominant form of craniosynostosis called Crouzon's syndrome.

It is becoming clear that specialised projections on the cell surface known as cilia are essential for normal signalling in many tissues. Cilia can be motile or non-motile. Motile cilia are crucial for normal respiratory tract function, with primary ciliary dyskinesia (PCD) resulting in early-onset bronchiectasis due to failure to clear lung secretions. PCD is commonly associated with situs inversus (left–right laterality reversal) as a result of failure of a specific signalling process in very early embryogenesis. Mutations in proteins that are essential for non-motile cilia formation or function are responsible for a large number of autosomal recessive disorders known collectively as ciliopathies, which are commonly associated with intellectual disability, renal cystic dysplasia and retinal degeneration. For example, in the Bardet–Biedl syndrome, mutations in a series of genes encoding ciliary structure cause polydactyly, obesity, hypogonadism, retinitis pigmentosa and renal failure.

Cell division, differentiation and migration

In normal tissues, molecules such as hormones, growth factors and cytokines provide the signal to activate the cell cycle, a controlled programme of biochemical events that culminates in cell division. During the first phase, G1, synthesis of the cellular components necessary to complete cell division occurs. In S phase, the cell produces an identical copy of each chromosome – which carries the cell's genetic information – via a process called DNA replication. The cell then enters G2, when any errors in the replicated DNA are repaired before proceeding to mitosis, in which identical copies of all chromosomes are segregated to the daughter cells. The progression from one phase to the next is tightly controlled by cell cycle checkpoints. For example, the checkpoint between G2 and mitosis ensures that all damaged DNA is repaired prior to segregation of the chromosomes. Failure of these control processes is a crucial driver in the pathogenesis of cancer, as discussed in Chapter 11 (p. 262).

During development, cells must become progressively less like a stem cell and acquire the morphological and biochemical configuration of the tissue to which they will contribute. This process is called differentiation and it is achieved by activation of tissue-specific genes and inactivation or silencing of genes that maintain the cell in a progenitor state. This epigenetic process enables cells containing the same genetic material to have very different structures and functions. The programme of differentiation is often deranged or partially reversed in cancer cells. A similar mechanism allows adult stem cells to maintain and repair tissues. Cell migration is a process that is also necessary for development and wound healing. Migration also requires the activation of a specific set of genes, such as the transcription factor *TWIST*, that give the cell polarity and enable the leading edge of the cell to interact with the extracellular environment to control the speed and direction of travel. Again, this process can be reactivated in cancer cells and is thought to facilitate tumour metastasis.

Cell death, apoptosis and senescence

With the exception of stem cells, human cells have only a limited capacity for cell division. The Hayflick limit is the number of divisions a cell population can go through in culture before division stops and the cell enters a state known as senescence. This 'biological clock' is of great interest in the study of the normal ageing process. Rare human diseases associated with premature ageing, called progeric syndromes, have been very helpful in identifying the importance of DNA repair mechanisms in senescence (p. 168). For example, in Werner syndrome, a DNA helicase (an enzyme that separates the two DNA strands) is mutated, leading to failure of DNA repair and premature ageing. A distinct mechanism of cell death is seen in apoptosis, or programmed cell death.

Apoptosis is an active process that occurs in normal tissues and plays an important role in development, tissue remodelling and the immune response. The signal that triggers apoptosis is specific to each tissue or cell type. This signal activates enzymes, called caspases, which actively destroy cellular components, including chromosomal DNA. This degradation results in cell death, but the cellular corpse contains characteristic vesicles called apoptotic bodies. The corpse is then recognised and removed by phagocytic cells of the immune system, such as macrophages, in a manner that does not provoke an inflammatory response.

A third mechanism of cell death is necrosis. This is a pathological process in which the cellular environment loses one or more of the components necessary for cell viability. Hypoxia is probably the most common cause of necrosis.

GENETIC DISEASE AND INHERITANCE

Meiosis

Meiosis is a special form of cell division that only occurs in the post-pubertal testis and the fetal and adult ovary (Fig. 3.6). Meiosis differs from mitosis in two main ways; there are two separate cell divisions and before the first of these there is extensive swapping of genetic material between homologous chromosomes, a process known as recombination. The result of recombination is that each chromosome that a parent passes to his or her offspring is a mix of the chromosomes that the parent inherited from his or her own mother and father. The

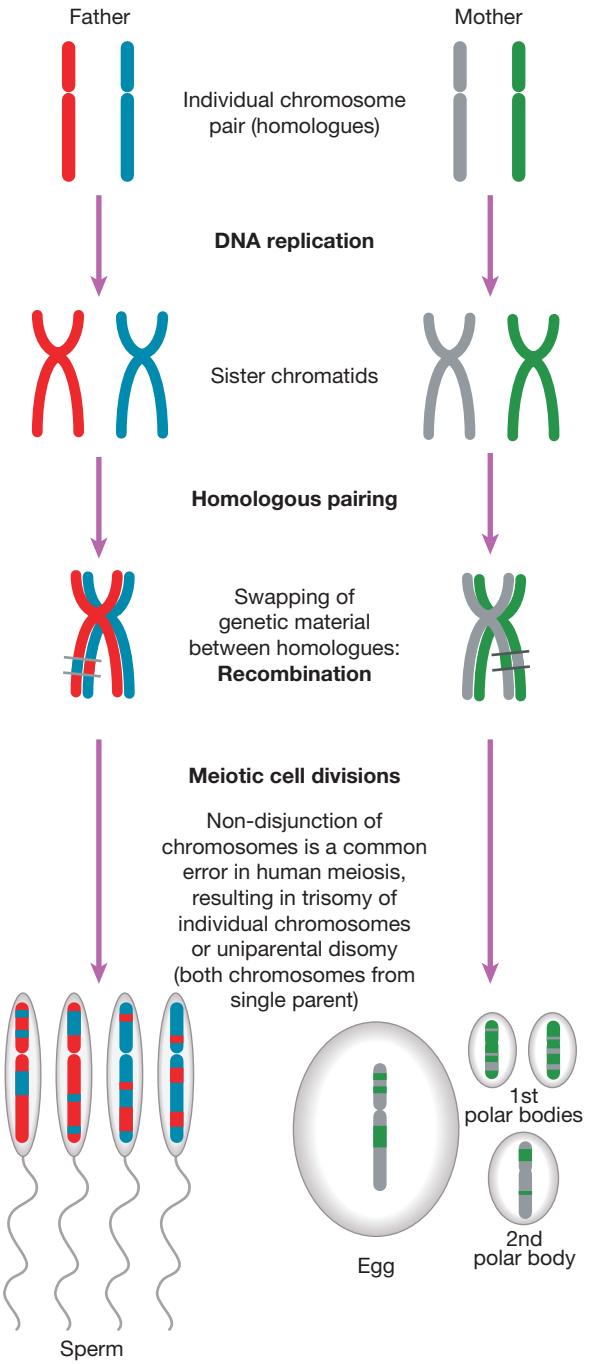

Fig. 3.6 Meiosis and gametogenesis. The main chromosomal stages of meiosis in both males and females. A single homologous pair of chromosomes is represented in different colours. The final step is the production of haploid germ cells. Each round of meiosis in the male results in four sperm cells; in the female, however, only one egg cell is produced, as the other divisions are sequestered on the periphery of the mature egg as peripheral polar bodies.

end products of meiosis are sperm and egg cells (gametes), which contain only 23 chromosomes: one of each homologous pair of autosomes and a sex chromosome. When a sperm cell fertilises the egg, the resulting zygote will thus return to a diploid chromosome complement of 46 chromosomes. The sperm determines the sex of the offspring, since 50% of sperm will carry an X chromosome and 50% a Y chromosome, while each egg cell carries an X chromosome.

The individual steps in meiotic cell division are similar in males and females. However, the timing of the cell divisions is very different (see Fig. 3.6). In females, meiosis begins in fetal life but does not complete until after ovulation. A single meiotic cell division can thus take more than 40 years to complete. In males, meiotic division does not begin until puberty and continues throughout life. In the testes, both meiotic divisions are completed in a matter of days.

Patterns of disease inheritance

Five modes of genetic disease inheritance are discussed below and illustrated in Figures 3.7 and 3.8.

Autosomal dominant inheritance

Autosomal dominant disorders result from a genetic abnormality in one of the two copies (alleles) of a single gene. The risk of an affected individual transmitting an autosomal disease to his or her offspring is 50% for each pregnancy, since half the affected individual gametes (sperm or egg cells) will contain the affected chromosome and half will contain the normal chromosome. However, even within a family, individuals with the same mutation rarely have identical patterns of disease due to variable penetrance and/or expressivity. Penetrance is defined as the proportion of individuals bearing a mutated allele who develop the disease phenotype. The mutation is said to be fully penetrant if all individuals who inherit a mutation develop the disease. Expressivity describes the level of severity of each aspect of the disease phenotype. Neurofibromatosis type 1 (NF1, neurofibromin, 17q11.2) is an example of a disease that is fully (100%) penetrant but which shows extremely variable expressivity. The environmental factors and/or variation in other genes that act as modifiers of the mutated gene's function are mostly unknown. A good example of an environmental influence that can profoundly influence expression of autosomal dominant

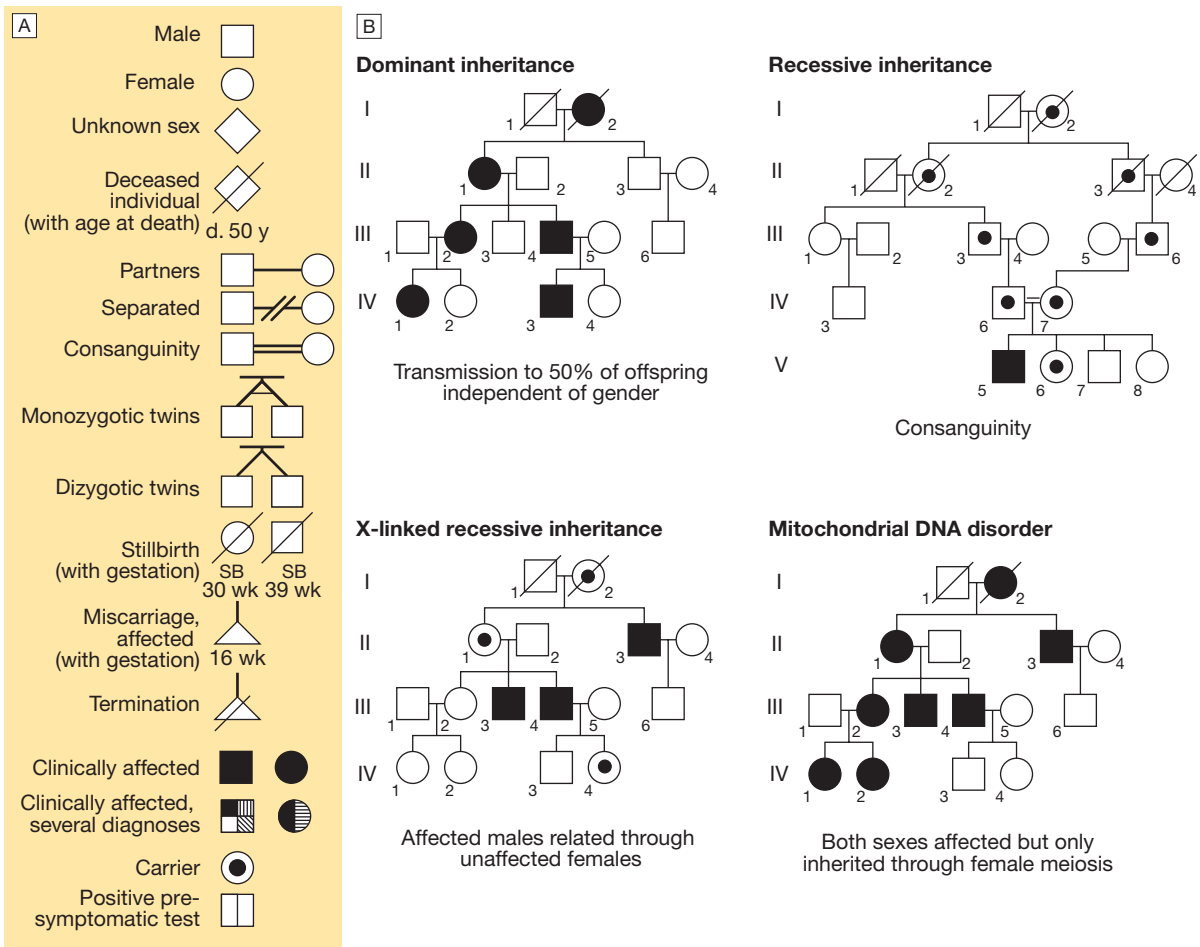

Fig. 3.7 Drawing a pedigree and patterns of inheritance. A The main symbols used to represent pedigrees in diagrammatic form. B The main modes of disease inheritance (see text for details).

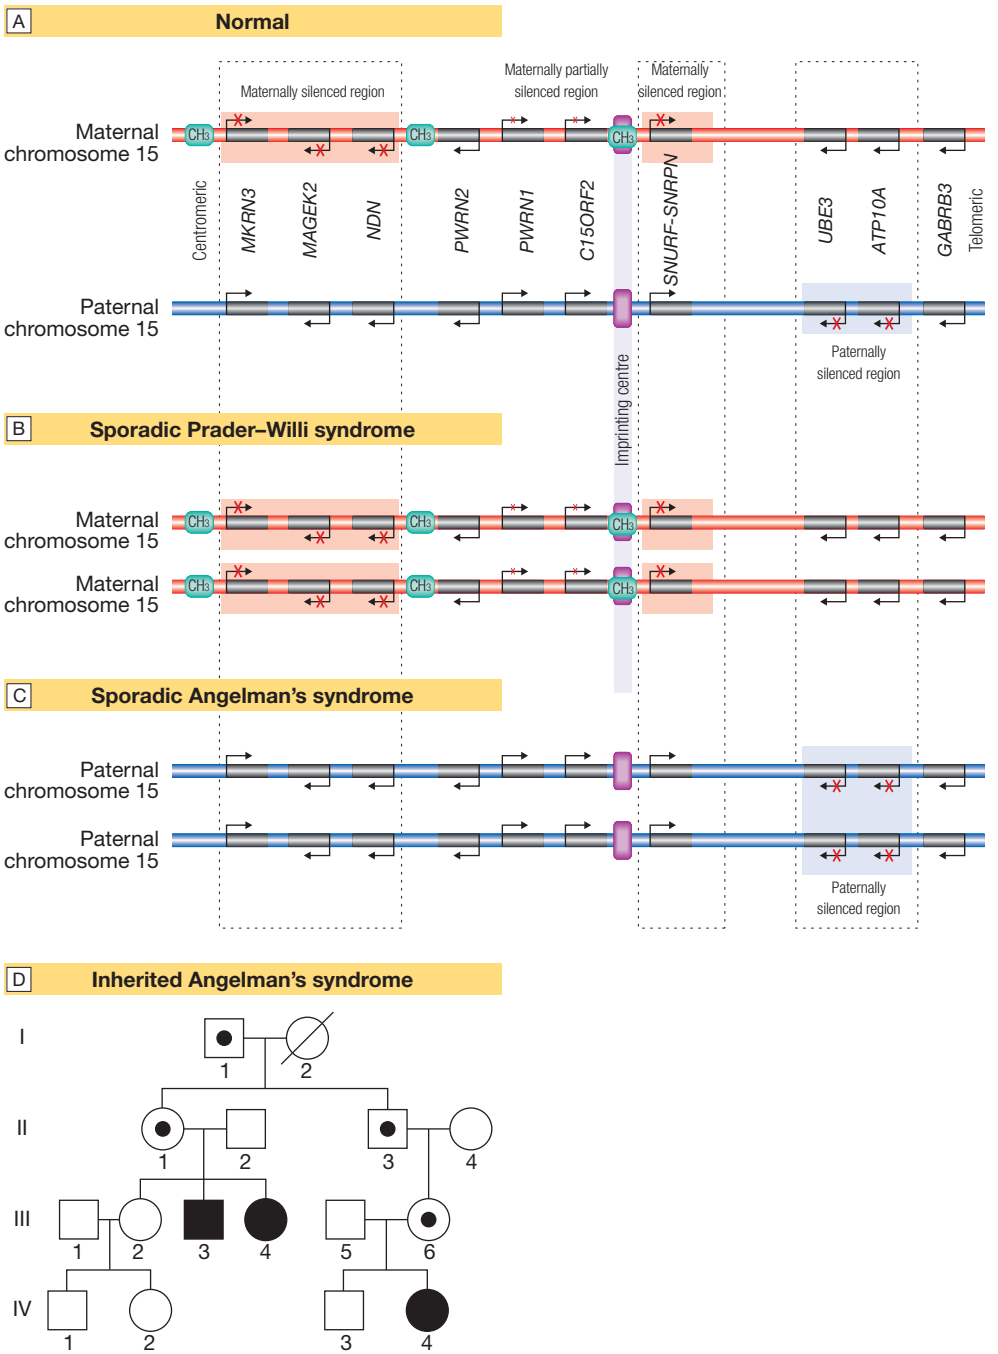

Fig. 3.8 Genomic imprinting and associated diseases. Several regions of the genome exhibit the phenomenon of imprinting, whereby expression of one or a group of genes is influenced by whether the chromosome is derived from the mother or the father; one such region lies on chromosome 15. **A** Normal imprinting. Under normal circumstances, expression of several genes is suppressed (silenced) on the maternal chromosome (red), whereas these genes are expressed normally by the paternal chromosome (blue). However, two genes in the paternal chromosome (*UBE3* and *ATP10A*) are silenced. **B** In sporadic Prader–Willi syndrome, there is a non-disjunction defect on chromosome 15, and both copies of the chromosomal region are derived from the mother (maternal uniparental disomy). In this case, Prader–Willi syndrome occurs because there is loss of function of several paternally expressed genes, including *MKRN3*, *MAGEK2*, *NDN*, *PWRN2*, *C15ORF2* and *SNURF-SNRNP*. **C** In sporadic Angelman's syndrome, both chromosomal regions are derived from the father (paternal uniparental disomy) due to non-disjunction during paternal meiosis. As a result, both copies of the *UBE3* gene are silenced and this causes Angelman's syndrome. Note that the syndrome can also be caused by deletion of this region on the maternal chromosome or a loss-of-function mutation on the maternal copy of *UBE3*, causing an inherited form of Angelman's, as illustrated in panel D. **D** Pedigree of a family with inherited Angelman's syndrome due to a loss-of-function mutation in *UBE3*. Inheriting this mutation from a father causes no disease (because the gene is normally silenced in the paternal chromosome) (see individuals I-1, II-1, II-3, III-6), but the same mutation inherited from the mother causes the syndrome (individuals III-3, III-4, IV-4), as this is the only copy expressed and the *UBE3* gene is mutated.

disease is seen in the triggering of malignant hyperpyrexia by anaesthetic agents in the presence of *RYR1* mutations. Autosomal dominant disorders may be the result of either loss or gain of function of the affected gene. For example, adult polycystic kidney disease type 1 is caused by loss-of-function mutations in *PKD1*, which encodes polycystin I on 16p13.1. Hereditary motor and sensory neuropathy type 1 is caused by increased number of copies (resulting in increased gene dosage) of *PMP22*, encoding peripheral myelin protein 22 on 17p11.2.

Autosomal recessive inheritance

In autosomal recessive disorders, both alleles of a gene must be mutated before the disease is manifest in an individual, and an affected individual must inherit one mutant allele from each parent. What distinguishes autosomal dominant and recessive diseases is that carrying one mutant allele does not produce a disease phenotype. Autosomal recessive disorders are rare in most populations. For example, the most common serious autosomal recessive disorder in the UK is cystic fibrosis, which has a birth incidence of 1:2000. The frequency of autosomal recessive disorders increases with the degree of inbreeding of a population because the risk of inheriting the same mutant allele from both parents (homozygosity) is increased. Genetic risk calculation for a fully penetrant autosomal recessive disorder is straightforward. Each subsequent pregnancy of a couple who have had a previous child affected by an autosomal recessive disorder will have a 25% (1:4) risk of being affected; a healthy individual who has a sibling with an autosomal recessive disorder will have 2/3 chance of being a carrier. The risk of an affected individual having children with the same condition is usually low but is dependent on the carrier rate of the mutant allele in the population.

X-linked inheritance

Genetic diseases caused by mutations on the X chromosome have specific characteristics. X-linked diseases are mostly recessive and restricted to males who carry the mutant allele. This is because males have only one X chromosome, whereas females have two. Thus females who carry a single mutant allele are generally unaffected. Occasionally, female carriers may exhibit signs of an X-linked disease due to a phenomenon called skewed X-inactivation. All female embryos, at about 100 cells in size, stably inactivate one of their two X chromosomes in each cell. This process is random in each cell but if, by chance, there is a disproportionate inactivation of normal X chromosomes carrying the normal allele, then an affected female carrier will be more likely, an extreme example being the rare cases of carrier females affected with Duchenne muscular dystrophy. X-linked recessive disorders have a recognisable pattern of inheritance, with transmission of the disease from carrier females to affected males and absence of father-to-son transmission. The risk of a female carrier having an affected child is 25% (1:4; half of her male offspring). If the carrier status of a woman is unclear, then the risk may be altered by conditional information, as discussed in the autosomal dominant disease section above. Bayes' theorem is commonly used to calculate such modified risks and this is discussed in more detail later in this chapter (p. 68).

Mitochondrial inheritance

The inheritance of mtDNA disorders is characterised by transmission from females, but males and females are generally affected equally. Unlike the other inheritance patterns mentioned above, mitochondrial inheritance has nothing to do with meiosis but reflects the fact that mitochondrial DNA is transmitted by oöcytes. Mitochondrial disorders tend to be very variable in penetrance and expressivity within families, and this is mostly accounted for by the fact that only a proportion of multiple mtDNA molecules within mitochondria contain the causal mutation (the degree of mtDNA heteroplasmy).

Epigenetic inheritance and imprinting

Several chromosomal regions (loci) have been identified where gene repression is inherited in a parent-of-origin-specific manner; these are called imprinted loci. Within these loci the paternal alleles of a gene may be active while the maternal one may be silenced, or vice versa (see Fig. 3.8). Mutations within imprinted loci lead to a very unusual pattern of inheritance in which the phenotype is only manifest if inherited from the parent who contributes the transcriptionally active allele (see Fig. 3.8). Examples of these disorders are given in Box 3.3.

Classes of genetic variant

There are many different classes of variation in the human genome (Figs 3.9 and 3.10). Rare genetic variations that result in a disease are generally referred to as mutations, whereas common variations and those that do not cause disease are referred to as polymorphisms. These different types of variation are further categorised by the size of the DNA segment involved and/or by the mechanism giving rise to the variation.

Nucleotide substitutions

The substitution of one nucleotide for another is the most common type of variation in the human genome. Depending on their frequency and functional consequences, these changes are known as a point mutation or a single nucleotide polymorphism (SNP). They occur by misincorporation of a nucleotide during DNA synthesis or by the action of a chemical mutagen. When these substitutions occur within ORFs of a protein-coding gene, they are further classified into:

- synonymous – resulting in a change in the codon but no change in the amino acid and thus no phenotype
- missense – altering a codon, resulting in an amino acid change in the protein
- nonsense – introducing a premature stop codon, resulting in truncation of the protein
- splicing – occurring at the junction of an intron and an exon, thereby adversely affecting splicing.

Examples of these types of variation are shown in Figures 3.9 and 3.10.

3.3 Epigenetic disease

Disease	Locus	Genes	Notes
Imprinting disorders			
Beckwith–Wiedemann syndrome	11p15	*p57^{KIP2} HASH2, INS2, IGF2, H19*	General 'over-growth', advanced bone age and increased childhood tumours. Some cases due to mutations in *p57^{KIP2}*
Prader–Willi syndrome	15q11–q13	*SNRPN, Necdin* and others	Obesity, hypogonadism and learning disability. Lack of paternal contribution (due to deletion of paternal 15q11–q13, or inheritance of both chromosome 15q11–q13 regions from the mother)
Angelman's syndrome (AS)	15q11–q13	*UBE3A*	Severe mental retardation, ataxia, epilepsy and inappropriate laughing bouts. Due to loss-of-function mutations in the maternal *UBE3A* gene. The neurological phenotype results because most tissues express both maternal and paternal alleles of *UBE3A*, whereas the brain expresses predominantly the maternal allele
Pseudohypoparathyroidism (p. 770)	20q13	*GNAS1*	Inheritance of the mutation from the mother results in hypocalcaemia, hyperphosphataemia, raised parathyroid hormone (PTH) levels, ectopic calcification, obesity, delayed puberty, shortened 4th and 5th metacarpals and ectopic calcification. When the mutation is inherited from the father, PTH, calcium and phosphate levels are normal but the other features are present. These differences are due to the fact that, in the kidney (the main target organ through which PTH regulates serum calcium and phosphate), the paternal allele is silenced and the maternal allele is expressed, whereas both alleles are expressed in other tissues
X-inactivation disorders			
Duchenne muscular dystrophy (DMD) in females	Xp22	*DMD*	If, by chance, a sufficient number of the X chromosomes containing the normal *dystrophin* gene are inactivated in muscle, heterozygous females may rarely develop full-blown DMD. Conversely, if a higher proportion of the disease gene-carrying chromosome is inactivated, a carrier female may test negative on biochemical screening for elevated creatine kinase levels
Epigenetic silencing (oncogenesis)			
Colon cancer	3p21	*MLH1*	Hypermethylation of the promoter results in silencing of *MLH1*, which encodes a DNA repair gene

Fig. 3.9 Different types of mutation affecting coding exons. A Normal sequence. B A synonymous nucleotide substitution changing the third base of a codon; the resulting amino acid sequence is unchanged. C A missense mutation in which the nucleotide substitution results in a change in a single amino acid from the normal sequence (AAG) encoding lysine to glutamine (CAG). D Insertion of a G residue (boxed) causes a frameshift mutation, completely altering the amino acid sequence downstream. This usually results in a loss-of-function mutation. E A nonsense mutation resulting in a single nucleotide change from a lysine codon (AAG) to a premature stop codon (TAG).

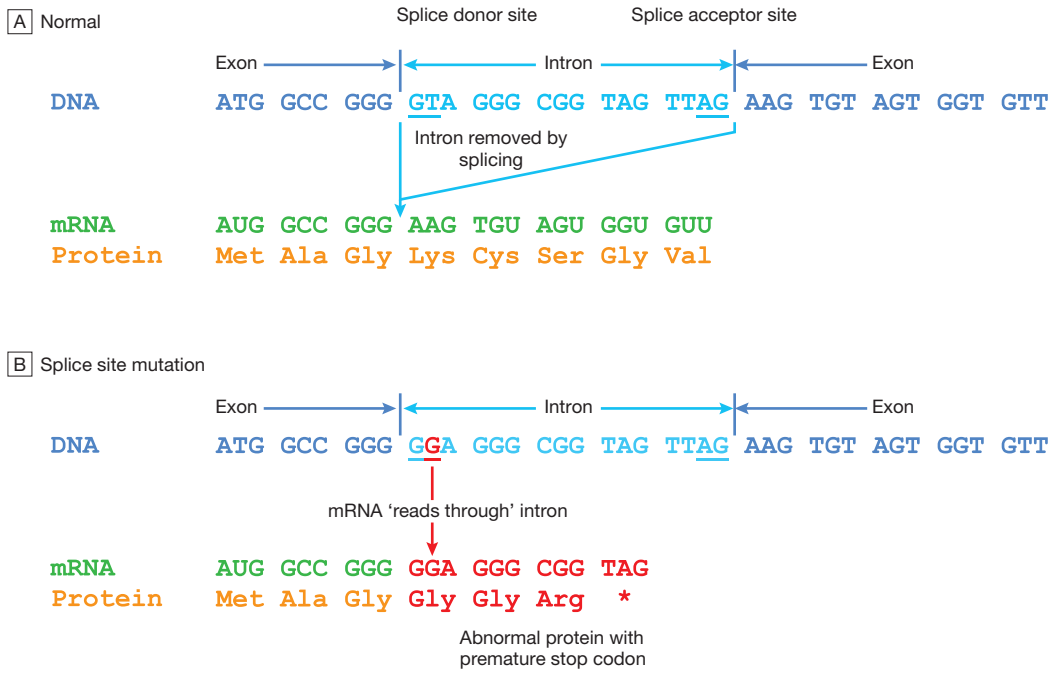

Fig. 3.10 Splice site mutations. A The normal sequence is shown, illustrating two exons, and intervening intron (blue) with splice donor (AG) and splice acceptor sites (GT) underlined. Normally, the intron is removed by splicing to give the mature mRNA that encodes the protein. B In a splice site mutation the donor site is mutated. As a result, splicing no longer occurs, leading to read-through of the mRNA into the intron, which contains a premature termination codon downstream of the mutation.

Insertions and deletions

One or more nucleotides may be inserted or lost in a DNA sequence, resulting in an insertion/deletion (indel) polymorphism or mutation (see Fig. 3.9). If an indel change affects one or two nucleotides within the ORF of a protein-coding gene, this can have serious consequences because the triple nucleotide sequence of the codons is disrupted, resulting in a frameshift mutation. The effect upon the gene is typically severe because the amino acid sequence is totally disrupted.

Simple tandem repeat mutation

Variations in the length of simple tandem repeats of DNA are thought to arise as the result of slippage of DNA during meiosis and are termed microsatellite (small) or minisatellite (larger) repeats. These repeats are unstable and can expand or contract in different generations. This instability is proportional to the size of the original repeat, in that longer repeats tend to be more unstable. Many microsatellites and minisatellites occur in introns or in chromosomal regions between genes and have no obvious adverse effects. However, some genetic diseases, including Huntington's disease and myotonic dystrophy, are caused by microsatellite repeats, which result in duplication of amino acids within the affected gene product or affect gene expression (Box 3.4).

Copy number variations

Variation in the number of copies of an individual segment of the genome from the usual diploid (two copies) content can be categorised by the size of the segment involved. Rarely, individuals may gain or lose a whole chromosome. Such numerical chromosome anomalies most commonly occur by a process known as meiotic non-dysjunction (Box 3.5). This is the most common cause of Down's syndrome, which results from trisomy (three copies) of chromosome 21.

Large insertions or deletions of chromosomal DNA also occur and are usually associated with learning disability and/or malformations. Such structural chromosomal anomalies arise as the result of two different processes:

- non-homologous end-joining
- non-allelic homologous recombination.

Random double-stranded breaks in DNA are a necessary process in meiotic recombination and also occur during mitosis at a predictable rate. The rate of these breaks is dramatically increased by exposure to ionising radiation. When such breaks occur, they are usually repaired accurately by DNA repair mechanisms within the cell. However, a proportion of breaks undergoes non-homologous end-joining, which results in the joining of two segments of DNA that are not normally contiguous. If the joined fragments are from different chromosomes, this results in a translocation. If they are from the same chromosome, this will result in inversion, duplication or deletion of a chromosomal fragment (Fig. 3.11). Large insertions and deletions may be cytogenetically visible as chromosomal deletions or duplications. If the anomalies are too small to be detected by microscopy, they are termed microdeletions and microduplications. Many microdeletion syndromes have been described and most stem from non-allelic homologous recombination between repeats of highly similar DNA sequences, which results in identical chromosome

3.4 Diseases associated with triplet and other repeat sequences

	Repeat	No. of repeats		Gene	Gene location	Inheritance
		Normal	Mutant			
Coding repeat expansion						
Huntington's disease	[CAG]	6–34	> 35	*Huntingtin*	4p16	AD
Spinocerebellar ataxia (type 1)	[CAG]	6–39	> 40	*Ataxin*	6p22–23	AD
Spinocerebellar ataxia (types 2, 3, 6, 7)	[CAG]	Various	Various	Various	Various	AD
Dentatorubral-pallidoluysian atrophy	[CAG]	7–25	> 49	*Atrophin*	12p12–13	AD
Machado–Joseph disease	[CAG]	12–40	> 67	*MJD*	14q32	AD
Spinobulbar muscular atrophy	[CAG]	11–34	> 40	Androgen receptor	Xq11–12	XL recessive
Non-coding repeat expansion						
Myotonic dystrophy	[CTG]	5–37	> 50	*DMPK-3′UTR*	19q13	AD
Friedreich's ataxia	[GAA]	7–22	> 200	*Frataxin-intronic*	9q13	AR
Progressive myoclonic epilepsy	$[CCCCGCCCCGCG]_{4-8}$	2–3	> 25	*Cystatin B-5′UTR*	21q	AR
Fragile X mental retardation	[CGG]	5–52	> 200	*FMR1–5′UTR*	Xq27	XL dominant
Fragile site mental retardation 2 (FRAXE)	[GCC]	6–35	> 200	*FMR2*	Xq28	XL, probably recessive

Note The triplet repeat diseases fall into two major groups: those with disease resulting from expansion of $[CAG]_n$ repeats in coding DNA, resulting in multiple adjacent glutamine residues (polyglutamine tracts), and those with non-coding repeats. The latter tend to be longer. Unaffected parents usually display 'pre-mutation' allele lengths that are just above the normal range. (AD/AR = autosomal dominant/recessive; UTR = untranslated region; XL = X-linked)

3.5 Chromosome and contiguous gene disorders

Disease	Locus	Incidence	Clinical features
Numerical chromosomal abnormalities			
Down's syndrome (trisomy 21)	47,XY,+21 or 47,XX+21	1:800	Characteristic facies, IQ usually < 50, congenital heart disease, reduced life expectancy
Edwards' syndrome (trisomy 18)	47,XY,+18 or 47,XX,+18	1:6000	Early lethality, characteristic skull and facies, frequent malformations of heart, kidney and other organs
Patau's syndrome (trisomy 13)	47,XY,+13 or 47, XX,+13	1:15000	Early lethality, cleft lip and palate, polydactyly, small head, frequent congenital heart disease
Klinefelter's syndrome	47,XXY	1:1000	Phenotypic male, infertility, gynaecomastia, small testes (p. 766)
XYY	47,XYY	1:1000	Usually asymptomatic, some impulse control problems
Triple X syndrome	47,XXX	1:1000	Usually asymptomatic, may have reduced IQ
Turner's syndrome	45,X	1:5000	Phenotypic female, short stature, webbed neck, coarctation of the aorta, primary amenorrhoea (p. 765)
Recurrent deletions, microdeletions and contiguous gene defects			
Di George/ velocardiofacial syndrome	22q11.2	1 in 4000	Cardiac outflow tract defects, distinctive facial appearance, thymic hypoplasia, cleft palate and hypocalcaemia. Major gene seems to be *TBX1* (cardiac defects and cleft palate)
Prader–Willi syndrome	15q11–q13	1:15000	Distinctive facial appearance, hyperphagia, small hands and feet, distinct behavioural phenotype. Imprinted region, deletions on paternal allele in 70% of cases
Angelman's syndrome	15q11–q13	1:15000	Distinctive facial appearance, absent speech, EEG abnormality, characteristic gait. Imprinted region, deletions on maternal allele in *UBE3A*
Williams' syndrome	7q11.23	1:10000	Distinctive facial appearance, supravalvular aortic stenosis, learning disability and infantile hypercalcaemia. Major gene for supravalvular aortic stenosis is *elastin*
Smith–Magenis syndrome	17p11.2	1 in 25000	Distinctive facial appearance and behavioural phenotype, self-injury and rapid eye movement (REM) sleep abnormalities. Major gene seems to be *RAH*

anomalies – and clinical syndromes – occurring in unrelated individuals (see Fig. 3.11 and Box 3.5).

Polymorphic copy number variants

In addition to the disease-causing structural chromosomal anomalies mentioned above, there are also a considerable number of polymorphic CNVs that exist as common genetic polymorphisms in humans. These involve duplication of large segments of the genome, often containing multiple genes and regulatory elements. These duplications usually result from non-allelic homologous recombination via misalignment of tandem

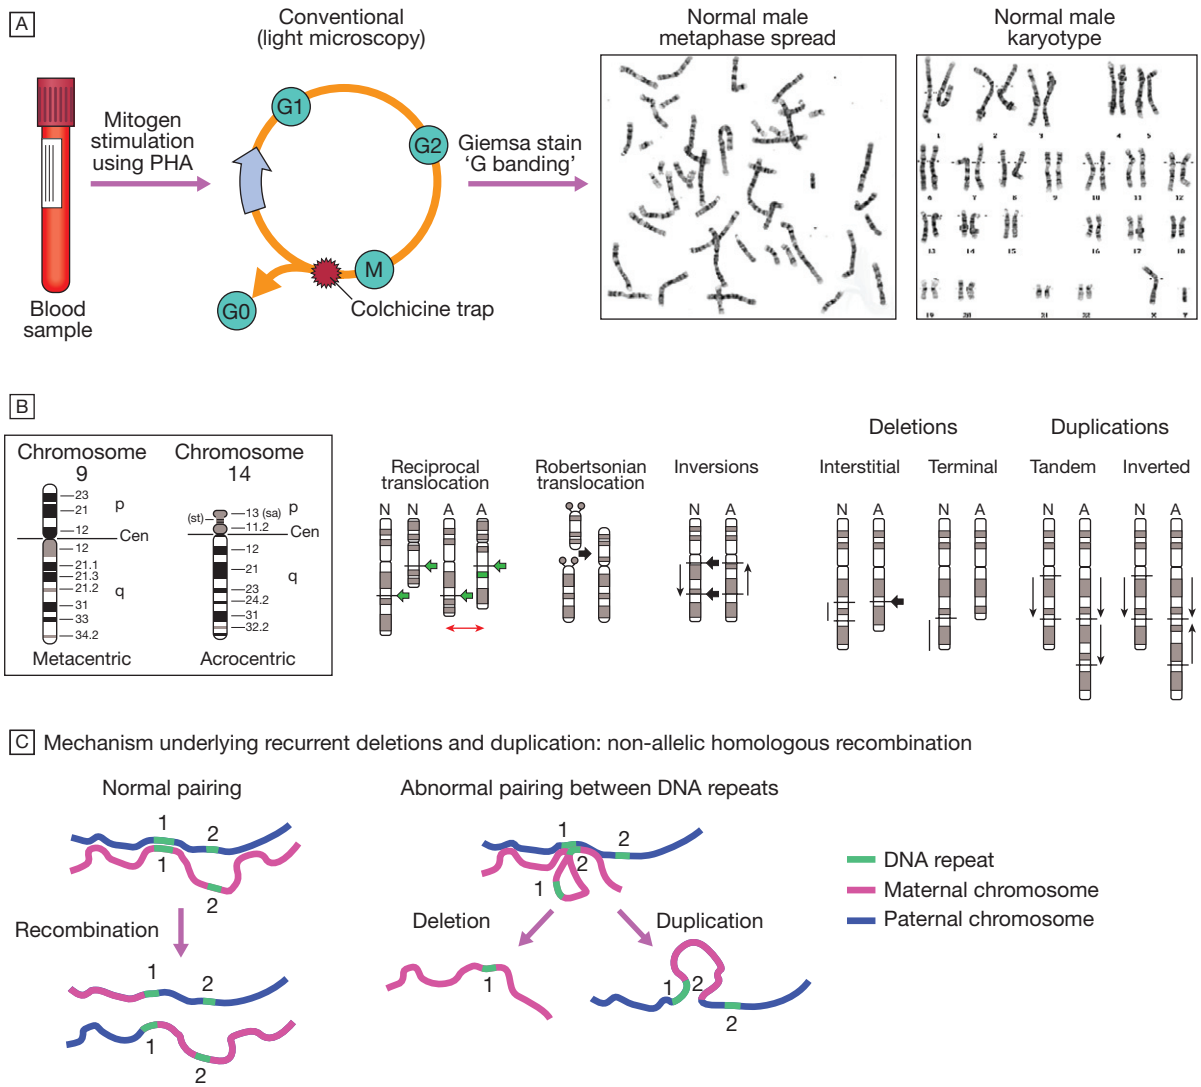

Fig. 3.11 Chromosomal analysis and structural chromosomal disorders. A How chromosome analysis is carried out. Starting with a blood sample, the white cells are stimulated to divide by adding the mitogen phytohaemagglutinin (PHA), and colchicine is used to trap the cells in metaphase, which allows the chromosomes to be seen using light microscopy following staining with Giemsa, resulting in a banding pattern. B How structural chromosomal anomalies are described. Human chromosomes can be classed as metacentric if the centromere is near the middle, or acrocentric if the centromere is at the end. The bands of each chromosome are given a number, starting at the centromere and working out along the short (p) arm and long (q) arm. Translocations and inversions are balanced structural chromosome anomalies where no genetic material is missing but it is in the wrong order. Translocations can be divided into reciprocal (direct swap of chromosomal material between non-homologous chromosomes) and Robertsonian (fusion of acrocentric chromosomes). Deletions and duplications can also occur due to non-allelic homologous recombination (illustrated in panel C). Deletions are classified as interstitial if they lie within a chromosome, and terminal if the terminal region of the chromosome is affected. Duplications can either be in tandem (where the duplicated fragment is orientated in the correct direction) or inverted (where the duplicated fragment is in the wrong direction). (N = normal; A = abnormal) C A common error of meiotic recombination, known as non-allelic homologous recombination, can occur (right panel), resulting in a deletion on one chromosome and a duplication in the homologous chromosome. The error is induced by tandem repeats in the DNA sequences (green), which can misalign and bind to each other, thereby 'fooling' the DNA into thinking the pairing prior to recombination is correct.

repeated DNA elements in the chromosome during recombination (see Fig. 3.11). The consequences of CNV for genetic disease have not been fully explored, although recent studies have shown a strong association between an increased copy number of the gene *FCGR3B* and the risk of systemic lupus erythematosus.

Consequences of genetic variation

Genetic variants can generally be classed into three groups:

- those associated with no detectable change in gene function (neutral variants)
- those which cause a loss of function of the gene product
- those which cause a gain of function of the gene product.

The consequence of an individual mutation depends on many factors, including the mutation type, the nature of the gene product and the position of the variant in the protein. Mutations can have profound effects or subtle effects on gene and cell function (Box 3.6). Variations

3.6 Examples of recessive diseases caused by common genetic variants*

Disease	Inheritance	Gene	Genetic variant	Population frequency
Haemochromatosis	AR	*HFE*	p.Cys282Tyr (p.C282Y; nucleotide c.845G>A) p.His63Asp (p.H63D; nucleotide c.187C>G)	3% 5%
α_1-antitrypsin deficiency	AR	*SERPINA1*	p.Glu342Lys (p.E342K, c.1197G>A)	3%
Spinal muscular atrophy	AR	*SMN1*	Gene deletion by non-allelic homologous recombination	2–3%
Cystic fibrosis	AR	*CFTR*	p.Phe508del (p.F508del aka δF508, c.1521_1523delCTT)	4%

*The genetic variants shown are common in the general population but heterozygotes do not exhibit any evidence of disease. In the homozygous form, however, these variants cause recessive disease due to loss of function of the affected gene.

that have profound effects are responsible for 'classical' genetic diseases, whereas those with subtle effects may contribute to the pathogenesis of complex diseases with a genetic component.

Loss-of-function mutations

These mutations cause the normal function of a protein to be reduced or lost. Deletion of the whole gene is the most extreme example but the same phenotype can be seen with a nonsense or frameshift mutation early in the ORF. Missense mutations that alter a critical domain within the protein can also result in loss of function. In autosomal recessive diseases, mutations that result in no protein function whatsoever are known as null mutations. If loss-of-function mutations result in an autosomal dominant disease, the genetic mechanism is known as haploinsufficiency and indicates that both functional copies of the gene are required for normal cellular function. Mutations in *PKD1* or *PKD2* that cause autosomal dominant adult polycystic kidney disease are mostly loss of function.

Gain-of-function and dominant negative mutations

Gain-of-function and dominant-negative effect mutations are most commonly the result of missense mutation or in-frame deletions but may also be caused by triplet repeat expansion mutations. Gain of function results where a mutation alters the protein structure, causing activation of its normal function, causing it to interact with a novel substrate or causing it to change its normal function. Constitutive activation of fibroblast growth factor receptors by missense mutation, which leads to many disorders such as achondroplasia, is an example of a gain-of-function mutation. Dominant-negative mutations are heterozygous changes that have a more deleterious effect on the protein function than a heterozygous 'null' mutation. For example, heterozygous mutations in *FBN1* cause Marfan's syndrome by the production of a protein with an abnormal amino acid sequence that disrupts the normal assembly of microfibrils. In comparison, complete loss of function of one allele of *FBN1* is usually completely benign.

Polymorphisms

A polymorphism is defined as a change in the nucleotide sequence that exists with a population frequency of more than 1%. Most common polymorphisms are neutral (see below), but some cause subtle changes in gene expression or in protein structure and function (see Box 3.15, p. 69). It is thought that these polymorphisms lead to variations in phenotype within the general population, including variations in susceptibility to common diseases. An example is polymorphism in the gene *SLC2A9* that not only explains a significant proportion of the normal population variation in serum urate concentration but also predisposes 'high-risk' allele carriers to the development of gout. Other examples are listed in Box 3.6.

Neutral variants

The vast majority of variations within the human genome have no discernible effect on the cell or organism. This may be because the variation is non-coding, occurring outside the gene but within an intron, or is within the coding regions of a gene but does not change the amino acid because of a synonymous substitution at the third base of a codon (see Fig. 3.9). Some variations that do change the amino acid may be completely tolerated with regard to protein function.

Evolutionary selection

Genetic variants play an important role in evolutionary selection; some are advantageous to an organism, resulting in positive selection through evolution via improved reproductive fitness. However, variations that decrease reproductive fitness become less common and are excluded through evolution. Given this simple paradigm, it would be tempting to assume that common mutations are all advantageous and all rare mutations are pathogenic. Unfortunately, it is often difficult to classify any common mutation as either advantageous or deleterious – or, indeed, neutral. Mutations that are advantageous in early life and thus enhance reproductive fitness may be deleterious in later life. There may be mutations that are advantageous for survival in particular conditions (for example, famine or pandemic), which may be disadvantageous in more benign circumstances by resulting in a predisposition to obesity or autoimmune disorders. This complexity of balancing selection through evolution is likely to be an important feature of the genetics of common disease.

Constitutional genetic disease

All familial genetic disease is caused by constitutional mutations, which are inherited through the germ line.

However, different mutations in the same gene can have different consequences, depending on the genetic mechanism underlying that disease. About 1% of the population carries constitutional mutations that cause disease.

Allelic heterogeneity

Allelic heterogeneity is where several different mutations cause the same phenotype. This is seen in almost all genetic disease. In familial adenomatous polyposis coli, whole-gene deletions, nonsense mutations, frameshift mutations and some missense mutations result in exactly the same phenotype because they all cause loss of function in the *FAP* gene on chromosome 5q. Many other Mendelian disorders show this phenomenon with loss-of-function mutations, including adult polycystic kidney disease (PKD1, 16p13; PKD2, 4q21). Allelic heterogeneity can also be seen in gain-of-function and dominant-negative mutations. In connective tissue disorders, dominant-negative mutations are almost always missense mutations or in-frame deletions or insertions, since the aberrant protein has to be made for the disease to manifest. In most diseases caused by gain-of-function mutations, allelic heterogeneity is severely restricted. A good example of this is achondroplasia, in which the mutations in *FGFR3* are restricted to a few specific codons that cause constitutive activation of the receptor that is required to cause the disease.

Locus heterogeneity

Locus heterogeneity is where a similar phenotype results from mutations in several different genes. One of the best examples is retinitis pigmentosa, which can occur as the result of mutations in more than 75 genes, each of which has a different chromosomal location.

De novo mutations

Although the vast majority of constitutional mutations are inherited, each gamete will contain mutations that have occurred as a result of meiosis; these are called de novo mutations. Each individual has approximately 70 de novo mutations scattered throughout their genome. This occurs in each generation and is presumably required for evolution to occur. Most are neutral but such mutations may also cause human disease. De novo mutations cause severe congenital disorders such as thanatophoric dysplasia (*FGFR3* gain-of-function mutation), bilateral anophthalmia (*SOX2* haploinsufficiency), campomelic dysplasia (*SOX9* loss of function) (Fig. 3.2) and the severe form of osteogenesis imperfecta (dominant-negative mutations in *COL1A1* or *COL1A2*).

Somatic genetic disease

Somatic mutations are not inherited but instead occur during post-zygotic mitotic cell divisions at any point from embryonic development to late adult life. An example of this phenomenon is polyostotic fibrous dysplasia (McCune–Albright syndrome), in which a somatic mutation in the G_s alpha gene causes constitutive activation of receptor signalling downstream of many G protein-coupled receptors, resulting in focal lesions in the skeleton and endocrine dysfunction (p. 770).

The most important example of human disease caused by somatic mutations is cancer. Here, 'driver' mutations occur within genes that are involved in regulating cell division or apoptosis, resulting in abnormal cell growth and tumour formation. The two general categories of cancer-causing mutation are gain-of-function mutations in growth-promoting genes (oncogenes) and loss-of-function mutations in growth-suppressing genes (tumour suppressor genes). Whichever mechanism is acting, most tumours require an initiating mutation in a single cell that can then escape from normal growth controls. This cell replicates more frequently or fails to undergo programmed death, resulting in clonal expansion. As the size of the clone increases, one or more cells may acquire additional mutations that confer further growth advantage, leading to proliferation of these subclones, which may ultimately lead to aggressive metastatic cancer. The cell's complex self-regulating machinery means that more than one mutation is usually required to produce a malignant tumour (see Fig. 11.3, p. 264). For example, if a mutation results in activation of a growth factor gene or receptor, then that cell will replicate more frequently as a result of autocrine stimulation. However, this mutant cell will still be subject to normal cell cycle checkpoints to promote DNA integrity in its progeny. But if additional mutations in the same cell result in defective cell cycle checkpoints, it will rapidly accumulate further mutations, which may allow completely unregulated growth and/or separation from its matrix and cellular attachments and/or resistance to apoptosis. As cell growth becomes increasingly dysregulated, cells de-differentiate, lose their response to normal tissue environment and cease to ensure appropriate mitotic chromosomal segregation. These processes combine to generate the classical malignant characteristics of disorganised growth, variable levels of differentiation, and numerical and structural chromosome abnormalities. An increase in somatic mutation rate can occur on exposure to external mutagens, such as ultraviolet light or cigarette smoke, or if the cell has defects in DNA repair systems. Cancer therefore affects the fundamental processes of molecular and cell biology.

In many familial cancer syndromes, somatic mutations act together with an inherited mutation to cause cancer. Familial cancer syndromes may be due to loss-of-function mutations in tumour suppressor genes or genes encoding DNA repair enzymes. In DNA repair diseases, the inherited mutations increase the somatic mutation rate. Autosomal dominant mutations in genes encoding components of specific DNA repair systems are relatively common causes of familial colon cancer and breast cancer (e.g. *BRCA1*). Autosomal recessive DNA repair disorders are rare and are associated with almost complete loss of DNA repair enzymes. This is usually associated with a severe multifaceted degenerative disorder with cancer susceptibility as a significant component (e.g. xeroderma pigmentosum, p. 267).

Cancer syndromes are also caused by loss-of-function mutations in tumour suppressor genes. At the cellular level, loss of one functional copy of a tumour suppressor gene does not have any functional consequences, as the cell is protected by the remaining normal copy. However, a somatic mutation affecting the normal allele is likely to occur in one cell at some point during life, resulting in complete loss of tumour suppressor activity and a tumour developing by clonal expansion of that cell. This

two-hit mechanism (one inherited, one somatic) for cancer development is known as the Knudsen hypothesis. It explains why tumours may not develop for many years (or ever) in some members of these cancer-prone families. Yet another group of cancer syndromes are the result of gain-of-function mutations in tumour promoter genes (proto-oncogenes).

INVESTIGATION OF GENETIC DISEASE

General principles of diagnosis

Many genetic diseases can be diagnosed by a careful clinical history and examination together with an awareness and knowledge of rare diseases. Although DNA-based diagnostic tools are now widely used, not all diagnostic genetic tests involve analysis of DNA. For example, an electrocardiogram (ECG) can establish the diagnosis in long QT syndrome or a renal ultrasound can detect adult polycystic kidney disease. By definition, all genetic testing (whether DNA-based or not) has implications for both the patient and other members of the family. These issues should be considered before genetic testing is undertaken and a plan should be in place to deliver medical information and support to family members and to organise any relevant downstream investigations.

Constructing a family tree

The family tree – or pedigree – is fundamental to the diagnosis of genetic diseases. The basic symbols and nomenclature used in drawing a pedigree are shown in Figure 3.7 (p. 51). A three-generation family history taken in a routine medical clerking may reveal important genetic information of relevance to the presenting complaint, particularly relating to cancer.

A pedigree should include details from both sides of the family, any history of pregnancy loss or infant death, consanguinity, and details of all medical conditions in family members, including dates of birth and age at death.

It is important to be aware that a diagnosis given by a family member, or even obtained from a death certificate, may be wrong. This is often true in cases of cancer, where 'stomach' may mean any part of the bowel, and 'brain' may refer to secondary deposits or be used where the primary site has not been identified.

Polymerase chain reaction and DNA sequencing

The polymerase chain reaction (PCR) is a fundamental laboratory technique that amplifies targeted sections of the human genome for DNA diagnostic analysis. Almost any tissue can be used to extract DNA for PCR analysis, but most commonly, a sample of peripheral blood is used. PCR is very often used in association with DNA sequencing to determine the exact nucleotide sequence of a specific region of a gene or chromosome. The principles of PCR are shown in Figure 3.12. The technique of DNA sequencing is used for DNA diagnostic analysis in clinical practice. Until recently, most diagnostic DNA laboratories used Sanger sequencing for diagnosis (Fig. 3.13A), but

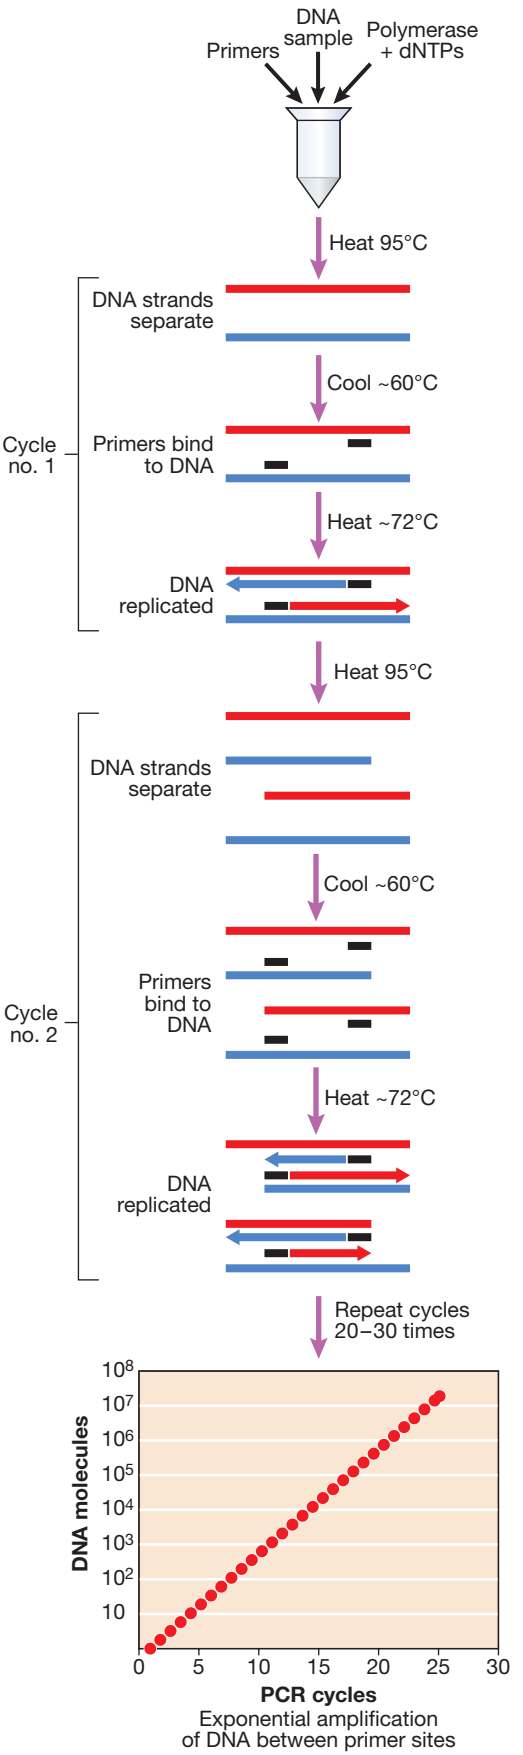

Fig. 3.12 (see opposite) The polymerase chain reaction. The polymerase chain reaction (PCR) involves adding a tiny amount of the patient's DNA to a reaction containing primers (short oligonucleotides 18–21 bp in length, which bind to the DNA flanking the region of interest) and deoxynucleotide phosphates (dATP, dCTP, dGTP, dTTP), which are used to synthesise new DNA and a heat-stable polymerase. The reaction mix is first heated to 95°C, which causes the double-stranded DNA molecules to separate. The reaction is then cooled to 50–60°C, which allows the primers to bind to the target DNA. The reaction is then heated to 72°C, at which point the polymerase starts making new DNA strands. These cycles are repeated 20–30 times, resulting in exponential amplification of the DNA fragment between the primer sites. The resulting PCR products can then be used for further analysis – most commonly DNA sequencing (see Fig. 3.13).

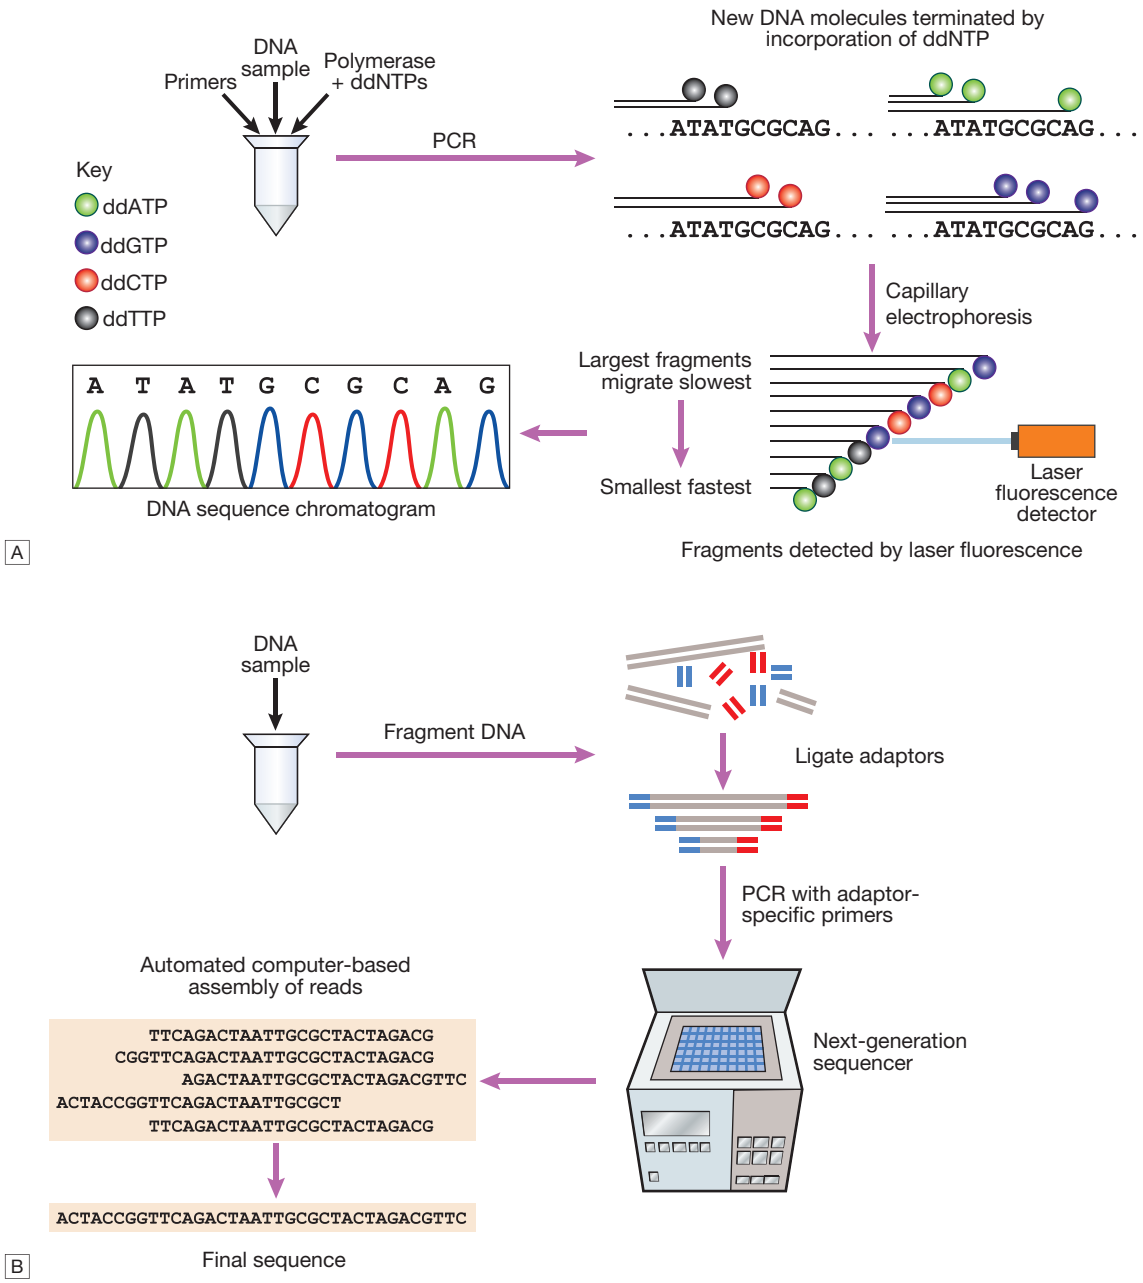

Fig. 3.13 DNA sequencing. A Sanger sequencing of DNA, which is very widely used in DNA diagnostics. This is performed using PCR-amplified fragments of DNA corresponding to the gene of interest. The sequencing reaction is performed using a combination dNTP and fluorescently labelled di-deoxy dNTP (ddATP, ddTTP, ddCTP and ddGTP), which become incorporated into the newly synthesised DNA, causing termination of the chain at that point. The reaction products are then subject to capillary electrophoresis and the different-sized fragments are detected by a laser, producing a sequence chromatogram that corresponds to the target DNA sequence. B Next-generation sequencing. Samples of patient DNA are fragmented and adapters ligated to each end of the fragment. The sequencing reaction is then performed with primers specific for the adaptors, much as described for Sanger sequencing. In next-generation sequencing, however, the reaction products are detected without the need for electrophoresis, and assembled by computer to produce the final sequence read. The absence of electrophoresis allows next-generation sequencing to generate data 100–1000 times faster than Sanger sequencing.

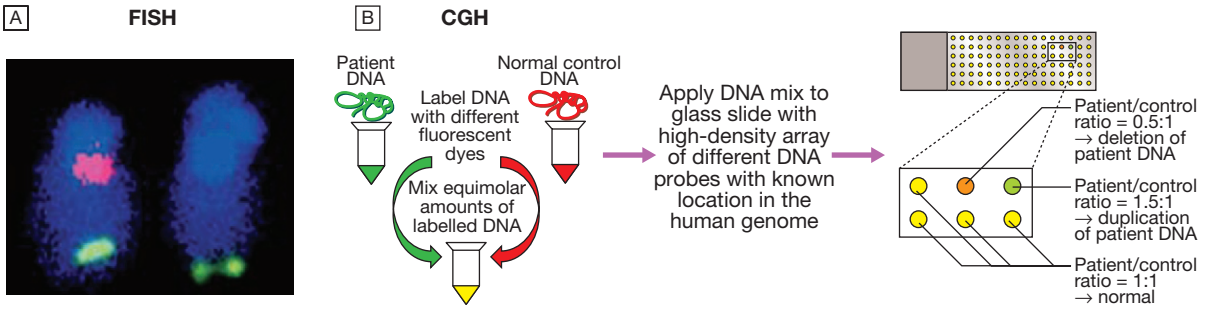

Fig. 3.14 Detection of chromosomal abnormalities by fluorescent in situ hybridisation (FISH) and comparative genomic hybridisation (CGH). A An example of FISH analysis showing a pair of homologous metaphase chromosome 22 stained with a blue fluorescent dye. The green spots represent a telomeric probe that has hybridised to both sister chromatids (there are two spots on the right-hand chromosome, whereas on the left the two spots are overlapping). The pink spot shows hybridisation of a probe mapping to band 22q11.2. The left chromosome has a normal signal that is absent on the right. This represents the microdeletion associated with velocardiofacial syndrome on the chromosome on the right. B Overview of comparative genomic hybridisation (CGH). Deletions and duplications are detected by looking for deviation from the 1 : 1 ratio of patient and control DNA in a microarray. Ratios in excess of 1 indicate duplications, whereas ratios below 1 indicate deletions.

3.7 Examples of non-DNA-based investigations for common genetic diseases

Disease	Investigation	Page reference
Sickle-cell disease	Haemoglobin electrophoresis	1032
Haemophilia	Clotting factor levels	1051
Hypogammaglobulinaemia	Immunoglobulin levels, complement levels	81
Phenylketonuria	Enzyme assays, amino acid levels	449
Congenital adrenal hyperplasia	Hormone levels, enzyme assays	782
Autosomal dominant polycystic kidney disease	Radiology, renal biopsy	505
Mitochondrial myopathy	Muscle biopsy, enzyme assay	1229
Pseudohypoparathyroidism	Radiology and calcium biochemistry	770

increasingly this is being replaced by next-generation sequencing, which has higher throughput (Fig. 3.13B).

Assessing DNA copy number

For decades, metaphase chromosome analysis by light microscopy has been the mainstay of clinical cytogenetic analysis to detect gain or loss of whole chromosomes or large chromosomal segments (> 4 million bp); such anomalies are collectively known as aneuploidy. More recently, whole-genome microarrays have replaced chromosome analysis, allowing rapid and precise detection of segmental gain or loss of DNA throughout the genome (see Box 3.5, p. 56). Microarrays consist of dense grids of short sequences of DNA (probes) that are complementary to known sequences in the genome (Fig. 3.14B). Each probe is fixed at a known position on the array (often printed on to a specially coated glass slide). The patient's fluorescently labelled DNA sample is hybridised to the array, and results for each probe are read by a laser scanner. This allows a copy number map of the patient's DNA to be constructed and abnormalities to be identified. Many clinically recognisable syndromes are the result of aneuploidy. The specific phenotype associated with individual deletion syndromes is the result of loss of one copy of several adjacent genes – a contiguous gene syndrome (see Box 3.5). Fluorescent in situ hybridisation (FISH, Fig. 3.14A) can be used to confirm specific deletions or duplications on metaphase chromosomes as a follow-up to microarray analysis.

Non-DNA-based methods of assessment

Although DNA-based diagnostic tools are used in the majority of patients with suspected genetic disease, direct analysis of protein function, such as measurement of specific enzyme activity, can also be used to diagnose single-gene disorders. An example of this is the investigation of myopathy thought to be due to defects in mitochondrial complex 1 proteins (Box 3.7). Complex 1 is made up of at least 36 nuclear-encoded and 7 mitochondrial DNA-encoded subunits, and mutations in any of these subunits can cause the disorder, which makes sequence analysis impractical as a first-line clinical test. Conversely, the biochemical measurement of respiratory chain complex I proteins can easily be analysed in muscle biopsies, and this can be diagnostic of a specific mitochondrial cytopathy (see Fig. 3.3, p. 45, and Box 3.1, p. 46).

Genetic testing in pregnancy and pre-implantation genetic testing

Genetic testing may be performed during pregnancy. Invasive tests, such as amniocentesis and chorionic

3.8 Some indications for prenatal testing

- Advanced maternal age and a high-risk serum screening result
- A previous child with a detectable chromosome abnormality or a parent with a chromosome abnormality such as a balanced translocation
- A parent or child with a genetic disease for which testing is available
- Abnormal antenatal scan

3.9 Methods used in prenatal testing

Test	Gestation	Comments
Ultrasound	1st trimester onwards	Increased nuchal translucency (an oedematous flap of skin at the base of the neck) for trisomies and Turner's; all major abnormalities such as NTDs, congenital heart disease
Chorionic villus biopsy	From 11 weeks	2% risk of miscarriage; used for early chromosomal, DNA and biochemical analysis; a specialised test
Amniocentesis	From 14 weeks	< 1 % risk of miscarriage; used for chromosomal and some biochemical analysis, e.g. α-fetoprotein for NTD
Cordocentesis	From 19 weeks	2–3% risk of miscarriage; a highly specialised test; used for chromosomal and DNA analysis

(NTD = neural tube defect)

EBM 3.10 Screening for Down's syndrome

'Antenatal screening in the first and second trimesters identifies fetuses at risk of Down's syndrome. Tests which currently have sensitivity > 60% and specificity > 95% include:

- *First trimester* (11–14 weeks): nuchal translucency; or nuchal translucency, human chorionic gonadotrophin (hCG) and pregnancy-associated plasma protein-A (PAPP-A)
- *Second trimester* (3–20 weeks): triple test (hCG, α-fetoprotein, unconjugated oestriol, uE3)
- Other combinations are available for use from 11 to 20 weeks.'

For further information: http://publications.nice.org/antenatal-care-cg62

villus sampling, are most often carried out to diagnose conditions that result in early infant death or severe disability. Such tests are only offered after careful explanation of the risks involved. Many couples will use the result of such tests to decide about termination of pregnancy. Some indications for testing are listed in Box 3.8; the methods used are summarised in Boxes 3.9 and 3.10. Non-invasive ultrasound scanning is offered to all pregnant couples and is particularly important if there is a previous history of serious developmental abnormalities. It is now possible to test single cells from a developing human embryo for the presence of deleterious mutations to select unaffected embryos as part of in vitro fertilisation procedures. As the range of tests for genetic diseases increases, demand for prenatal testing and preimplantation genetic diagnosis is likely to rise. There is considerable ethical debate about the types of disease for which such procedures are appropriate.

Genetic testing in children

Ethical issues often arise with regard to genetic testing of children. For conditions with onset during childhood and for which useful medical interventions are available, it is clearly important to test a child. An example of this is neonatal testing for cystic fibrosis, when early therapy reduces disease progression (p. 680), or in multiple endocrine neoplasia type 2B (MEN 2B), when early thyroidectomy prevents medullary thyroid carcinoma (p. 755). However, testing a healthy child for an adult-onset disorder where no benefit from early intervention exists should be avoided. Instead, the child should be left to make his or her own informed decision as an adult.

Identifying a disease gene in families

In families with a genetic disease for which the causative gene is unknown, single nucleotide polymorphisms (SNPs) can be used to track or 'map' disease genes using a technique called genome-wide linkage analysis. Microarray-based techniques allow more than 500 000 SNPs to be typed in a single experiment, and by comparison of the segregation of patterns of contiguous SNPs (called haplotypes) in affected and unaffected individuals, the 'locus' of DNA where the responsible gene resides can be identified. The confidence of association ('linkage') with the disease in question is influenced by the number of subjects studied, the strength of the effect of the gene on the disease, and the closeness of the SNP to the gene in question. The confidence can be expressed as a LoD (logarithm of the odds) score, which is $-\log_{10}$ of the probability (p value) of linkage; by convention, a LoD score of more than 3 ($p < 0.001$) is taken to be statistically significant. Once a locus has been identified, more detailed mapping within the locus can be undertaken and the relevant mutation confirmed by sequencing the relevant gene. Over recent years, next-generation sequencing of every exon in the genome (exome sequencing) has been used as an alternative to linkage analysis in identifying disease-causing mutations in families. Typically affected individuals within the family are sequenced and the results compared with unaffected family members and controls from the general population. For a fully penetrant disorder, the disease-causing mutation will be present in affected individuals and not present in unaffected family members or unrelated controls.

Genetic investigation in populations

Genetic screening may be applied to whole populations. The criteria for the use of population screening are well established; they depend on the incidence of specific conditions in individual populations and on whether an intervention is available to ameliorate the effects of the disease. In the UK, examples include screening for phenylketonuria and cystic fibrosis in the newborn, and prenatal screening for neural tube defects and Down's syndrome in pregnant women (see Box 3.10). Screening for carriers of haemoglobinopathies and Tay–Sachs disease is also carried out in some countries where the incidence of these conditions may be high enough to merit screening the entire population (p. 1031).

Predictive genetic testing

In the absence of symptoms or signs of disease in an individual at risk, a genetic test can be used to determine whether that individual carries the disease-causing mutation. This is known as pre-symptomatic or predictive genetic testing. Predictive tests are usually carried out for adult-onset disorders such as familial cancer syndromes and neurodegenerative disorders such as Huntington's disease (Box 3.11), or when a positive result in children will affect screening and management, such as in familial polyposis coli (p. 911). However, many complicated ethical issues arise with testing of children and such tests should only be carried out by clinicians experienced in their use.

Whilst a negative predictive test is clearly a favourable outcome for the individual concerned, a positive test may have significant negative consequences. These should have been explained fully in the counselling process (see below), and include employment discrimination and psychological effects. Providing this is done, current evidence suggests that serious psychological sequelae are uncommon.

3.11 Predictive testing for Huntington's disease

- Currently, no medical benefit can be derived from knowing pre-symptomatic genetic status. In this situation, predictive testing is not offered to children but is available to capable adults
- Individuals have several reasonably spaced appointments with a genetic counsellor (or medical geneticist or specialist psychiatrist) prior to testing to ensure that the implications of testing are fully understood
- Fully informed patient consent is required prior to testing and individuals must be free to withdraw from testing at any time
- Follow-up support must be available and the result must not be disclosed to any other person without written consent of the tested individual

PRESENTING PROBLEMS IN GENETIC DISEASE

There are many thousands of known single-gene diseases. Individually these are rare, but collectively they are relatively common. This diversity makes clinical genetics a fascinating clinical specialty but it does mean that it is difficult, if not impossible, for any individual clinician to memorise the features associated with all these disorders. It is therefore important to have an awareness of the existence of genetic diseases and some general rules or 'triggers' in mind. Although single-gene disorders can present at any age (Box 3.12) and affect any tissue or organ system, they share some general characteristics:

- positive family history
- early age of onset
- multisystem involvement
- no obvious non-genetic explanation.

It is important to recognise any unusual clinical presentation and to consider genetic disease in the context of the clinical findings and the family history. Publicly accessible online catalogues of Mendelian diseases can be useful sources of potential diagnoses.

3.12 Genetic disease and counselling in old age

- **Genetic disease**: may present for the first time in elderly patients, e.g. Huntington's disease.
- **Family investigation**: remains essential in the management of genetic disease presenting in old age and referral to clinical genetics services should be considered.

MAJOR CATEGORIES OF GENETIC DISEASE

It is clearly impossible to discuss all Mendelian disease in this chapter, as there are many thousands of single-gene disorders. However, the major categories of genetic disease that are commonly encountered by clinical geneticists in adult practice are discussed below.

Inborn errors of metabolism

Inborn errors of metabolism (IEM) are caused by mutations that disrupt the normal function of a biochemical pathway. A good example is the glycogen storage diseases (see Box 16.23, p. 450), which are caused by mutations in various genes involved in regulating glucose metabolism. Most IEM are due to autosomal or X-linked recessive loss-of-function mutations in genes encoding specific enzymes or enzymatic co-factors. Knowledge of the biochemical pathway involved means that specific blocks have predictable consequences, including deficiency of the end product and build-up of intermediary compounds. Many hundreds of different IEM have been identified and these disorders have contributed a great deal to our understanding of human biochemistry. Most IEM are very rare and some are restricted to paediatric practice; however, a growing number may now present during adult life and some of these are discussed below.

Intoxicating IEM

A subgroup of IEM, termed 'intoxicating IEM', can present as a sudden deterioration in a previously well individual. Such deteriorations are usually precipitated

by physiological stress, such as infection, pregnancy, exercise or changes in diet. The intoxication is due to the build-up of intermediary, water-soluble compounds, which will vary according to the pathway involved. For example, in urea cycle disorders ammonia is the toxic substance, whereas in maple syrup urine disease it is branched-chain amino acids. The intoxication is often associated with derangement of the acid–base balance and, if not recognised and treated, will often proceed to multi-organ failure, coma and death. In the porphyrias (Box 16.32, p. 460), the intoxication is caused by a build-up in the metabolites involved in haem synthesis. The diagnosis of these disorders requires specialist biochemical analysis of blood and/or urine. In some disorders, treatment relies on removal of the toxic substance using haemodialysis or chemical conjugation, or prevention of further accumulation by restricting intake of the precursors, such as total protein restriction in urea cycle disorders and avoidance of branched-chain amino-acid intake in maple syrup urine disease. In other disorders, such as the porphyrias, treatment is based on avoiding precipitating factors and supportive care (p. 460).

Mitochondrial disorders

Disorders of energy production are the most common type of IEM presenting in adult life, and some of these disorders have been mentioned in the section on mitochondrial function (see Fig. 3.3, p. 45, and Box 3.1, p. 46). The tissues that are most commonly affected in this group of disorders are those with the highest metabolic energy requirements, such as muscle, heart, retina and brain. Therapy in this group of disorders is based on giving antioxidants and co-factors, such as vitamin C and ubiquinone, that can improve the function of the respiratory chain.

Storage disorders

Storage disorders involve enzyme deficiency in lysosomal degradation pathways. The clinical consequences depend on the specific enzyme involved. For example, Fabry disease, an X-linked recessive deficiency of α-galactosidase A, results in abdominal pain, episodic diarrhoea, renal failure and angiokeratoma. Niemann–Pick disease type C is caused by autosomal recessive loss-of-function mutations in either the *NPC1* or *NPC2* gene. These result in lysosomal cholesterol accumulation, causing hepatosplenomegaly, dysphagia, loss of speech, very early dementia, spasticity and dystonia. An increasing number of storage disorders are treatable with enzyme replacement or substrate depletion therapies, making awareness and diagnosis more important. More details of specific disorders are provided in Chapter 16 (Box 16.24, p. 451).

Neurological disorders

Progressive neurological deterioration is one of the most common presentations of adult genetic disease. These diseases are mostly autosomal dominant and can be grouped into specific neurological syndromes and early-onset forms of well-known, non-Mendelian clinical entities. In the latter group, the best examples would be early-onset familial forms of dementia, Parkinson's disease and motor neuron disease. The triplet repeat disorders cause an interesting group of syndromes and have specific features that are dealt with below.

Huntington's disease

Huntington's disease (HD) is the paradigm of triplet repeat disorders. This condition can present with a movement disorder, weight loss or psychiatric symptoms (depression, addiction, psychosis, dementia), or with a combination of all three. The disease is the result of a $[CAG]_n$ triplet repeat expansion mutation in the *HD* gene on chromosome 4. Since CAG is a codon for glutamine and this mutation is positioned in the ORF, this results in an expansion of a polyglutamine tract in the protein. The mutation probably leads to gain of function, as deletions of the gene do not cause HD. The function of the protein encoded by the *HD* gene is not fully understood, but expansion of the repeat to above the normal range of 3–35 results in neurological disease. In general, the severity of disease and age at onset are related to the repeat length. In HD, atrophy of the caudate nuclei and the putamen is obvious on magnetic resonance imaging (MRI) of the brain, and in later stages cerebral atrophy is also apparent. There is currently no therapy that will alter the progression of the disease, which will often be the cause of the patient's death. Within families there is a tendency for disease severity to increase and age at onset to fall due to further expansion of the repeat, a phenomenon known as anticipation. The mutation is more likely to expand through the male germ line than through female meiosis.

Other triplet repeat disorders

Other progressive neurological disorders caused by triplet repeat expansion mutations in different genes include several forms of autosomal dominant spinocerebellar ataxias, dentatorubral-pallidoluysian atrophy (DRPLA), Machado–Joseph disease and Kennedy disease. These polyglutamine disorders all show intracellular inclusions in affected cells. It is thought that this accumulation may, in itself, be deleterious and is the result of defective protein degradation. Myotonic dystrophy and Friedreich's ataxia are also triplet repeat expansion disorders but the pathogenetic mechanism associated with these diseases is different, as these repeats do not lie within the coding regions of the affected genes.

Connective tissue disorders

Mutations in different types of collagen, fibrillin and elastin make up the majority of connective tissue disorders. The clinical features of these disorders vary, depending on the structural function and tissue distribution of the protein that is mutated. For example, autosomal dominant loss-of-function mutations in the gene encoding elastin cause either supravalvular aortic stenosis, cutis laxa or a combination of both conditions. The most commonly involved systems are:

- *skin* (increased or decreased elasticity, poor wound healing)
- *eyes* (myopia, lens dislocation)
- *blood vessels* (vascular fragility)
- *bones* (osteoporosis, skeletal dysplasia)
- *joints* (hypermobility, dislocation, arthropathy).

Learning disability, dysmorphism and malformations

Congenital global cognitive impairment (also called mental handicap or learning disability) affects about 3% of the population. It is commonly divided into broad categories of mild to moderate (IQ 50–70), moderate to severe (IQ 20–50), and severe to profound (IQ < 20). There are important 'environmental' causes of global cognitive impairment, including:

- *teratogen exposure* during pregnancy (alcohol, anticonvulsants)
- *congenital infections* (cytomegalovirus, rubella, toxoplasmosis, syphilis)
- *the sequelae of prematurity* (intraventricular haemorrhage)
- *birth injury* (hypoxic ischaemic encephalopathy).

Genetic disorders contribute very significantly to the aetiology of global cognitive impairment. Given the complexity of brain development, it is not surprising that global cognitive impairment shows extreme locus heterogeneity. The three most important groups of disorder are reviewed below.

Chromosome disorders

Any significant gain or loss of autosomal chromosomal material (known as aneuploidy) usually results in learning disability and other phenotypic abnormalities (see Fig. 3.11, p. 57). Down's syndrome is the most frequently found and best known of these disorders, and is caused by an increased dosage of genes on chromosome 21. Most cases of Down's syndrome are due to a numerical chromosome abnormality with trisomy of chromosome 21, e.g. 47,XX,+21 or 47,XY,+21. The clinical features are:

- globally delayed development
- characteristic facial appearance
- a significant risk of specific malformations (atrioventricular septal defect, duodenal atresia)
- a predisposition to several late-onset disorders, including hypothyroidism, acute leukaemias and Alzheimer's disease.

Recent surveys have shown that DNA microarray analysis can identify causative structural chromosome abnormalities in 10–25% of cases of significant learning disability. These deletions and duplications are mostly de novo and unique. An interest group of recurrent deletions and duplication caused by non-allelic homologous recombination events has been mentioned above. These result in specific microdeletion or microduplication syndromes, such as:

- *velocardiofacial syndrome* due to deletion of 22q11.2 (learning disability, malformations of the cardiac outflow tract, cleft palate, distinctive facial appearance and immune disorders)
- *Williams' syndrome* due to deletion of 7q11.23 (learning disability, supravalvular aortic stenosis and mild cutis laxa as a result of deletion of the *elastin* gene, distinctive facial appearance and over-friendly, chatty personality).

Dysmorphic syndromes

There are several thousand different dysmorphic syndromes; all are rare but they are characterised by the occurrence of cognitive impairment, malformations and a distinctive facial appearance – or 'gestalt' – associated with various other clinical features. Making the correct diagnosis is important, as it has profound implications on immediate patient management, detection of future complications and assessment of recurrence risks in the family. Clinical examination remains the mainstay of diagnosis and the patient often needs to be evaluated by a clinician who specialises in the diagnosis of these syndromes. The differential diagnosis in dysmorphic syndromes is often very wide and this has resulted in computer-aided diagnosis becoming an established clinical tool. Dysmorphology databases such as POSSUM and LMD have been established that are curated catalogues of the many thousands of known syndrome entities; they can be searched to identify possible explanations of unusual combinations of clinical features. The clinical diagnosis may then be confirmed by specific genetic investigations, as the genetic basis of a wide range of dysmorphic syndromes has been identified.

X-linked mental handicap

X-linked mental handicap (XLMH) accounts for approximately 10% of cases of moderate to severe learning disability. There are over 100 genes on the X chromosome that can cause learning disability but the most common disorder is fragile X syndrome, characterised by a distinctive facial appearance, attention deficit, joint hypermobility, macro-orchism (increased testicular size) and a non-staining gap on the X chromosome on chromosome analysis. Fragile X is caused by a triplet repeat expansion mutation but of a different type from the polyglutamine repeat disorders mentioned above. The repeat in fragile X syndrome is not in the coding region and is a $[CGG]_n$ expansion (see Box 3.4, p. 56). Methylation of the expanded repeat results in silencing of a specific gene called *FMR1*, which encodes an RNA-binding protein.

De novo mutations

Next-generation sequencing technology has made possible trio-based, whole-exome sequencing, in which the affected individual and both of their parents are analysed. It has recently become clear that de novo mutations in the coding regions of one of the many genes that are involved in normal brain development are collectively responsible for severe intellectual disability in at least 25% of affected patients. Trio-exome sequencing is thus likely to become a first-line diagnostic test for such cases in the near future.

Familial cancer syndromes

Most cancers are not inherited but occur as the result of an accumulation of somatic mutations, as discussed previously in this chapter. However, it has been recognised for many decades that some families are prone to one or more specific types of cancer. Affected individuals tend to present with tumours at an early age and are more likely to have multiple primary foci of carcinogenesis.

Retinoblastoma

Patients with autosomal dominant familial retinoblastoma have an inherited mutation in one copy of the *RB*

gene, which is a tumour suppressor. This strongly predisposes individuals to the formation of retinoblastoma in one or both eyes. It is possible for more than one primary tumour to form in the same eye and for retinoblastoma to occur in the pineal gland. From a clinical perspective, it is important to screen the eyes and pineal gland of such individuals regularly so that tumours can be treated early and sight preserved. This gene is widely expressed and it is not clear why the retina is the main site of oncogenesis in this syndrome. An increased incidence of osteogenic sarcoma is also seen in affected individuals.

Familial adenomatous polyposis coli

Familial adenomatous polyposis coli (FAP) is an autosomal dominant condition due to inactivation mutations in the *FAP* tumour suppressor gene on 5q. The gene product is thought to modulate a specific signalling cascade (*Wnt* signalling) that regulates cell proliferation. Mutation carriers usually develop many thousands of intestinal polyps in their second and third decades and have a very high risk of malignant change in the colon. Prophylactic colectomy in the third decade is necessary in most cases. Regular screening for polyps in the upper gastrointestinal tract is also recommended.

Li–Fraumeni syndrome

Heterozygous loss-of-function mutations in the gene encoding p53 cause Li–Fraumeni syndrome. Families with this condition have a very significant increased predisposition to early-onset leukaemias, sarcomas, and breast and brain malignancies. Screening for presymptomatic tumours in this condition is very difficult and of unproven benefit, as almost any tissue can be affected.

Hereditary non-polyposis colorectal cancer

Hereditary non-polyposis colorectal cancer (HNPCC) is an autosomal dominant disorder that presents with early-onset familial colon cancer, particularly affecting the proximal colon. Other cancers, such as endometrial cancer, are often observed in affected families. This disorder shows marked locus heterogeneity, as mutations can occur in several different genes encoding proteins involved in DNA mismatch repair.

Familial breast cancer

Familial breast cancer is an autosomal dominant disorder that is most often due to mutations in genes encoding either *BRCA1* or *BRCA2*. Both of these proteins are involved in DNA repair. Individuals who carry a *BRCA1* or *BRCA2* mutation are at high risk of early-onset breast and ovarian tumours, and require regular screening for both of these conditions. Because of the very high risk of cancer, many women who carry these mutations elect to have prophylactic bilateral mastectomy and oophorectomy in the absence of a detectable tumour.

Xeroderma pigmentosum

Xeroderma pigmentosum (XP) is the name given to a group of rare disorders in which there are autosomal recessive defects in DNA repair genes that deal primarily with the effects of non-ionising radiation. The skin is particularly involved, and affected patients develop skin cancers with increased frequency.

GENETIC COUNSELLING

Genetic counselling provides information about the medical and family implications of a specific disease in a clear and non-directive manner. Such counselling aims to help individuals make informed decisions about planning a family, taking part in screening programmes and accepting prophylactic therapies. Genetic counselling may be provided by a medical geneticist, a specialist nurse, or a clinician with particular skills in this area, such as an obstetrician or paediatrician (Box 3.13). Perception of genetic risks clearly depends on perceived hazard. For example, a 5% (or 1:20) risk of genetic disease may be perceived as low if the disease is treatable, but unacceptably high if not.

Specific problems encountered in genetic counselling include:

- accurate assessment of genetic risk
- identification of children at risk of genetic disorders
- the increase in genetic risks associated with consanguinity
- non-paternity as an incidental finding in DNA.

3.13 Clinical genetics services

Component	Role
Medical geneticist	Diagnosis and management of genetic disease, assessment of genetic risk, managing screening programmes, interpretation of genetic test results. Subspecialties include prenatal genetics, dysmorphology (syndrome identification), cancer genetics
Genetic counsellor	Assessing genetic risk, provision of genetic counselling (providing accurate risk information in a comprehensible format), predictive testing for genetic disease and provision of information and support
DNA diagnostic laboratory	Identifying and reporting disease-causing mutations in validated disease genes. Some laboratories also provide linkage analysis to track diseases in families. Laboratories often work in a consortium, as so many different disease genes have now been identified
Cytogenetics laboratory	Identifying pathogenic numerical and structural chromosome anomalies in prenatal, postnatal and oncology samples
Biochemical genetics laboratory	Metabolite and enzymatic-based diagnosis of IEM. Metabolite-based monitoring of treatment of IEM
Newborn screening laboratory	Provision of population-based newborn screening, e.g. PKU, cystic fibrosis, etc.

(IEM = inborn errors of metabolism; PKU = phenylketonuria)

Genetic tests are increasingly used for the diagnosis and prediction of Mendelian disease in a medical context, and such skills will become increasingly important for many clinicians.

Genetic risk is often calculated using Bayes' theorem (Box 1.6, p. 6), which takes prior risk into account to calculate future risk. A simple Bayesian calculation is illustrated here. Consider a woman who is at risk of being a carrier of an X-linked recessive disease. Her grandfather and brother are affected, which makes her mother an obligate gene carrier. Her risk of being a carrier is therefore 50%. However, she has two unaffected sons. This information can be used to modify her risk. The prior probability that she is a carrier is 1:2 and that she is not a carrier also 1:2. The conditional probability that she would have two normal sons if she were a carrier is $1/2 \times 1/2$, i.e. 1/4. If she were not a carrier, the probability of having normal sons is 1. From this, the joint probability for each outcome can be calculated (the prior risk × the conditional risk): $1/2 \times 1/4$ (1/8) for being a carrier and $1/2 \times 1$ (1/2) for not being a carrier. The final risk, or relative probability, for each outcome can then be obtained by dividing the joint probability for that outcome by the sum of the joint probabilities. The probability that she is a carrier is therefore $1/8(1/8 + 1/2) = 1/5$ (20%).

GENETICS OF COMMON DISEASES

Many common disorders, such as diabetes, atherosclerosis, hypertension, cancer, osteoarthritis, inflammatory bowel disease and osteoporosis, have an important genetic component but are not caused by a single mutation. Techniques are now available both to measure the contribution and to identify genes with significant effects. This means that the result of genetic testing is beginning to have an impact on diagnosis, prognosis and therapy for common diseases, and this trend is likely to expand significantly in the years to come. Some of the most useful approaches to clinical interpretation of the genetic aspects of common disorders are outlined below.

Measuring the genetic contribution to complex disease

Genetic contributions to complex disease can be detected and quantified by twin studies and/or by analysing familial clustering. Twin studies use the difference in disease concordance between monozygotic (MZ) and dizygotic (DZ) twins to calculate genetic contribution. MZ twins are genetically identical, whereas DZ twins, like all siblings, are identical for only about 50% of their genetic variation. However, both MZ and DZ twins share an almost identical intrauterine environment and similar postnatal environment. Thus, any evidence of a higher concordance of the disease in MZ compared to DZ twins is assumed to be evidence of genetic contribution. Many common diseases and quantitative traits, such as height, weight, blood pressure and bone mineral density, show higher concordance rates in MZ twins compared to DZ twins. Genetic contributions to common diseases can also be assessed by studying the incidence of the disease in first-degree relatives of affected individuals, as compared with the general population (Fig. 3.15). The difference in incidence is used to calculate a disease risk, which is measured by the λ_s value (Box 3.14).

3.14 Risk to siblings of affected patients for common polygenic diseases

Disease	λ_s
Type 1 diabetes mellitus	15
Systemic lupus erythematosus	10–20
Multiple sclerosis	20–40
Schizophrenia	10
Ischaemic heart disease	4–12

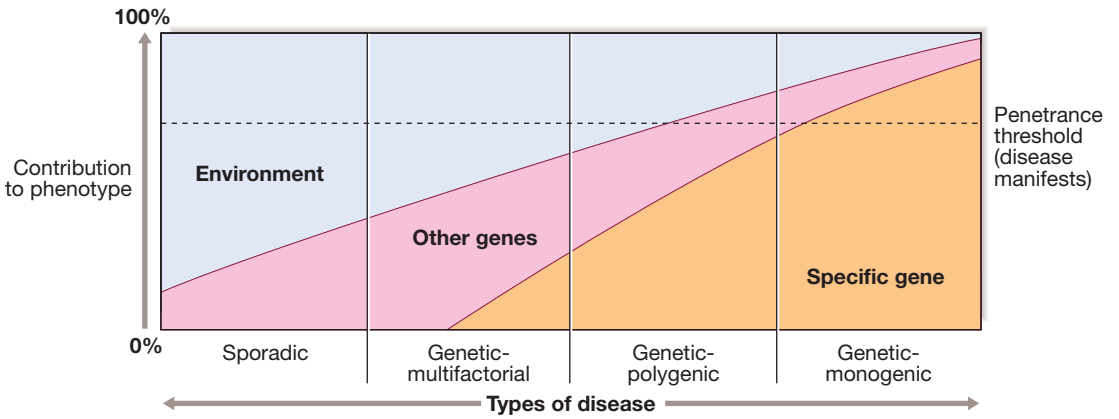

Fig. 3.15 The spectrum of genetic disease: how the genotype influences the phenotype. A particular characteristic or disease in an individual may be due to a specific genetic abnormality (monogenic disease) or may reflect several predisposing genes (polygenic disease). In each case, environmental factors may further influence the phenotype; in their absence, genetic factors alone may be insufficient to allow the disease to develop, resulting in non-penetrance or reduced penetrance (see text).

3.15 Polymorphisms that predispose to common diseases

Disease	Inheritance	No. of loci	Pathways
Colorectal cancer	Polygenic	20	DNA repair enzymes, growth factor signalling pathways, Wnt signalling
Osteoporosis	Polygenic	56	Cytokines, receptors and intracellular signalling molecules in RANK and Wnt pathways. Regulators of stem cell differentiation and bone mineralisation
Systemic lupus erythematosus	Polygenic	60	Cytokines, receptors and intracellular signalling pathways that regulate immune function; complement, intracellular nucleases
Gout	Polygenic	9	Renal solute transporters; regulators of glucose and insulin metabolism

(RANK = receptor activator of nuclear factor κ B)

Genetic testing in complex disease

Most common diseases are determined by interactions between a number of genes and the environment. In this situation, the genetic contribution to disease is termed polygenic. Until recently, very little progress had been made in identifying the genetic variants that predispose to common diseases, but this has been changed by the advent of genome-wide association studies (GWAS). A GWAS typically involves genotyping many (> 500 000) genetic markers spread across the genome in a large group of individuals with the disease and controls. By comparing the genotypes in cases and controls, it is possible to identify regions of the genome and candidate genes that contribute to the disease under study. Some of the candidate genes for common diseases identified by this approach are listed in Box 3.15.

Pharmacogenomics

Pharmacogenomics is the science of dissecting the genetic determinants of drug kinetics and effects using information from the human genome. For more than 50 years, it has been appreciated that polymorphic mutations within genes can affect individual responses to some drugs, such as loss-of-function mutations in *CYP2D6* causing hypersensitivity to debrisoquine, an adrenergic-blocking medication formerly used for the treatment of hypertension, in 3% of the population. This gene is part of a large family of highly polymorphic genes encoding cytochrome P450 proteins, mostly expressed in the liver, which determine the metabolism of a host of specific drugs. Polymorphisms in the *CYP2D6* gene also determine codeine activation, while those in the *CYP2C9* gene affect warfarin inactivation. Polymorphisms in these and other drug metabolic genes determine the persistence of drugs and, therefore, should provide information about dosages and toxicity. At the present time, genetic testing for assessment of drug response is seldom used routinely, but in the future it may be possible to predict the best specific drugs and dosages for individual patients based on genetic profiling: so-called 'personalised medicine'. An example is the enzyme thiopurine methyltransferase (TPMT), which catabolises azathioprine, a drug that is used in the treatment of autoimmune diseases and in cancer chemotherapy. Genetic screening for polymorphic variants of TPMT can be useful in identifying patients who have increased sensitivity to the effects of azathioprine and who can be treated with lower doses than normal.

RESEARCH FRONTIERS IN MOLECULAR MEDICINE

Gene therapy

Replacing or repairing mutated genes (gene therapy) is very difficult in humans. Retroviral-mediated ex vivo replacement of the defective gene in bone marrow cells for the treatment of severe combined immune deficiency syndrome (p. 80) has been partially successful. There have been two major problems with the clinical trials of virally delivered gene therapy conducted to date:

- The random integration of the retroviral DNA (which contains the replacement gene) into the genome has caused leukaemia in some treated children via activation of proto-oncogenes.
- A severe immune response to the viral vector may be induced. It has not yet been possible to use non-viral means to introduce sufficient numbers of copies of replacement genes to produce significant biological effects.

Other therapies for genetic disease include PTC124, a compound that can 'force' cells to read through a mutation that results in a premature termination codon in an ORF with the aim of producing a near-normal protein product. This therapeutic approach could be applied to any genetic disease caused by nonsense mutations.

Induced pluripotent stem cells and regenerative medicine

Adult stem cell therapy has been in wide use for decades in the form of haematopoietic stem cell transplantation. The identification of adult stem cells for other tissues, coupled with the ability to purify and maintain such cells in vitro, now offers exciting therapeutic potential for other diseases. Many different adult cell types can be transdifferentiated to form cells termed induced pluripotent stem cells (iPS cells) with almost all the characteristics of embryonic stem cells. In mammals, iPS cells can be used to regenerate various tissues such as the

heart and brain. They have great potential both to develop tissue models of human disease and for regenerative medicine. In mammalian model species, such cells can be taken and used to regenerate differentiated tissue cells, such as in heart and brain.

Pathway medicine

The ability to manipulate pathways that have been altered in genetic disease has tremendous therapeutic potential for Mendelian disease, but a firm understanding of both disease pathogenesis and drug action at a biochemical level is required. An exciting example of this has been the discovery that the vascular pathology associated with Marfan's syndrome is due to the defective fibrillin molecules causing up-regulation of transforming growth factor (TGF)-β signalling in the vessel wall. Losartan is an antihypertensive drug that is marketed as an angiotensin II receptor antagonist. However, it also acts as a partial antagonist of TGF-β signalling and is effective in preventing aortic dilatation in a mouse model of Marfan's syndrome, showing promising effects in early human clinical trials.

The immune system has evolved to protect the host from pathogens while minimising damage to self tissue. Despite the ancient observation that recovery from some diseases results in protection against that condition, the existence of the immune system as a functional entity was not recognised until the end of the 19th century. More recently, it has become clear that the immune system not only protects against infection, but also influences healing and governs the responses that can lead to autoimmune diseases. Dysfunction or deficiency of the immune response leads to a wide variety of diseases, involving every organ system in the body.

The aim of this chapter is to provide a general understanding of immunology and how it contributes to human disease. A review of the key components of the immune response is followed by five sections that illustrate the clinical presentation of the most common forms of immune dysfunction. Clinical immunologists are usually involved in managing patients with allergy and immune deficiency. More detailed discussion of individual conditions can be found in the relevant organ-specific chapters of this book.

FUNCTIONAL ANATOMY AND PHYSIOLOGY OF THE IMMUNE SYSTEM

The immune system consists of an intricately linked network of cells, proteins and lymphoid organs that are strategically placed to ensure maximal protection against infection. Immune defences are normally categorised into the innate immune response, which provides immediate protection against an invading pathogen, and the adaptive or acquired immune response, which takes more time to develop but confers exquisite specificity and long-lasting protection.

The innate immune system

Innate defences against infection include anatomical barriers, phagocytic cells, soluble molecules, such as complement and acute phase proteins, and natural killer cells. The innate immune system recognises generic microbial structures present on non-mammalian tissue and can be mobilised within minutes. A specific stimulus will elicit essentially identical responses in different individuals (in contrast with antibody and T-cell responses, which vary greatly between individuals).

Constitutive barriers to infection

The tightly packed, highly keratinised cells of the skin constantly undergo renewal and replacement, which physically limits colonisation by microorganisms. Microbial growth is inhibited by physiological factors, such as low pH and low oxygen tension, and sebaceous glands secrete hydrophobic oils that further repel water and microorganisms. Sweat also contains lysozyme, an enzyme that destroys the structural integrity of bacterial cell walls; ammonia, which has antibacterial properties; and several antimicrobial peptides such as defensins. Similarly, the mucous membranes of the respiratory, gastrointestinal and genitourinary tract provide a constitutive barrier to infection. Secreted mucus acts as a physical barrier to trap invading pathogens, and immunoglobulin A (IgA) prevents bacteria and viruses attaching to and penetrating epithelial cells. As in the skin, lysozyme and antimicrobial peptides within mucosal membranes can directly kill invading pathogens, and additionally lactoferrin acts to starve invading bacteria of iron. Within the respiratory tract, cilia directly trap pathogens and contribute to removal of mucus, assisted by physical manœuvres, such as sneezing and coughing. In the gastrointestinal tract, hydrochloric acid and salivary amylase chemically destroy bacteria, while normal peristalsis and induced vomiting or diarrhoea assist clearance of invading organisms.

Endogenous commensal bacteria provide an additional constitutive defence against infection (p. 136). They compete with pathogenic microorganisms for space and nutrients, and produce fatty acids and bactericidins that inhibit the growth of many pathogens. In addition, commensal bacteria help to shape the immune response by inducing specific regulatory T cells within the intestine (p. 78).

These constitutive barriers are highly effective, but if external defences are breached by a wound or pathogenic organism, the specific soluble proteins and cells of the innate immune system are activated.

Phagocytes

Phagocytes ('eating cells') are specialised cells which ingest and kill microorganisms, scavenge cellular and infectious debris, and produce inflammatory molecules which regulate other components of the immune system. They include neutrophils, monocytes and macrophages, and are particularly important for defence against bacterial and fungal infections.

Phagocytes express a wide range of surface receptors that allow them to identify microorganisms. These pattern recognition receptors include the Toll-like receptors, NOD (nucleotide-oligomerisation domain protein)-like receptors and mannose receptors. They recognise generic molecular motifs not present on mammalian cells, including bacterial cell wall components, bacterial DNA and viral double-stranded RNA. While phagocytes can recognise microorganisms through pattern recognition receptors alone, engulfment of microorganisms is greatly enhanced by opsonisation. Opsonins include acute phase proteins such as C-reactive protein (CRP), antibodies and complement. They bind both to the pathogen and to phagocyte receptors, acting as a bridge between the two to facilitate phagocytosis (Fig. 4.1).

Neutrophils

Neutrophils, also known as polymorphonuclear leucocytes, are derived from the bone marrow (Fig. 4.2). They are short-lived cells with a half-life of 6 hours in the blood stream, and are produced at the rate of approximately 10^{11} cells daily. Their functions are to kill microorganisms directly, facilitate the rapid transit of cells through tissues, and non-specifically amplify the immune response. This is mediated by enzymes contained in granules which also provide an intracellular milieu for the killing and degradation of microorganisms.

The two main types of granule are primary or azurophil granules, and the more numerous secondary or specific granules. Primary granules contain myeloperoxidase and other enzymes important for

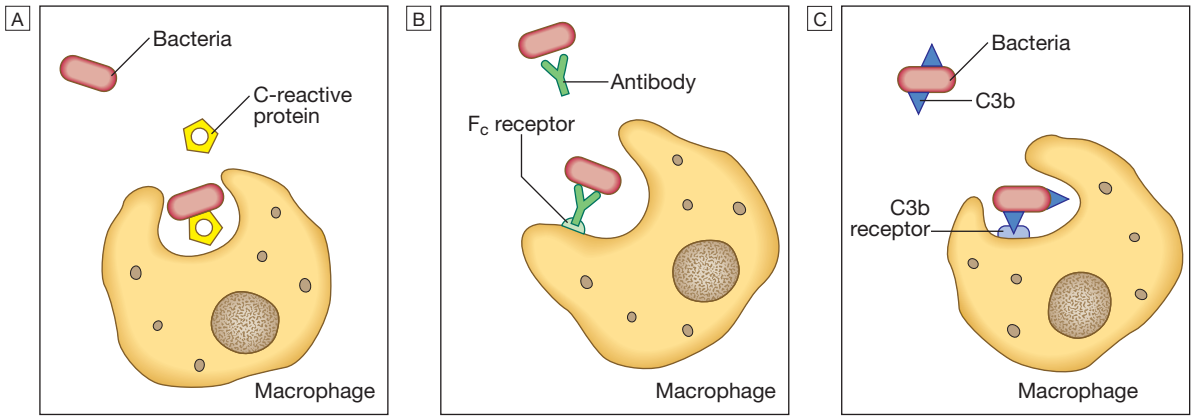

Fig. 4.1 Opsonisation. Phagocytosis of microbial products may be augmented by several opsonins. A C-reactive protein. B Antibody. C Complement fragments.

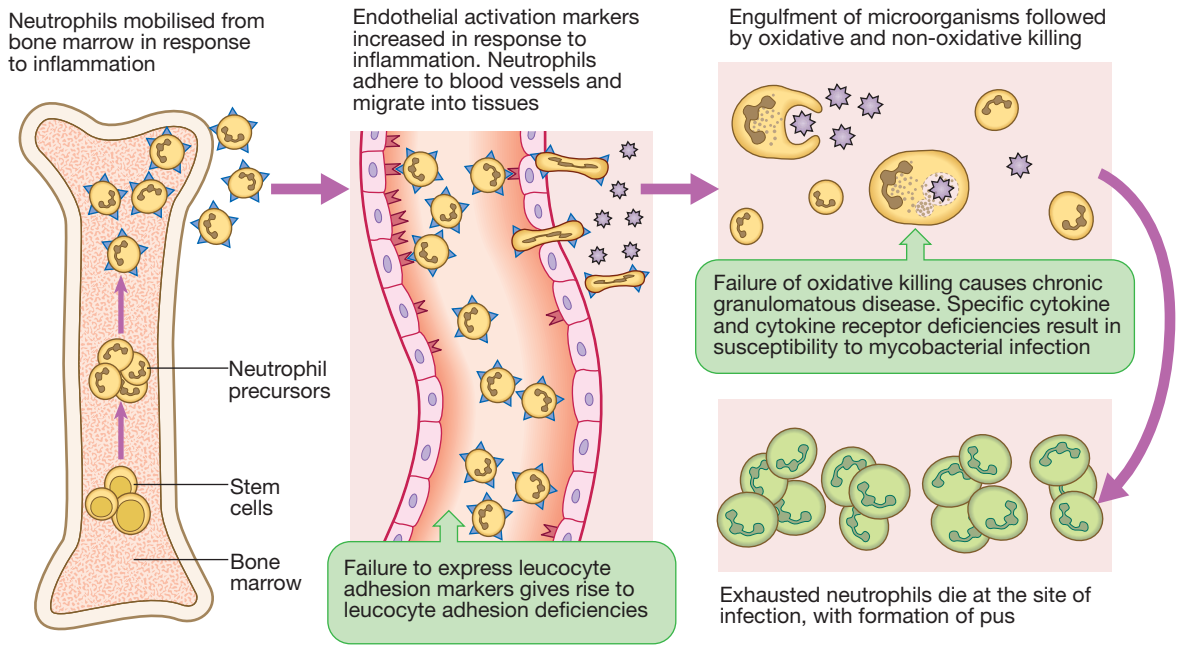

Fig. 4.2 Neutrophil function and dysfunction (green boxes).

intracellular killing and digestion of ingested microbes. Secondary granules are smaller and contain lysozyme, collagenase and lactoferrin, which can be released into the extracellular space. Granule staining becomes more intense in response to infection ('toxic granulation'), reflecting increased enzyme production.

When tissues are changed or damaged, they trigger the local production of inflammatory molecules and cytokines. These stimulate the production and maturation of neutrophils in the bone marrow, and their release into the circulation. The neutrophils are recruited to the inflamed site by chemotactic agents and by activation of local endothelium. Transit of neutrophils through the blood stream is responsible for the rise in leucocyte count that occurs in early infection. Once within infected tissue, activated neutrophils seek out and engulf invading microorganisms. These are initially enclosed within membrane-bound vesicles which fuse with cytoplasmic granules to form the phagolysosome. Within this protected compartment, killing of the organism occurs through a combination of oxidative and non-oxidative killing. Oxidative killing, also known as the respiratory burst, is mediated by the NADPH (nicotinamide adenine dinucleotide phosphate) oxidase enzyme complex. This converts oxygen into reactive oxygen species such as hydrogen peroxide and superoxide that are lethal to microorganisms. When combined with myeloperoxidase, hypochlorous ions ($HOCl^-$, analogous to bleach) are produced, which are highly effective oxidants and antimicrobial agents. Non-oxidative (oxygen-independent) killing occurs through the release of bactericidal enzymes into the phagolysosome. Each enzyme has a distinct antimicrobial spectrum, providing broad coverage against bacteria and fungi.

The process of phagocytosis depletes neutrophil glycogen reserves and is followed by neutrophil cell death. As the cells die, their contents are released and lysosomal enzymes degrade collagen and other components

4.1 Functions of macrophages

Initiation and amplification of the inflammatory response
• Stimulation of the acute phase response • Activation of vascular endothelium • Stimulation of neutrophil maturation and chemotaxis • Stimulation of monocyte chemotaxis
Killing of microorganisms
• Phagocytosis • Microbial killing through oxidative and non-oxidative mechanisms
Clearance, resolution and repair
• Scavenging of necrotic and apoptotic cells • Clearance of toxins and other inorganic debris • Tissue remodelling (elastase, collagenase, matrix proteins) • Down-regulation of inflammatory cytokines • Wound healing and scar formation (interleukin (IL)-1, platelet-derived growth factor, fibroblast growth factor)
Link between innate and adaptive immune system
• Activation of T cells by presenting antigen in a recognisable form • T cell-derived cytokines increase phagocytosis and microbicidal activity of macrophages

of the interstitium, causing liquefaction of closely adjacent tissue. The accumulation of dead and dying neutrophils results in the formation of pus, which, if extensive, may result in abscess formation.

Monocytes and macrophages

Monocytes are the precursors of tissue macrophages. They are produced in the bone marrow and constitute about 5% of leucocytes in the circulation. From the blood stream, they migrate to peripheral tissues, where they differentiate into tissue macrophages and reside for long periods. Specialised populations of tissue macrophages include Kupffer cells in the liver, alveolar macrophages in the lung, mesangial cells in the kidney, and microglial cells in the brain. Macrophages, like neutrophils, are capable of phagocytosis and killing of microorganisms but also play an important role in the amplification and regulation of the inflammatory response (Box 4.1). They are particularly important in tissue surveillance, monitoring their immediate surroundings for signs of tissue damage or invading organisms.

Dendritic cells

Dendritic cells are specialised antigen-presenting cells which are prevalent in tissues in contact with the external environment, such as the skin and mucosa. They can also be found in an immature state in the blood. They sample the environment for foreign particles, and once activated, carry microbial antigens to regional lymph nodes, where they interact with T cells and B cells to initiate and shape the adaptive immune response.

Cytokines

Cytokines are small soluble proteins that act as multipurpose chemical messengers. Examples are listed in Box 4.2. They are produced by cells involved in immune responses and by stromal tissue. More than 100 cytokines have been described, with overlapping, complex roles in intercellular communication. Their clinical importance is demonstrated by the efficacy of 'biological' therapies (often abbreviated to 'biologics') that target specific cytokines (pp. 1102 and 18).

4.2 Some roles for cytokines in regulating the immune response

Cytokine	Source	Actions
Interferon-alpha (IFN-α)	T cells and macrophages	Antiviral activity Activates NK cells, $CD8^+$ T cells and macrophages
Interferon-gamma (IFN-γ)	T cells and NK cells	Increases antimicrobial and antitumour activity of macrophages Regulates cytokine production by T cells and macrophages
Tumour necrosis factor alpha (TNF-α)	Macrophages and NK cells	Pro-inflammatory Increases apoptosis and expression of cytokines and adhesion molecules Directly cytotoxic
Interleukin-1 (IL-1)	Macrophages and neutrophils	Acute phase reactant Stimulates neutrophil recruitment, fever, T-cell and macrophage activation, and immunoglobulin production
Interleukin-2 (IL-2)	T cells	Stimulates proliferation and differentiation of antigen-specific T lymphocytes
Interleukin-4 (IL-4)	$CD4^+$ T cells and mast cells	Stimulates maturation of B and T cells, and production of IgE antibody
Interleukin-6 (IL-6)	Monocytes and macrophages	Acute phase reactant Stimulates maturation of B cells into plasma cells
Interleukin-12 (IL-12)	Monocytes and macrophages	Stimulates IFN-γ and TNF-α release by T cells, activates NK cells

(NK = natural killer)

Complement

The complement system is a group of more than 20 tightly regulated, functionally linked proteins that act to promote inflammation and eliminate invading pathogens. Complement proteins are produced in the liver and are present in the circulation as inactive molecules. When triggered, they enzymatically activate other proteins in a rapidly amplified biological cascade analogous to the coagulation cascade (p. 995).

There are three mechanisms by which the complement cascade may be triggered (Fig. 4.3):

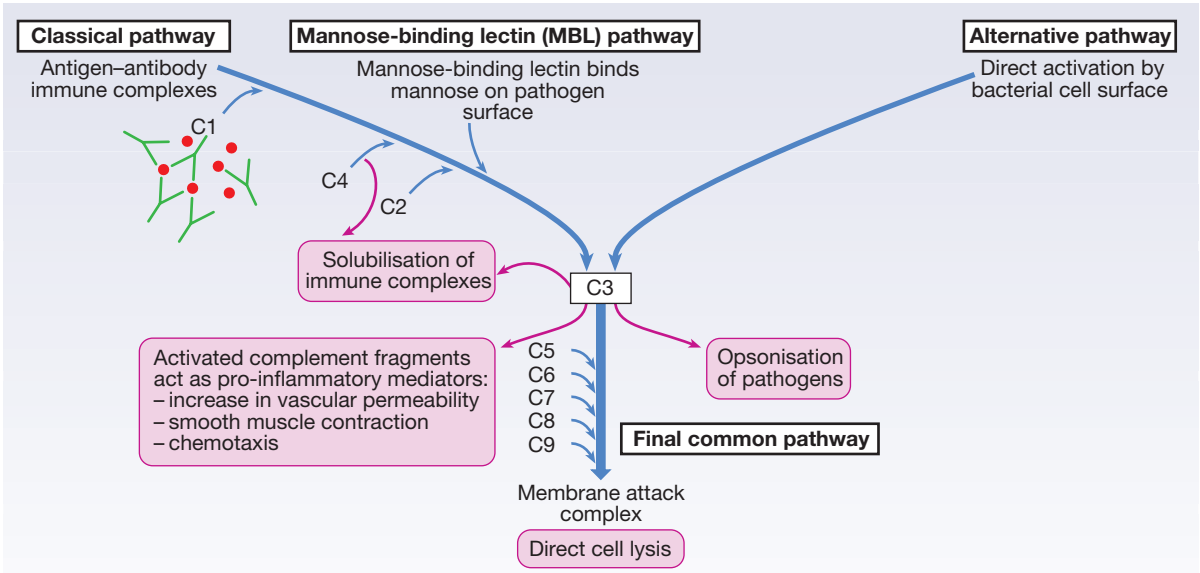

Fig. 4.3 The complement pathway. The activation of C3 is central to complement activation.

- *The alternative pathway* is triggered directly by binding of C3 to bacterial cell wall components, such as lipopolysaccharide of Gram-negative bacteria and teichoic acid of Gram-positive bacteria.
- *The classical pathway* is initiated when two or more IgM or IgG antibody molecules bind to antigen, forming immune complexes. The associated conformational change exposes binding sites on the antibodies for C1. C1 is a multiheaded molecule which can bind up to six antibody molecules. Once two or more 'heads' of a C1 molecule are bound to antibody, the classical cascade is triggered.
- *The lectin pathway* is activated by the direct binding of mannose-binding lectin to microbial cell surface carbohydrates. This mimics the binding of C1 to immune complexes and directly stimulates the classical pathway.

Activation of complement by any of these pathways results in activation of C3. This, in turn, activates the final common pathway, in which the complement proteins C5–C9 assemble to form the membrane attack complex. This can puncture target cell walls, leading to osmotic cell lysis. This step is particularly important in the defence against encapsulated bacteria, such as *Neisseria* spp. and *Haemophilus influenzae*. Complement fragments generated by activation of the cascade can also act as opsonins, rendering microorganisms more susceptible to phagocytosis by macrophages and neutrophils (see Fig. 4.1). In addition, they are chemotactic agents, promoting leucocyte trafficking to sites of inflammation. Some fragments act as anaphylotoxins, binding to complement receptors on mast cells and triggering release of histamine, which increases vascular permeability. The products of complement activation also help to target immune complexes to antigen-presenting cells, providing a link between the innate and the acquired immune systems. Finally, activated complement products dissolve the immune complexes that triggered the cascade, minimising bystander damage to surrounding tissues.

Mast cells and basophils

Mast cells and basophils are bone marrow-derived cells which play a central role in allergic disorders. Mast cells reside predominantly in tissues exposed to the external environment, such as the skin and gut, while basophils are located in the circulation and are recruited into tissues in response to inflammation. Both contain large cytoplasmic granules which contain preformed vasoactive substances such as histamine (see Fig. 4.9, p. 89). Mast cells and basophils express IgE receptors on their cell surface (see Fig. 4.5). On encounter with specific antigen, the cell is triggered to release preformed mediators and synthesise additional mediators, including leukotrienes, prostaglandins and cytokines. These trigger an inflammatory cascade which increases local blood flow and vascular permeability, stimulates smooth muscle contraction, and increases secretion at mucosal surfaces.

Natural killer cells

Natural killer (NK) cells are large granular lymphocytes which play a major role in defence against tumours and viruses. They exhibit features of both the adaptive and innate immune systems: they are morphologically similar to lymphocytes and recognise similar ligands, but they are not antigen-specific and cannot generate immunological memory.

NK cells express a variety of cell surface receptors. Some recognise stress signals, while others recognise the absence of human leucocyte antigen (HLA) molecules on cell surfaces (down-regulation of HLA molecules by viruses and tumour cells is an important mechanism by which they evade T lymphocytes). NK cells can also be activated by binding of antigen–antibody complexes to surface receptors. This physically links the NK cell to its target in a manner analogous to opsonisation, and is known as antibody-dependent cellular cytotoxicity (ADCC).

Activated NK cells can kill their targets in various ways. Pore-forming proteins, such as perforin, induce

direct cell lysis, while granzymes are proteolytic enzymes which stimulate apoptosis. In addition, NK cells produce a variety of cytokines, such as tumour necrosis factor (TNF)-α and interferon-γ (IFN-γ), which have direct antiviral and antitumour effects.

The adaptive immune system

If the innate immune system fails to provide effective protection against an invading pathogen, the adaptive immune system (Fig. 4.4) is mobilised. This has three key characteristics:

- It has exquisite specificity and is able to discriminate between very small differences in molecular structure.
- It is highly adaptive and can respond to an unlimited number of molecules.
- It possesses immunological memory, such that subsequent encounters with a particular antigen produce a more effective immune response than the first encounter.

There are two major arms of the adaptive immune response: humoral immunity involves antibodies produced by B lymphocytes; cellular immunity is mediated by T lymphocytes, which release cytokines and kill immune targets. These interact closely with each other and with the innate immune system, to maximise the effectiveness of the response.

Lymphoid organs

- *Primary lymphoid organs*. The primary lymphoid organs are involved in lymphocyte development. They include the bone marrow, where both T and B lymphocytes are derived from haematopoietic stem cells (p. 993) and where B lymphocytes also mature, and the thymus, where T lymphocytes mature.
- *Secondary lymphoid organs*. After maturation, lymphocytes migrate to the secondary lymphoid organs. These include the spleen, lymph nodes and mucosa-associated lymphoid tissue. These organs trap and concentrate foreign substances, and are the major sites of interaction between naïve lymphocytes and microorganisms.

The thymus

The thymus is a bilobed structure organised into cortical and medullary areas. The cortex is densely populated with immature T cells, which migrate to the medulla to undergo selection and maturation. The thymus is most active in the fetal and neonatal period, and involutes after puberty. Failure of thymic development is associated with profound T-cell immune deficiency (p. 80), but surgical removal of the thymus in childhood (usually in the context of major cardiac surgery) is not associated with significant immune dysfunction.

The spleen

The spleen is the largest of the secondary lymphoid organs. It is highly effective at filtering blood and is an important site of phagocytosis of senescent erythrocytes, bacteria, immune complexes and other debris. It is also a major site of antibody synthesis. It is particularly important for defence against encapsulated bacteria, and asplenic individuals are at risk of overwhelming

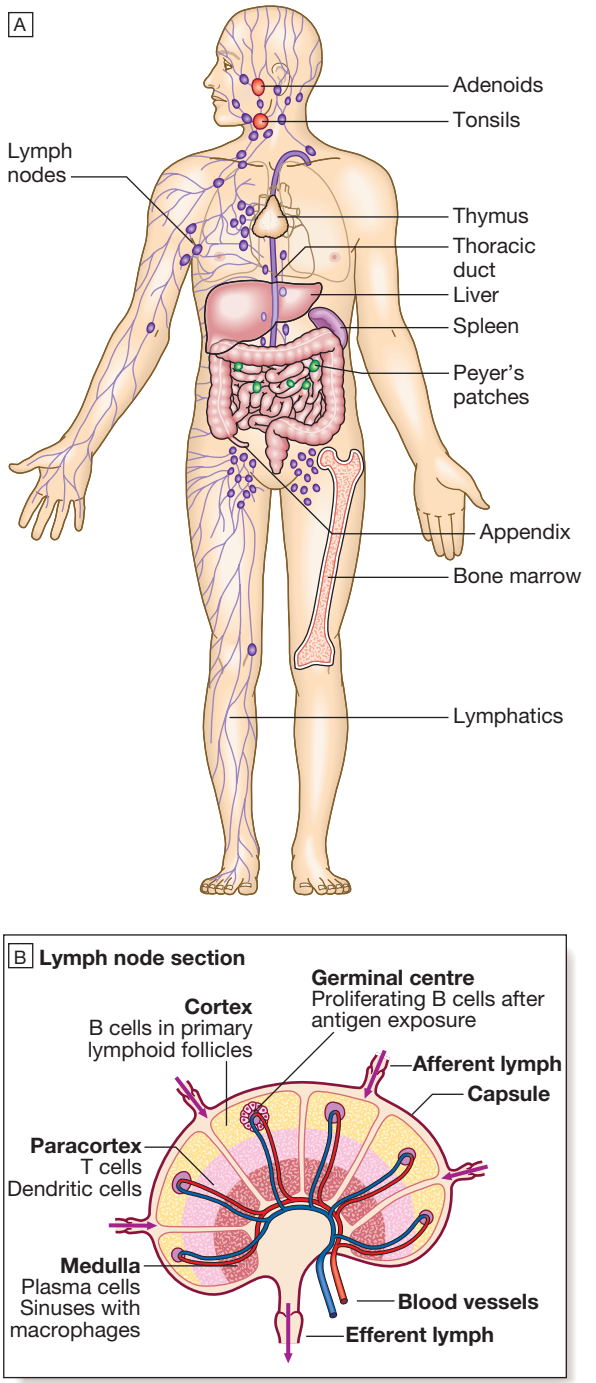

Fig. 4.4 Anatomy of the adaptive immune system.
A Macroanatomy B Anatomy of a lymph node.

Streptococcus pneumoniae and *H. influenzae* infection (see Box 24.40, p. 1028).

Lymph nodes and mucosa-associated lymphoid tissue

Lymph nodes are positioned to maximise exposure to lymph draining from sites of external contact. Their structure is highly organised, as shown in Figure 4.4B.

More diffuse unencapsulated lymphoid cells and follicles are also present on mucosal surfaces: for example, in Peyer's patches in the small intestine.

Lymphatics

Lymphoid tissues are physically connected by a network of lymphatics, which has three major functions: it provides access to lymph nodes, returns interstitial fluid to the venous system, and transports fat from the small intestine to the blood stream (see Fig. 16.14, p. 452). The lymphatics begin as blind-ending capillaries, which come together to form lymphatic ducts. These enter and then leave regional lymph nodes as afferent and efferent ducts respectively. They eventually coalesce and drain into the thoracic duct and thence into the left subclavian vein. Lymphatics may be either deep or superficial, and, in general, follow the distribution of major blood vessels.

Humoral immunity

B lymphocytes

These specialised cells arise in the bone marrow. Mature B lymphocytes (also known as B cells) are found in bone marrow, lymphoid tissue, spleen and, to a lesser extent, the blood stream. They express a unique immunoglobulin receptor on their cell surface (the B-cell receptor), which binds to soluble antigen. Encounters with antigen usually occur within lymph nodes, where, if provided with appropriate signals from nearby T lymphocytes, stimulated antigen-specific B cells respond by proliferating rapidly in a process known as clonal expansion. This is accompanied by a highly complex series of genetic rearrangements, which generates B-cell populations that express receptors with greater affinity for antigen than the original. These cells differentiate into either long-lived memory cells, which reside in the lymph nodes, or plasma cells, which produce antibody.

Immunoglobulins

Immunoglobulins (Ig) are soluble proteins made up of two heavy and two light chains (Fig. 4.5). The heavy chain determines the antibody class or isotype, i.e. IgG, IgA, IgM, IgE or IgD. Subclasses of IgG and IgA also occur. The antigen is recognised by the antigen-binding regions (F_{ab}) of both heavy and light chains, while the consequences of antibody-binding are determined by the constant region of the heavy chain (F_c) (Box 4.3).

Antibodies can initiate a number of different actions. They facilitate phagocytosis by acting as opsonins (see Fig. 4.1), and can also facilitate cell killing by cytotoxic cells (ADCC, p. 75). Binding of antibodies to antigen can trigger activation of the classical complement pathway (see Fig. 4.3). In addition, antibodies may act directly to neutralise the biological activity of toxins. This is a particularly important feature of IgA antibodies, which act predominantly at mucosal surfaces.

The humoral immune response is characterised by immunological memory: that is, the antibody response to successive exposures to antigen is qualitatively and quantitatively different from that on first exposure. When a previously unstimulated (naïve) B lymphocyte is activated by antigen, the first antibody to be produced is IgM, which appears in the serum after 5–10 days. Depending on additional stimuli provided by T lymphocytes, other antibody classes (IgG, IgA and IgE) are produced 1–2 weeks later. If, some time later, a memory B cell is re-exposed to antigen, the lag time between antigen exposure and the production of antibody is decreased (to 2–3 days), the amount of antibody produced is increased, and the response is dominated by IgG antibodies of high affinity. Furthermore, in contrast

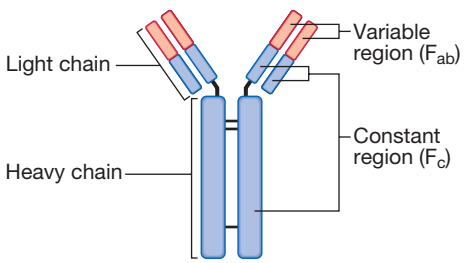

Fig. 4.5 The structure of an immunoglobulin (antibody) molecule.

4.3 Classes and properties of antibody

Antibody/properties	Concentration in adult serum	Complement activation*	Opsonisation
IgG 4 subclasses: IgG1, IgG2, IgG3, IgG4 Distributed equally between blood and extracellular fluid, and transported across placenta IgG2 is the predominant antibody produced against polysaccharides	8.0–16.0 g/L	IgG1 +++ IgG2 + IgG3 +++	IgG1 ++ IgG3 ++
IgA 2 subclasses: IgA1, IgA2 Highly effective at neutralising toxins Particularly important at mucosal surfaces	1.5–4.0 g/L	–	–
IgM Highly effective at agglutinating pathogens	0.5–2.0 g/L	++++	–
IgE Mostly bound to mast cells, basophils and eosinophils Important in allergic disease and defence against parasite infection	0.003–0.04 g/L	–	–
IgD Function unknown	Not detected	–	–

*Refers to activation of the classical complement pathway, also called 'complement fixation'.

to the initial antibody response, secondary antibody responses do not require additional input from T lymphocytes. This allows the rapid generation of highly specific responses on pathogen re-exposure.

Cellular immunity

T lymphocytes (also known as T cells) mediate cellular immunity and are important for defence against viruses, fungi and intracellular bacteria. They also play an important immunoregulatory role, orchestrating and regulating the responses of other components of the immune system. T-lymphocyte precursors arise in bone marrow and are exported to the thymus while still immature (see Fig. 4.6 below). Within the thymus, each cell expresses a T-cell receptor with a unique specificity. These cells undergo a process of stringent selection to ensure that autoreactive T cells are deleted. Mature T lymphocytes leave the thymus and expand to populate other organs of the immune system. It has been estimated that an individual possesses 10^7–10^9 T-cell clones, each with a unique T-cell receptor, ensuring at least partial coverage for any antigen encountered.

T cells respond to protein antigens, but they cannot recognise these in their native form. Instead, intact protein must be processed into component peptides which bind to a structural framework on the cell surface known as HLA (human leucocyte antigen). This process is known as antigen processing and presentation, and it is the peptide/HLA complex which is recognised by individual T cells. While all nucleated cells have the capacity to process and present antigens, specialised antigen-presenting cells include dendritic cells, macrophages and B lymphocytes. HLA molecules exhibit extreme polymorphism; as each HLA molecule has the capacity to present a subtly different peptide repertoire to T lymphocytes, this ensures enormous diversity in recognition of antigens within the population.

T lymphocytes can be segregated into two subgroups on the basis of function and recognition of HLA molecules. These are designated $CD4^+$ and $CD8^+$ T cells, according to the 'cluster of differentiation' (CD) antigen expressed on their cell surface. $CD8^+$ T cells recognise antigenic peptides in association with HLA class I molecules (HLA-A, HLA-B, HLA-C). They kill infected cells directly through the production of pore-forming molecules such as perforin, or by triggering apoptosis of the target cell, and are particularly important in defence against viral infection. $CD4^+$ T cells recognise peptides presented on HLA class II molecules (HLA-DR, HLA-DP and HLA-DQ) and have mainly immunoregulatory functions. They produce cytokines and provide co-stimulatory signals that support the activation of $CD8^+$ T lymphocytes and assist the production of mature antibody by B cells. In addition, their close interaction with phagocytes determines cytokine production by both cell types.

$CD4^+$ lymphocytes can be further subdivided into subsets on the basis of the cytokines they produce:

- Typically, Th1 cells produce IL-2, IFN-γ and TNF-α, and support the development of delayed type hypersensitivity responses (p. 87).
- Th2 cells typically secrete IL-4, IL-5 and IL-10, and promote allergic responses (p. 89).
- A further subset of specialised $CD4^+$ lymphocytes known as regulatory cells are important in immune regulation of other cells and the prevention of autoimmune disease.

IMMUNE DEFICIENCY

The consequences of deficiencies of the immune system include recurrent infections, autoimmunity and susceptibility to malignancy. Immune deficiency may arise through intrinsic defects in immune function, but is much more commonly due to secondary causes, including infection, drug therapy, malignancy and ageing. This chapter gives an overview of the rare primary immune deficiencies. More than a hundred genetically determined deficiencies have been described, most of which present in childhood or adolescence. The clinical manifestations are dictated by the component of the immune system involved (Box 4.4), but there is considerable overlap and redundancy in the immune

4.4 Immune deficiencies and common patterns of infection

	Phagocyte deficiency	Complement deficiency	T-lymphocyte deficiency	Antibody deficiency
Bacteria	*Staphylococcus aureus* *Pseudomonas aeruginosa* *Serratia marcescens* *Burkholderia cenocepacia* *Mycobacterium tuberculosis* Atypical mycobacteria	*Neisseria meningitidis* *Neisseria gonorrhoeae* *Haemophilus influenzae* *Streptococcus pneumoniae*	*Mycobacterium tuberculosis* Atypical mycobacteria	*Haemophilus influenzae* *Streptococcus pneumoniae* *Staphylococcus aureus*
Fungi	*Candida* spp. *Aspergillus* spp.		*Candida* spp. *Aspergillus* spp. *Pneumocystis jirovecii*	
Viruses			Cytomegalovirus (CMV) Enteroviruses Epstein–Barr virus (EBV) Herpes zoster	
Protozoa			*Toxoplasma gondii* Cryptosporidia	*Giardia lamblia*

4.5 Warning signs of primary immune deficiency*

The presence of ≥ 2 warning signs may indicate an underlying primary immunodeficiency:

- ≥ 4 new ear infections within 1 yr
- ≥ 2 serious sinus infections within 1 yr
- ≥ 2 mths on antibiotics with little effect
- ≥ 2 pneumonias within 1 yr
- Failure of an infant to gain weight or grow normally
- Recurrent, deep skin or organ abscesses
- Persistent thrush in mouth or fungal infection on skin
- Need for intravenous antibiotics to clear infections
- ≥ 2 deep-seated infections, including septicaemia
- A family history of primary immune deficiency

*Developed by the Jeffrey Modell Foundation (www.info4pi.org/).

network so some diseases do not fall easily into this classification.

Presenting problems in immune deficiency

Recurrent infections

Most patients with an immune deficiency present with recurrent infections. While there is no accepted definition of 'too many' infections, features that may indicate immune deficiency are shown in Box 4.5. Frequent, severe infections or infections caused by unusual organisms or at unusual sites are the most useful indicator.

Baseline investigations include full blood count with white cell differential, acute phase reactants (CRP, see below), renal and liver function tests, urine dipstick, serum immunoglobulins with protein electrophoresis, and total IgE level. Additional microbiological, virological and radiological tests may be appropriate. At this stage, it may be clear which category of immune deficiency should be considered, and specific investigation can be undertaken, as described below.

If an immune deficiency is suspected but has not yet been formally characterised, patients should not receive live vaccines because of the risk of vaccine-induced disease. Discussion with specialists will help determine whether additional preventative measures, such as prophylactic antibiotics, are indicated.

Primary phagocyte deficiencies

Primary phagocyte deficiencies (see Fig. 4.2, p. 73) usually present with recurrent bacterial and fungal infections which may affect unusual sites. Aggressive management of existing infections, including intravenous antibiotics and surgical drainage of abscesses, and long-term prophylaxis with antibacterial and antifungal agents, is required. Specific treatment depends upon the nature of the defect; haematopoietic stem cell transplantation may be considered (p. 1017).

Leucocyte adhesion deficiencies

These are rare disorders of phagocyte migration, when failure to express adhesion molecules on the surface of leucocytes results in their inability to exit the blood stream. They are characterised by recurrent bacterial infections with high blood neutrophil counts but sites of infection lack pus or other evidence of neutrophil infiltration.

Chronic granulomatous disease

This is caused by mutations in the genes encoding the NADPH oxidase enzymes, which results in failure of oxidative killing. The defect leads to susceptibility to catalase-positive organisms, such as *Staphylococcus aureus*, *Burkholderia cenocepacia* and *Aspergillus*. Intracellular killing of mycobacteria is also impaired. Infections most commonly involve the lungs, lymph nodes, soft tissues, bone, skin and urinary tract, and are characterised histologically by granuloma formation.

Defects in cytokines and cytokine receptors

Defects of cytokines such as IFN-γ, IL-12 or their receptors also result in failure of intracellular killing, with particular susceptibility to mycobacterial infections.

Complement pathway deficiencies

Genetic deficiencies of almost all the complement pathway proteins (see Fig. 4.3, p. 75) have been described. Many present with recurrent infection with encapsulated bacteria, particularly *Neisseria* species, reflecting the importance of the membrane attack complex in defence against these bacteria. In addition, genetic deficiencies of the classical complement pathway (C1, C2 and C4) are associated with a high prevalence of autoimmune disease, particularly systemic lupus erythematosus (SLE, p. 1109).

In contrast to other complement deficiencies, mannose-binding lectin deficiency is very common (5% of the northern European population). Complete deficiency may predispose to bacterial infections in the presence of an additional cause of immune compromise, such as premature birth or chemotherapy, but is otherwise well tolerated. Deficiency of the complement regulatory protein Cl inhibitor is not associated with recurrent infections but causes recurrent angioedema (p. 93).

Investigations and management

Complement C3 and C4 are the only complement components that are routinely measured. Screening for complement deficiencies is performed using more specialised functional tests of complement-mediated haemolysis, known as CH50 and AP50 (classical haemolytic pathway 50 and alternative pathway 50). If abnormal, these haemolytic tests should be followed by measurement of individual complement components.

There is no definitive treatment for complement deficiencies. Patients should be vaccinated with meningococcal, pneumococcal and *H. influenzae* B vaccines in order to boost their adaptive immune responses. Lifelong prophylactic penicillin to prevent meningococcal infection is recommended. At-risk family members should also be screened.

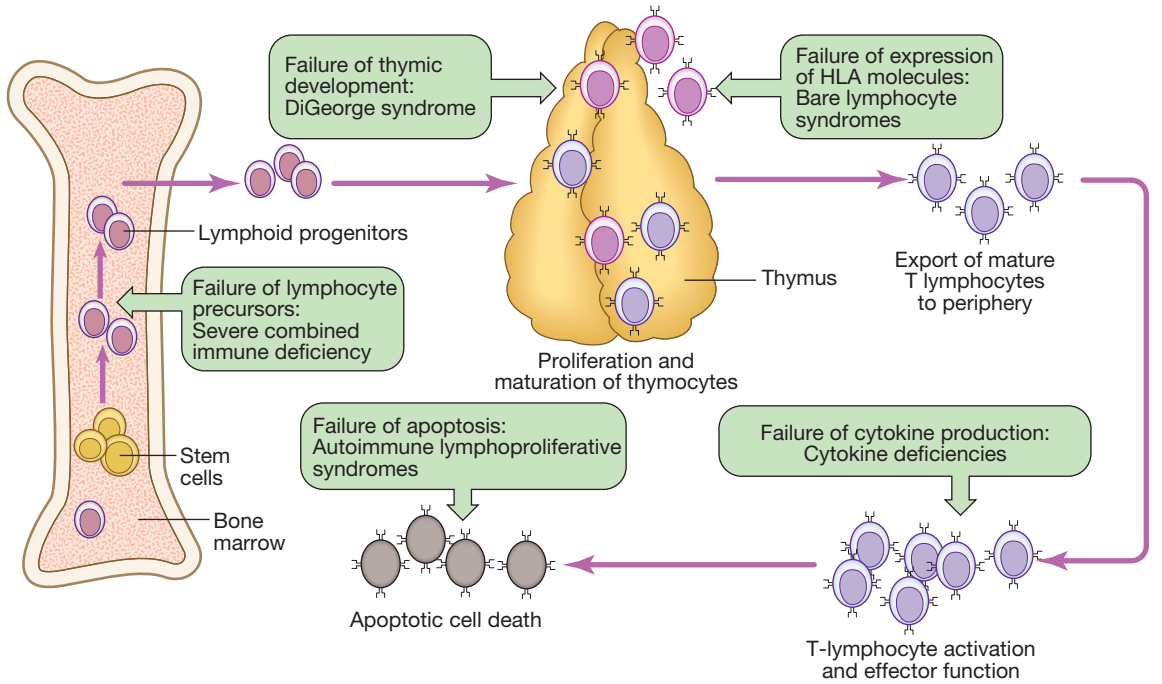

Fig. 4.6 T-lymphocyte function and dysfunction (green boxes).

Primary deficiencies of the adaptive immune system

Primary T-lymphocyte deficiencies

These are characterised by recurrent viral, protozoal and fungal infections (see Box 4.4). In addition, many T-cell deficiencies are associated with defective antibody production because of the importance of T cells in regulating B cells. These disorders generally present in childhood and are illustrated in Figure 4.6.

DiGeorge syndrome

This results from failure of development of the 3rd/4th pharyngeal pouch, usually caused by a deletion of 22q11. It is associated with multiple abnormalities, including congenital heart disease, hypocalcaemia, tracheo-oesophageal fistulae, cleft lip and palate, and absent thymic development. The immune deficiency is characterised by very low numbers of circulating T cells, despite normal development in the bone marrow.

Bare lymphocyte syndromes

These are caused by absent expression of HLA molecules within the thymus. If HLA class I molecules are affected, $CD8^+$ lymphocytes fail to develop, while absent expression of HLA class II molecules affects $CD4^+$ lymphocyte maturation. In addition to recurrent infections, failure to express HLA class I is associated with systemic vasculitis caused by uncontrolled activation of NK cells.

Autoimmune lymphoproliferative syndrome

This is caused by failure of normal lymphocyte apoptosis (p. 50), leading to non-malignant accumulation of autoreactive cells. This results in lymphadenopathy, splenomegaly and a variety of autoimmune diseases.

Investigations and management

The principal tests for T-lymphocyte deficiencies are a total blood lymphocyte count and quantitation of lymphocyte subpopulations by flow cytometry. Serum immunoglobulins should also be measured. Second-line, functional tests of T-cell activation and proliferation may be indicated. Patients in whom T-lymphocyte deficiencies are suspected should be tested for human immunodeficiency (HIV) infection (p. 392).

Anti-*Pneumocystis* and antifungal prophylaxis, and aggressive management of infections, are required. Immunoglobulin replacement may be indicated if antibody production is impaired. Haematopoietic stem cell transplantation (HSCT, p. 1017) may be appropriate.

Combined B- and T-lymphocyte immune deficiencies

Severe combined immune deficiency (SCID) is caused by defects in lymphoid precursors and results in combined failure of B- and T-cell maturation. The absence of an effective adaptive immune response causes recurrent bacterial, fungal and viral infections soon after birth. HSCT (p. 1017) is the only current treatment, although gene therapy is under investigation.

Primary antibody deficiencies

Primary antibody deficiencies (Fig. 4.7) are characterised by recurrent bacterial infections, particularly of the respiratory and gastrointestinal tract. The most common causative organisms are encapsulated bacteria, such as *Strep. pneumoniae* and *H. influenzae*. These disorders may present in infancy, when the protective benefit of transferred maternal immunoglobulin has waned. However, three forms of primary antibody deficiency can also present in adulthood:

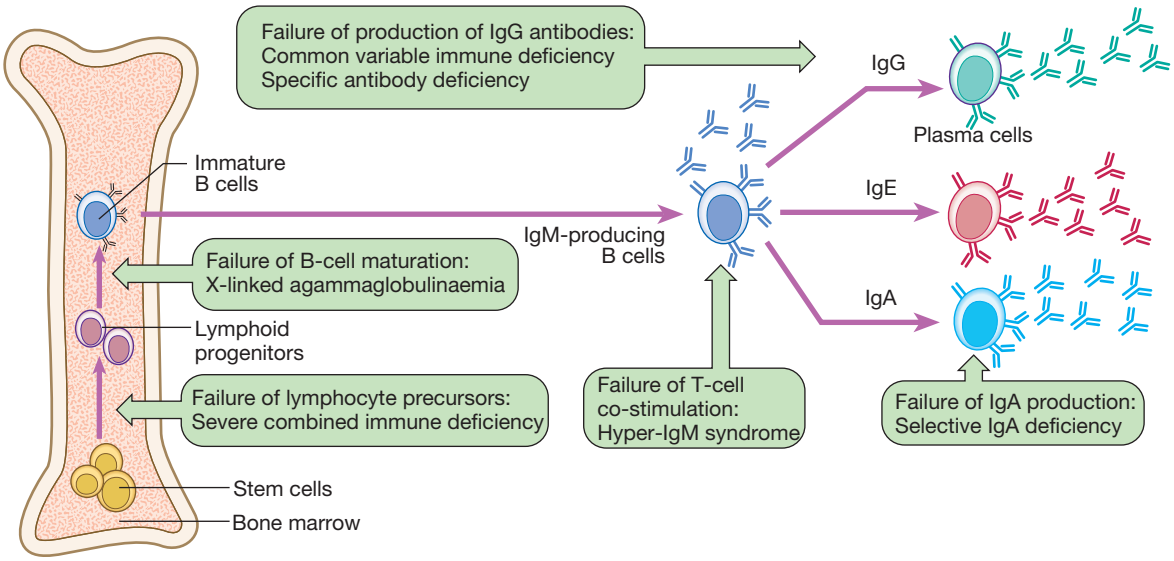

Fig. 4.7 B lymphocytes and primary antibody deficiencies (green boxes).

4.6 Investigation of primary antibody deficiencies

	Serum immunoglobulin concentrations				Blood cell count		
	IgM	IgG	IgA	IgE	B cells	T cells	Test immunisation
Selective IgA deficiency	Normal	Often elevated	Absent	Normal	Normal	Normal	
Common variable immune deficiency	Normal or low	Low	Low or absent	Low or absent	Variable	Variable	No antibody response
Specific antibody deficiency	Normal	Normal	Normal	Normal	Normal	Normal	No antibody response to polysaccharide antigens

- *Selective IgA deficiency* is the most common primary immune deficiency, affecting 1:600 northern Europeans. In most patients, low (< 0.05 g/L) or undetectable IgA is an incidental finding with no clinical sequelae. However, 30% of individuals experience recurrent mild respiratory and gastrointestinal infections. In some patients, there is a compensatory increase in serum IgG levels. Specific treatment is generally not required.
- *Common variable immune deficiency (CVID)* is a heterogeneous primary immune deficiency of unknown cause. It is characterised by low serum IgG levels and failure to make antibody responses to exogenous pathogens. Paradoxically, antibody-mediated autoimmune diseases, such as autoimmune haemolytic anaemia, are common. CVID is also associated with an increased risk of malignancy, particularly lymphoproliferative disease.
- *Specific antibody deficiency or functional IgG antibody deficiency* is a poorly characterised condition which causes defective antibody responses to polysaccharide antigens. Some patients are deficient in antibody subclasses IgG2 and IgG4, and this condition was previously called IgG subclass deficiency.

There is overlap between specific antibody deficiency, IgA deficiency and CVID, and some patients may progress to a more global antibody deficiency over time.

Investigations

Investigations include serum immunoglobulins (Box 4.6), with protein and urine electrophoresis to exclude secondary causes of hypogammaglobulinaemia, and B and T lymphocyte counts in blood by flow cytometry. Specific antibody responses to known pathogens can be assessed by measuring IgG antibodies against tetanus, *H. influenzae* and *Strep. pneumoniae* (most patients will have been exposed to these antigens through infection or immunisation). If specific antibody levels are low, immunisation with the appropriate killed vaccine should be followed by repeat antibody measurement 6–8 weeks later; failure to mount a response indicates a defect in antibody production. These functional tests have superseded IgG subclass quantitation.

Management

With the exception of individuals with selective IgA deficiency, patients with antibody deficiencies require aggressive treatment of infections, and prophylactic antibiotics may be indicated. The mainstay of treatment is life-long immunoglobulin replacement therapy. This

is derived from pooled plasma (p. 1011) and contains IgG antibodies to a wide variety of common organisms. Immunoglobulin replacement may be administered either intravenously or subcutaneously, often by the patient, with the aim of maintaining trough IgG levels within the normal range. Immunisation is generally not effective because of the defect in IgG antibody production. As with all primary immune deficiencies, live vaccines should be avoided (p. 148).

Secondary immune deficiencies

Secondary immune deficiencies are much more common than primary immune deficiencies (Box 4.7). Common causes include infections, such as HIV and measles, and cytotoxic and immunosuppressive drugs, particularly those used in the management of transplantation, autoimmunity and cancer. Physiological immune deficiency occurs at the extremes of life; the decline of the immune response in the elderly is known as immune senescence (Box 4.8). Management of secondary immune deficiency is described in the relevant chapters on infectious diseases (Ch. 13), HIV (Ch. 14), oncology (Ch. 11) and haematological disorders (Ch. 24).

4.7 Causes of secondary immune deficiency

Physiological	
• Ageing • Prematurity	• Pregnancy
Infection	
• HIV • Measles	• Mycobacterial infection
Iatrogenic	
• Immunosuppressive therapy • Antineoplastic agents • Corticosteroids	• Stem cell transplantation • Radiation injury • Some anti-epileptic agents
Malignancy	
• B-cell malignancies including leukaemia, lymphoma and myeloma	• Solid tumours • Thymoma
Biochemical and nutritional disorders	
• Malnutrition • Renal insufficiency/dialysis • Diabetes mellitus	• Specific mineral deficiencies, e.g. iron, zinc
Other conditions	
• Burns	• Asplenia/hyposplenism

4.8 Ageing and immune senescence

- **T-cell responses**: decline, with reduced delayed type hypersensitivity responses.
- **Antibody production**: decreased for many exogenous antigens. Although autoantibodies are frequently detected, autoimmune disease is less common.
- **Response to vaccination**: reduced, e.g. 30% of healthy older people may not develop protective immunity after influenza vaccination.
- **Allergic disorders and transplant rejection**: less common.
- **Susceptibility to infection**: increased, e.g. community-acquired pneumonia by threefold and urinary tract infection by 20-fold. Latent infections, including tuberculosis and herpes zoster, may be reactivated.
- **Manifestations of inflammation**: may be absent, e.g. lack of pyrexia or leucocytosis.

THE INFLAMMATORY RESPONSE

Inflammation is the response of tissues to injury or infection, and is necessary for normal repair and healing. This section focuses on the generic inflammatory response and its multisystem manifestations. The role of inflammation in specific diseases is illustrated in many other chapters of this book.

Physiology and pathology of inflammation

Acute inflammation

Acute inflammation is the result of rapid and complex interplay between the cells and soluble molecules of the innate immune system. The classical external signs include heat, redness, pain and swelling (calor, rubor, dolor and oedema, Fig. 4.8).

The inflammatory process is initiated by local tissue injury or infection. Damaged epithelial cells produce cytokines and antimicrobial peptides, causing early infiltration of phagocytic cells. As a result, there is production of leukotrienes, prostaglandins, histamine, kinins, anaphylotoxins and inducible nitric oxide synthase within inflamed tissue. The effect is vasodilatation and increased local vascular permeability, which increases trafficking of fluid and cells to the affected tissue. In addition, pro-inflammatory cytokines produced at the site of injury have profound systemic effects. IL-1, TNF-α and IL-6 act on the hypothalamus to raise the temperature set-point, causing fever, and also stimulate the production of acute phase proteins.

Acute phase proteins

Acute phase proteins are produced by the liver in response to inflammatory stimuli and have a wide range of activities. CRP and serum amyloid A may be increased 1000-fold, contributing to host defence and stimulating repair and regeneration. Fibrinogen plays an essential role in wound healing, and α_1-antitrypsin and α_1-antichymotrypsin control the pro-inflammatory cascade by neutralising the enzymes produced by activated neutrophils, preventing widespread tissue destruction. In addition, antioxidants, such as haptoglobin and manganese superoxide dismutase, scavenge for oxygen free radicals, while increased levels of iron-binding proteins, such as ferritin and lactoferrin, decrease the iron available for uptake by bacteria (p. 1023). Immunoglobulins are not acute phase proteins but are often increased in chronic inflammation.

Resolution of inflammation

Resolution of an inflammatory response is crucial for normal healing. This involves active down-modulation

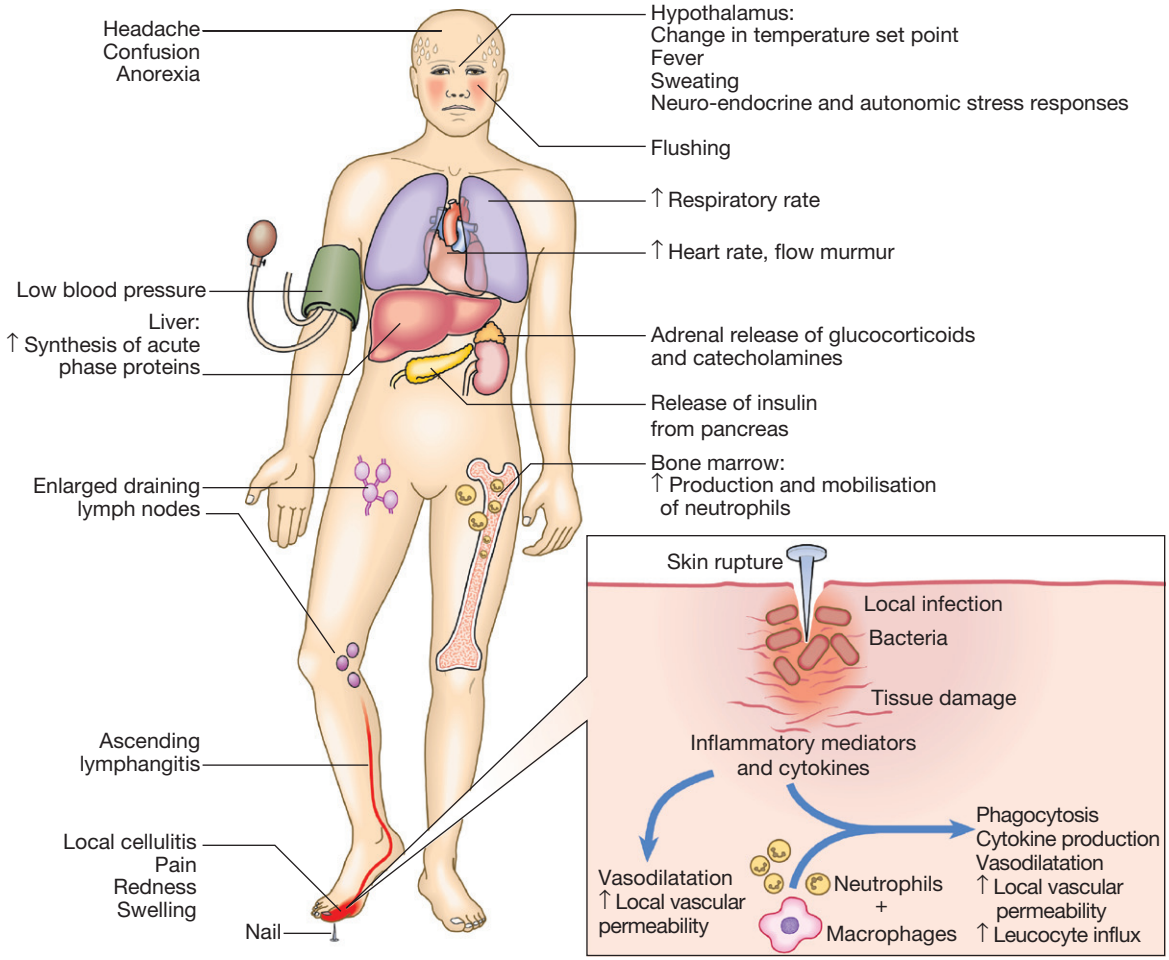

Fig. 4.8 Clinical features of acute inflammation. In this example, the response is to a penetrating injury and infection of the foot.

of inflammatory stimuli and repair of bystander damage to local tissues. Extravasated neutrophils undergo apoptosis and are phagocytosed by macrophages, along with the remains of microorganisms. Macrophages also synthesise collagenase and elastase, which break down local connective tissue and remove debris. Macrophage-derived cytokines, including transforming growth factor (TGF)-β and platelet-derived growth factor, attract fibroblasts and promote synthesis of new collagen, while angiogenic factors stimulate new vessel formation.

Sepsis and septic shock

Septic shock is the clinical manifestation of overwhelming inflammation (p. 190). Failure of normal inhibitory mechanisms results in excessive production of pro-inflammatory cytokines by macrophages, causing hypotension, hypovolaemia, decreased perfusion and tissue oedema. In addition, uncontrolled neutrophil activation causes release of proteases and oxygen free radicals within blood vessels, damaging the vascular endothelium and further increasing capillary permeability. Direct activation of the coagulation pathway combines with endothelial cell disruption to form clots within the damaged vessels. The clinical consequences include cardiovascular collapse, acute respiratory distress syndrome, disseminated intravascular coagulation, multi-organ failure and often death. Septic shock most frequently results from infection with Gram-negative bacteria, because lipopolysaccharide is particularly effective at activating the inflammatory cascade.

Chronic inflammation

In most instances, the development of an active immune response results in either clearance or control of the inflammatory stimulus with minimal local damage. Failure of elimination may result in chronic inflammation. Persisting microorganisms stimulate the ongoing accumulation of neutrophils, macrophages and activated T lymphocytes. If this is associated with local deposition of fibrous connective tissue, a granuloma may form. Granulomas are characteristic of infections such as tuberculosis and leprosy, in which the microorganism is protected by a robust cell wall which shields it from killing, despite phagocytosis.

Too vigorous or prolonged immune responses may cause bystander tissue damage, known as hypersensitivity responses. The Gell and Coombs classification of hypersensitivity disorders is discussed on page 87.

Investigations in inflammation

Changes associated with inflammation are reflected in many laboratory investigations. Leucocytosis is common,

and reflects the transit of activated neutrophils and monocytes to the site of infection. The platelet count may also be increased. The most widely used laboratory measure of acute inflammation is the C-reactive protein (see below). Plasma levels of many other acute phase reactants, including fibrinogen, ferritin and complement components, are increased in response to acute inflammation, while albumin levels are reduced. Chronic inflammation is frequently associated with a normocytic normochromic anaemia of chronic disease (p. 1023).

C-reactive protein

C-reactive protein (CRP) is an acute phase reactant synthesised by the liver, which opsonises invading pathogens. Levels of CRP increase within 6 hours of an inflammatory stimulus and may rise up to 1000-fold. Measurement of CRP provides a direct index of acute inflammation and, because the plasma half-life of CRP is 19 hours, levels fall promptly once the stimulus is removed. Sequential measurement is useful in monitoring disease (Box 4.9). For reasons that remain unclear, some diseases are associated with only minor elevations of CRP, despite unequivocal evidence of active inflammation. These include SLE, systemic sclerosis, ulcerative colitis and leukaemia. However, intercurrent infection does provoke a significant CRP response in these conditions.

Erythrocyte sedimentation rate

In contrast to the CRP, the erythrocyte sedimentation rate (ESR) is an indirect measure of inflammation. It measures how fast erythrocytes fall through anticoagulated blood, and is determined by a combination of the composition of plasma proteins and the morphology of circulating erythrocytes. These factors govern the propensity of red cells to aggregate, which is the major determinant of the ESR. Erythrocytes are inherently negatively charged, and this prevents them clumping together in the blood stream. Plasma proteins are positively charged and an increase in plasma proteins neutralises the surface charge of erythrocytes, overcoming their inherent repulsive forces and causing them to aggregate, or stack like tyres, forming rouleaux. Rouleaux have a higher mass/surface area ratio than single red cells, and therefore sediment faster.

The most common cause of an increased ESR is an acute phase response, which leads to an increase in the concentration of acute phase reactants, including CRP. However, other conditions that do not affect acute phase proteins may alter the composition and concentration of other plasma proteins (see Box 4.9). For example, immunoglobulins comprise a significant proportion of plasma proteins, but do not participate in the acute phase response. Thus, any condition that causes a monoclonal or polyclonal increase in serum immunoglobulins will increase the ESR without a corresponding rise in CRP. In addition, changes in erythrocyte surface area and density influence sedimentation, and abnormal red cell morphology can make rouleaux formation impossible. For these reasons, an inappropriately low ESR occurs in spherocytosis and sickle cell anaemia.

As CRP is a simple and sensitive early indicator of the acute phase response, it is increasingly used in preference to the ESR. If both ESR and CRP are used, any discrepancy should be resolved by assessing the individual determinants of the ESR, i.e. full blood count and blood film, serum immunoglobulins (IgG, IgA and IgM) and protein electrophoresis. The IgE concentration in

4.9 Conditions commonly associated with abnormal CRP and/or ESR

Condition	Consequence	Effect on CRP[1]	Effect on ESR[2]
Acute bacterial, fungal or viral infection	Acute phase response	Increased (range 50–150 mg/L; in severe infections may be > 300 mg/L)	Increased
Necrotising bacterial infection	Profound acute inflammatory response	Increased +++ (may be > 300 mg/L)	Increased
Acute inflammatory diseases, e.g. Crohn's disease, polymyalgia rheumatica	Acute phase response	Increased (range 50–150 mg/L)	Increased
Chronic bacterial or fungal infection, e.g. localised abscess, bacterial endocarditis or tuberculosis	Acute and chronic inflammatory response: increased acute phase proteins with polyclonal increase in immunoglobulins	Increased (range 50–150 mg/L)	Increase disproportionate to CRP
SLE, Sjögren's syndrome	Chronic inflammatory response with polyclonal increase in immunoglobulins	Normal (paradoxically)	Increased
Multiple myeloma	Monoclonal increase in immunoglobulin without acute inflammation	Normal	Increased
Pregnancy, old age, end-stage renal disease	Normal immunoglobulins but increased fibrinogen	Normal	Moderately increased

[1]Reference range < 10 mg/L.
[2]Reference range: adult males < 10 mm/hr, adult females < 20 mm/hr.

plasma is very low and does not contribute significantly to the ESR.

Plasma viscosity

Plasma viscosity is another surrogate measure of plasma protein concentration. Like the ESR, it is affected by the concentration of large plasma proteins, including fibrinogen and immunoglobulins. However, it is not affected by properties of erythrocytes and is generally considered to be more reliable than the ESR.

Presenting problems in inflammation

In most patients presenting with the manifestations of acute inflammation shown in Figure 4.8, it is possible to identify the source of the problem quickly and to assess the consequences, as discussed in other chapters. Systemic manifestations of inflammation include fever (p. 296), leucocytosis (p. 1005) and shock (p. 190).

Unexplained raised ESR

The ESR should not be used to screen asymptomatic patients for the presence of disease. However, in the era of frequent routine laboratory testing, an unexplained raised ESR is a common problem.

Clinical assessment

A comprehensive history and examination are crucial. Extreme elevations in the ESR (> 100 mm/hr) rarely occur in the absence of significant disease (see Box 4.9).

Investigations

Assessing the CRP, serum immunoglobulins and electrophoresis, and urine electrophoresis will help determine whether the elevation in ESR is due to an inflammatory process (see Box 4.9).

A full blood count and film may show a normocytic, normochromic anaemia, which occurs in many chronic diseases. Leucocytosis may reflect infection, inflammatory disease or tissue necrosis. Neutrophilia suggests infection or acute inflammation. Atypical lymphocytes may occur in some chronic infections, such as cytomegalovirus (CMV) and Epstein–Barr virus (EBV).

Abnormalities in liver function suggest either a local infective process (hepatitis, hepatic abscess or biliary sepsis) or systemic disease, including malignancy.

Blood and urine cultures should be performed. It may be relevant to measure antinuclear and antineutrophil cytoplasmic antibodies, and to exclude chronic infections, including HIV and syphilis.

In the unusual circumstances when ESR is elevated but both CRP and immunoglobulins are normal, fibrinogen should be measured. Elevated fibrinogen causes a higher ESR in older people, women, and patients with renal or heart failure, obesity and diabetes mellitus.

Imaging

If indicated by the clinical and laboratory features, a chest X-ray and abdominal computed tomography (CT) scan may identify a source of unknown infection or malignancy. An abdominal and pelvic ultrasound may identify hepatic lesions, abdominal nodes and local intra-abdominal or pelvic abscesses. Magnetic resonance imaging (MRI) is more appropriate for the diagnosis of soft tissue or bone/joint infections. Echocardiography is used to look for vegetations and assess valve function in suspected bacterial endocarditis. White cell scans are rarely indicated but may be useful in identifying the site of pyogenic infection. An isotope bone scan may provide evidence of malignancy or focal bone infection.

Periodic fever syndromes

These rare disorders are characterised by recurrent episodes of fever and systemic inflammation, associated with an elevated acute phase response.

Familial Mediterranean fever

Familial Mediterranean fever (FMF) is the most common of the familial periodic fevers, predominantly affecting Mediterranean people, including Arabs, Turks, Sephardic Jews and Armenians. It results from mutations of the *MEFV* gene, which encodes a protein called pyrin. Pyrin regulates neutrophil-mediated inflammation by indirectly suppressing the production of IL-1. FMF is characterised by recurrent painful attacks of fever associated with peritonitis, pleuritis and arthritis, which last for a few hours to 4 days and which are associated with markedly increased CRP levels. Symptoms resolve completely between episodes. The majority of individuals have their first attack before the age of 20 years. The major complication of FMF is AA amyloidosis (see below). Colchicine significantly reduces the number of febrile episodes in 90% of patients but is ineffective during acute attacks.

Mevalonate kinase deficiency

Mevalonate kinase deficiency (previously known as hyper-IgD syndrome, or HIDS) is an autosomal recessive disorder that causes recurrent attacks of fever, abdominal pain, diarrhoea, lymphadenopathy, arthralgia, skin lesions and aphthous ulceration. Most patients are from Western Europe, particularly the Netherlands and northern France. Mevalonate kinase is involved in the metabolism of cholesterol, but why mutations in its gene cause an inflammatory periodic fever remains unknown. Serum IgD and IgA levels are persistently elevated, and CRP levels are increased during acute attacks. Standard anti-inflammatory drugs (including colchicine and steroids) are ineffective.

TNF receptor-associated periodic syndrome

TNF receptor-associated periodic syndrome (TRAPS), also known as Hibernian fever, is an autosomal dominant syndrome, causing recurrent periodic fever, arthralgia, myalgia, serositis and rashes, which has been reported in many ethnic groups. Attacks may be prolonged (lasting over 1 week). During a typical attack, there is neutrophilia, increased CRP and elevated IgA levels. The diagnosis can be confirmed by low serum levels of the soluble type 1 TNF receptor and by analysis of the *TNFRSF1A* gene. As in FMF, the major complication is amyloidosis, and regular screening for proteinuria is advised. TRAPS responds to systemic corticosteroids and to biological therapies, including soluble TNF receptor therapy and IL-l receptor antagonists (p. 1102).

Amyloidosis

The amyloidoses are a group of acquired and hereditary disorders characterised by extracellular deposition of insoluble proteins (Box 4.10). These complex deposits consist of fibrils of the specific protein involved, linked to glycosaminoglycans, proteoglycans and serum amyloid P (SAP). Protein accumulation may be localised or systemic, and the clinical manifestations depend upon the organ(s) affected. The diagnosis of amyloidosis should be considered in all cases of unexplained nephrotic syndrome (p. 476), cardiomyopathy (p. 636) and peripheral neuropathy (p. 1223).

Diagnosis

The diagnosis is established by biopsy, which may be of an affected organ, rectum or subcutaneous fat. The pathognomonic histological feature is apple-green birefringence of amyloid deposits when stained with Congo red dye and viewed under polarised light. Immunohistochemical staining can identify the type of amyloid fibril present. Quantitative scintigraphy with radio-labelled SAP is a valuable tool in determining the overall load and distribution of amyloid deposits.

Management

The aims of treatment are to support the function of affected organs and, in acquired amyloidosis, to prevent further amyloid deposition through treatment of the primary cause. When the latter is possible, regression of existing amyloid deposits may occur. Liver transplantation may provide definitive treatment in selected patients with hereditary transthyretin amyloidosis.

AUTOIMMUNE DISEASE

Autoimmunity can be defined as the presence of immune responses against self tissue. This may be a harmless phenomenon, identified only by the presence of low titre autoantibodies or autoreactive T cells. However, if these responses cause significant organ damage, this results in autoimmune diseases, which are a major cause of chronic morbidity and disability, affecting up to 1 in 30 adults at some time (Box 4.11).

Pathophysiology of autoimmunity

Immunological tolerance

Autoimmunity results from the failure of immunological tolerance, the process by which the immune system recognises and accepts self tissue. There are a number of mechanisms of immune tolerance. Central tolerance occurs during lymphocyte development, when T and B lymphocytes that recognise self antigens are eliminated before they differentiate into fully immunocompetent cells. This process is most active in fetal life, but

4.10 Amyloid disorders

Disorder	Pathological basis	Predisposing conditions	Other features
Acquired systemic amyloidosis			
Reactive (AA) amyloidosis	Increased production of serum amyloid A as part of prolonged or recurrent acute inflammatory response	Chronic infection (TB, bronchiectasis, chronic abscess, osteomyelitis) Chronic inflammatory diseases (untreated rheumatoid arthritis, FMF)	90% of patients present with non-selective proteinuria or nephrotic syndrome
Light chain amyloidosis (AL)	Increased production of monoclonal light chain	Monoclonal gammopathies, including myeloma, benign gammopathies and plasmacytoma	Restrictive cardiomyopathy, peripheral and autonomic neuropathy, carpal tunnel syndrome, proteinuria, spontaneous purpura, amyloid nodules and plaques. Macroglossia occurs rarely but is pathognomonic. Prognosis is poor
Dialysis-associated (Aβ2M) amyloidosis	Accumulation of circulating β_2-microglobulin due to failure of renal catabolism in kidney failure	Renal dialysis	Carpal tunnel syndrome, chronic arthropathy and pathological fractures secondary to amyloid bone cyst formation. Manifestations occur 5–10 yrs after the start of dialysis
Senile systemic amyloidosis	Normal transthyretin protein deposited in tissues	Age > 70 yrs	Feature of normal ageing (affects > 90% of 90-year-olds). Usually asymptomatic
Hereditary systemic amyloidosis			
> 20 forms of hereditary systemic amyloidosis	Production of protein with an abnormal structure that predisposes to amyloid fibril formation. Most commonly due to mutations in *transthyretin* gene	Autosomal dominant inheritance	Peripheral and autonomic neuropathy, cardiomyopathy Renal involvement unusual 10% of gene carriers are asymptomatic throughout life

(FMF = familial Mediterranean fever)

4.11 The spectrum of autoimmune disease

Type	Disease	Page no.
Organ-specific		
Immune response directed against localised antigens	Graves' disease	747
	Hashimoto's thyroiditis	751
	Addison's disease	777
	Pernicious anaemia	1025
	Type 1 diabetes	803
	Sympathetic ophthalmoplegia	1169
	Multiple sclerosis	1188
	Goodpasture's syndrome	500
	Pemphigus vulgaris	1294
	Bullous pemphigoid	1292
	Idiopathic thrombocytopenic purpura	1050
	Autoimmune haemolytic anaemia	1029
	Myasthenia gravis	1226
	Primary antiphospholipid syndrome	1055
	Rheumatoid arthritis	1096
	Dermatomyositis	1114
	Primary biliary cirrhosis	963
	Autoimmune hepatitis	962
	Sjögren's syndrome	1114
Multisystem		
Immune response directed to widespread target antigens	Systemic sclerosis	1112
	Mixed connective tissue disease	1113
	SLE	1109

4.12 Some genetic variations predisposing to autoimmune diseases

Gene	Function	Diseases
HLA complex	Key determinants of antigen presentation to T cells	Most autoimmune diseases
PTPN22	Regulates T- and B-cell receptor signalling	Rheumatoid arthritis, type 1 diabetes, SLE
CTLA4	Important co-stimulatory molecule which transmits inhibitory signals to T cells	Rheumatoid arthritis, type 1 diabetes
TNFRSF1A	Control of TNF network	Multiple sclerosis
ATG5	Autophagy	SLE

continues throughout life as immature lymphocytes are generated. Inevitably some autoreactive cells evade deletion and reach the peripheral tissues, where they are controlled by peripheral tolerance mechanisms. These include suppression of autoreactive cells by regulatory T cells, generation of functional hyporesponsiveness ('anergy') in lymphocytes which encounter antigen in the absence of the co-stimulatory signals that accompany inflammation, and T cell death by apoptosis.

Autoimmune diseases develop when self-reactive lymphocytes escape from these tolerance mechanisms and become activated.

Factors predisposing to autoimmune disease

Autoimmune diseases are much more common in women than in men, for reasons which remain unclear. Most autoimmune diseases have multiple genetic determinants (Box 4.12). Many are associated with variation at specific HLA loci, reflecting the importance of HLA genes in shaping lymphocyte responses. Other important susceptibility genes include those determining cytokine activity, co-stimulation and cell death. Even though some of these associations are the strongest that have been identified in polygenic diseases (p. 68), they have limited predictive value, and are not useful in determining disease risk for individual patients. Several acquired factors can trigger autoimmunity in genetically predisposed individuals, including infection, cigarette smoking and hormone levels. The most widely studied of these is infection, as occurs in acute rheumatic fever following streptococcal infection or reactive arthritis following bacterial infection. A number of mechanisms have been postulated, such as cross-reactivity between the infectious pathogen and self antigens (molecular mimicry), and release of sequestered antigens, which are not usually visible to the immune system, from damaged tissue. Alternatively, infection may result in the production of inflammatory cytokines, which overwhelm the normal control mechanisms that prevent bystander damage. Occasionally, the development of autoimmune disease is a side-effect of drug treatment. For example, the metabolic products of the anaesthetic agent halothane bind to liver enzymes, resulting in a structurally novel protein. This is recognised as a new (foreign) antigen by the immune system, and the autoantibodies and activated T cells directed against it may cause hepatic necrosis.

Classification of autoimmune diseases

The spectrum of autoimmune diseases is broad. They can be classified by organ involvement (see Box 4.11) or by the predominant mechanism responsible for tissue damage. The Gell and Coombs classification of hypersensitivity is the most widely used, and distinguishes four types of immune response which result in bystander tissue damage (Box 4.13).

- *Type I hypersensitivity* is relevant in allergy but is not associated with autoimmune disease.
- In *type II hypersensitivity*, injury is localised to a single tissue or organ and is mediated by specific autoantibodies.
- *Type III hypersensitivity* is a generalised reaction resulting from immune complex deposition which initiates activation of the classical complement cascade, as well as recruitment and activation of phagocytes and $CD4^+$ lymphocytes. The site of immune complex deposition is determined by the relative amount of antibody, size of the immune complexes, nature of the antigen and local haemodynamics. Generalised deposition of immune complexes gives rise to systemic diseases such as SLE.
- In *type IV hypersensitivity*, activated T cells and macrophages mediate phagocytosis and tissue damage.

4.13 Gell and Coombs classification of hypersensitivity diseases

Type	Mechanism	Example of disease in response to exogenous agent	Example of autoimmune disease
Type I Immediate hypersensitivity	IgE-mediated mast cell degranulation	Allergic disease	None described
Type II Antibody-mediated	Binding of cytotoxic IgG or IgM antibodies to antigens on cell surface causes cell killing	ABO blood transfusion reaction Hyperacute transplant rejection	Autoimmune haemolytic anaemia Idiopathic thrombocytopenic purpura Goodpasture's disease
Type III Immune complex-mediated	IgG or IgM antibodies bind soluble antigen to form immune complexes which trigger classical complement pathway activation	Serum sickness Farmer's lung	SLE
Type IV Delayed type	Activation of T cells and phagocytes	Acute cellular transplant rejection Nickel hypersensitivity	Type 1 diabetes Hashimoto's thyroiditis

Investigations in autoimmunity

Autoantibodies

A number of autoantibodies can be identified in the laboratory and are used in disease diagnosis and monitoring, as discussed elsewhere in this book (e.g. p. 1067). Antibodies are quantified either by titre (the minimal dilution at which the antibody can be detected) or by concentration (in standardised units).

Measures of complement activation

Quantitation of complement components may be useful in the evaluation of immune complex-mediated diseases. Classical complement pathway activation leads to a decrease in circulating (unactivated) C4, and is often also associated with decreased C3 levels. Serial measurement of C3 and C4 is a useful surrogate measure of immune complex formation.

Cryoglobulins

Cryoglobulins are antibodies directed against other immunoglobulins, and which form immune complexes that precipitate in the cold. They are classified into three types on the basis of the properties of the immunoglobulin involved (Box 4.14). Testing for cryoglobulins requires the transport of a serum specimen to the laboratory at 37°C. Cryoglobulins should not be confused with cold agglutinins; the latter are autoantibodies specifically directed against the I/i antigen on the surface of red cells, which can cause intravascular haemolysis in the cold (p. 1030).

4.14 Classification of cryoglobulins

	Type I	Type II	Type III
Immunoglobulin isotype and specificity	Isolated monoclonal IgM paraprotein with no particular specificity	Immune complexes formed by monoclonal IgM paraprotein directed towards constant region of IgG	Immune complexes formed by polyclonal IgM or IgG directed towards constant region of IgG
Prevalence	25%	25%	50%
Disease association	Lymphoproliferative disease, especially Waldenström macroglobulinaemia (p. 1045)	Infection, particularly hepatitis B and hepatitis C; lymphoproliferative disease	Infection, particularly hepatitis B and C; autoimmune disease, including rheumatoid arthritis and SLE
Symptoms	*Hyperviscosity*: Raynaud's phenomenon Acrocyanosis Retinal vessel occlusion Arterial and venous thrombosis	*Small-vessel vasculitis*: Purpuric rash Arthralgia Cutaneous ulceration Hepatosplenomegaly Glomerulonephritis Raynaud's phenomenon	*Small-vessel vasculitis*: Purpuric rash Arthralgia Cutaneous ulceration Hepatosplenomegaly Glomerulonephritis Raynaud's phenomenon
Protein electrophoresis	Monoclonal IgM paraprotein	Monoclonal IgM paraprotein	No monoclonal paraprotein
Rheumatoid factor	Negative	Strongly positive	Strongly positive
Complement	Normal	Decreased C4	Decreased C4

ALLERGY

Allergic diseases are a common and increasing cause of illness, affecting between 15% and 20% of the population at some time. They comprise a range of disorders from mild to life-threatening, and affect many organs. Atopy is the tendency to produce an exaggerated IgE immune response to otherwise harmless environmental substances, while an allergic disease can be defined as the clinical manifestation of this inappropriate IgE immune response.

Pathology of allergy

Normally, the immune system does not make detectable responses to the many environmental substances to which it is exposed daily. However, in an allergic reaction, initial exposure to an otherwise harmless exogenous substance (known as an allergen) triggers the production of specific IgE antibodies by activated B cells (Fig. 4.9). These IgE antibodies bind to the surface of mast cells via high-affinity IgE receptors, a step that is not itself associated with clinical sequelae. However, upon re-exposure, the allergen binds to membrane-bound IgE which activates the mast cells, releasing a variety of mediators (the early phase response, Box 4.15). This type I hypersensitivity reaction is the basis of the symptoms of allergic reactions, which range from sneezing and rhinorrhoea to anaphylaxis (Box 4.16).

In some patients, the early phase response is followed by persistent activation of mast cells, manifest by ongoing swelling and local inflammation. This is known as the late phase reaction and is mediated by basophils, eosinophils and macrophages. Long-standing or recurrent allergic inflammation may give rise to a chronic inflammatory response characterised by a complex infiltrate of macrophages, eosinophils and T lymphocytes, in addition to mast cells and basophils. Once this has been established, inhibition of mast cell mediators with antihistamines is clinically ineffective.

Occasionally, mast cell activation may be non-specifically triggered through other signals, such as neuropeptides, anaphylotoxins and bacterial peptides.

Susceptibility to allergic diseases

The incidence of allergic diseases is increasing. This trend is largely unexplained but one widely held theory is the 'hygiene hypothesis'. This proposes that infections in early life are critically important in maturation of the immune response and bias the immune system against the development of allergies. It is suggested that the high prevalence of allergic disease is the penalty for the decreased exposure to infection that has resulted from improvements in sanitation and health care.

A number of factors predispose to allergic diseases, the strongest of which is a family history. A wide array of genetic determinants of disease susceptibility have been identified, including genes controlling innate immune responses, cytokine production, IgE levels and the ability of the epithelial barrier to protect against environmental agents. Contributory environmental factors include bacterial and viral infection, pollutants and cigarette smoke.

4.15 Products of mast cell degranulation

Mediator	Biological effects
Preformed and stored within granules	
Histamine	Vasodilatation, chemotaxis, bronchoconstriction, increased capillary permeability, increased mucus secretion
Tryptase	Bronchoconstriction, activates complement C3
Eosinophil chemotactic factor	Eosinophil chemotaxis
Neutrophil chemotactic factor	Neutrophil chemotaxis
Synthesised on activation of mast cells	
Leukotrienes	Increase vascular permeability, chemotaxis, mucus secretion, smooth muscle contraction
Prostaglandins	Bronchoconstriction, platelet aggregation, vasodilatation
Thromboxanes	Bronchoconstriction
Platelet-activating factor	Bronchoconstriction, chemotaxis of eosinophils and neutrophils

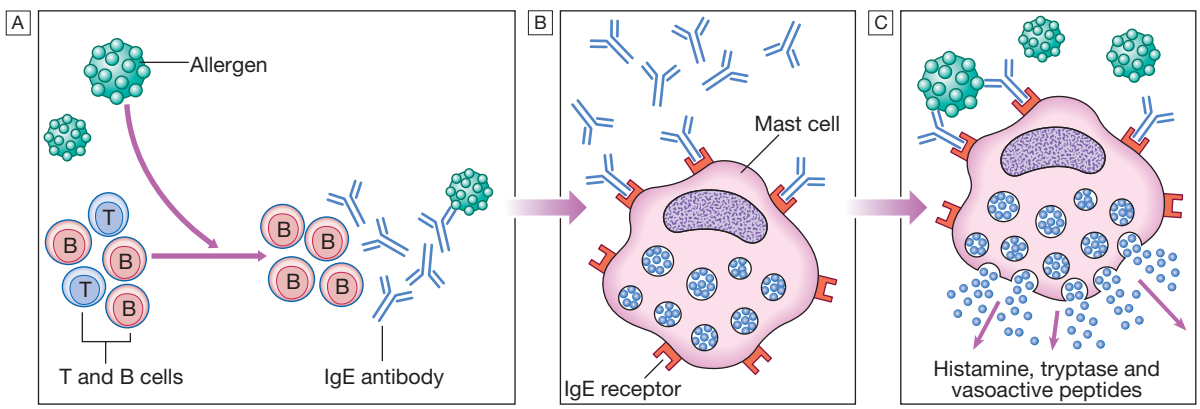

Fig. 4.9 Type I (immediate) hypersensitivity response. A After an encounter with allergen, B cells produce IgE antibody against the allergen. B Specific IgE antibodies bind to circulating mast cells via high-affinity IgE cell surface receptors. C On re-encounter with allergen, the allergen binds to the IgE antibody-coated mast cells. This triggers mast cell activation with release of vasoactive mediators (see Box 4.15).

Presenting problems in allergy

A general approach to the allergic patient

Common presentations of allergic disease are shown in Box 4.16. This chapter describes the general principles of the approach to the allergic patient and some of the more severe manifestations of allergy.

Clinical assessment

When assessing possible allergic disease, it is important to identify what the patient means by allergy, as up to 20% of the UK population describe themselves as having a food allergy, although fewer than 1% have an IgE-mediated hypersensitivity reaction confirmed on double blind challenge. The nature of symptoms should be established and specific triggers identified, along with the predictability of a reaction, and the time lag between exposure to a potential allergen and onset of symptoms. An allergic reaction usually occurs within minutes of exposure and provokes predictable symptoms (angioedema, urticaria, wheezing and so on). Specific enquiry should be made about other allergic symptoms, past and present, and about family history of allergic disease. Potential allergens in the home and workplace should be identified, and a detailed drug history should always be taken, including compliance, side-effects and the use of complementary therapies.

Investigations

Skin prick tests

These are the mainstay of allergy testing. A droplet of diluted standardised allergen solution is placed on the forearm and the skin is superficially punctured through the droplet with a sterile lancet. After 15 minutes, a positive response is indicated by a local weal and flare response at least 2 mm larger than the negative control. A major advantage of skin prick testing is that patients can clearly see the results, which may be useful in gaining compliance with avoidance measures. Disadvantages include the remote risk of a severe allergic reaction, so resuscitation facilities should be available. Results are unreliable in patients with extensive skin disease. Antihistamines inhibit the magnitude of the response and should be discontinued before testing; corticosteroids do not influence test results.

Specific IgE tests

An alternative to skin prick testing is the quantitation of IgE directed against the putative allergen. The sensitivity and specificity of specific IgE tests (previously known as radioallergosorbent tests, RAST) are lower than skin prick tests. However, IgE tests may be very useful if skin testing is inappropriate: for example, in patients taking antihistamines or those who have severe skin disease or dermatographism. They can also be used to test for cross-reactivity between insect venoms, and post mortem to identify allergens responsible for lethal anaphylaxis.

There is no indication for testing of specific IgG antibodies to allergens in the investigation of allergic diseases.

Supervised exposure to allergen (challenge test)

Allergen challenges are usually performed in specialist centres, and include bronchial provocation testing, nasal challenge and food challenge. These may be particularly useful in the investigation of occupational asthma or food allergy.

Mast cell tryptase

After a systemic allergic reaction, the circulating level of mast cell mediators increases dramatically. Tryptase is the most stable of these and serum levels peak at 1–2 hours. Measurement of serum mast cell tryptase is extremely useful in investigating a possible anaphylactic event. Ideally, measurements should be made at the time of the reaction, and 3 hours and 24 hours later.

Non-specific markers of atopic disease: total serum IgE and eosinophilia

Peripheral blood eosinophilia is common in atopic individuals. However, eosinophilia of more than 20% or an absolute eosinophil count over 1.5×10^9/L should initiate a search for a non-atopic cause (p. 311).

Atopy is the most common cause of elevated total IgE in developed countries. However, there are many other causes, including parasite and helminth infections (pp. 369 and 381), lymphoma (p. 1041), drug reactions and Churg–Strauss vasculitis (p. 1118). Moreover, significant allergic disease can occur despite a normal total IgE level. Thus total IgE quantitation is not indicated in the routine investigation of allergic disease.

Management

- *Avoidance of the allergen* should be rigorously attempted, and the advice of specialist dietitians and occupational physicians may be required.
- *Antihistamines* block histamine H_1 receptors, thereby inhibiting the effects of histamine release. Long-acting, non-sedating preparations are particularly useful for prophylaxis against frequent attacks.
- *Corticosteroids* down-regulate pro-inflammatory cytokine production. They are highly effective in allergic disease and, if used topically, their adverse effects may be minimised.
- *Sodium cromoglicate* stabilises the mast cell membrane, inhibiting release of vasoactive mediators. It is effective as a prophylactic agent in asthma and allergic rhinitis, but has no role in acute attacks. It is poorly absorbed and therefore ineffective in the management of food allergies.
- *Antigen-specific immunotherapy* involves the sequential administration of escalating amounts of dilute allergen over a prolonged period of time. Its mechanism of action is unknown, but it is highly

effective in the prevention of insect venom anaphylaxis, and allergic rhinitis secondary to grass pollen (Box 4.17). The traditional route of administration is via subcutaneous injections, which carry a risk of anaphylaxis and should only be performed in specialised centres. More recently, sublingual immunotherapy has been shown to be effective in the management of moderate grass pollen allergy, and clinical trials of immunotherapy for food allergy are ongoing.

- *Omalizumab*, a monoclonal antibody against IgE, inhibits the binding of IgE to mast cells and basophils. It is effective in moderate and severe allergic asthma and rhinitis.

EBM 4.17 Immunotherapy for allergy

'Immunotherapy is effective for treatment of allergic rhinitis, allergic asthma and stinging insect hypersensitivity. Clinical studies to date do not support the use of allergen immunotherapy for food hypersensitivity, chronic urticaria and/or angioedema.'

- Joint Task Force on Practice Parameters. Ann Allergy Asthma Immunol 2003; 90:1–40.

For further information: www.cochrane.org/cochrane-reviews

- *Preloaded self-injectable adrenaline (epinephrine)* may be life-saving in acute anaphylaxis.

Anaphylaxis

Anaphylaxis is a potentially life-threatening, systemic allergic reaction caused by the release of histamine and other vasoactive mediators from mast cells. The risk of death is increased in patients with pre-existing asthma, particularly if this is poorly controlled, and when treatment with adrenaline (epinephrine) is delayed.

Clinical assessment

The clinical features are shown in Figure 4.10. The severity of a reaction should be assessed; the time between allergen exposure and onset of symptoms provides a guide. Enquiry should be made about potential triggers; if these are not immediately obvious, a detailed history of the previous 24 hours may be helpful. The most common triggers are foods, latex, insect venom and drugs (Box 4.18). A history of previous allergic responses to the offending agent is common. The route of allergen exposure may influence the principal clinical features of a reaction; for example, if an allergen is inhaled, the major symptom is frequently wheezing. Features of anaphylaxis may overlap with the direct toxic effects of drugs and venoms (Ch. 9). Potentiating factors, such as

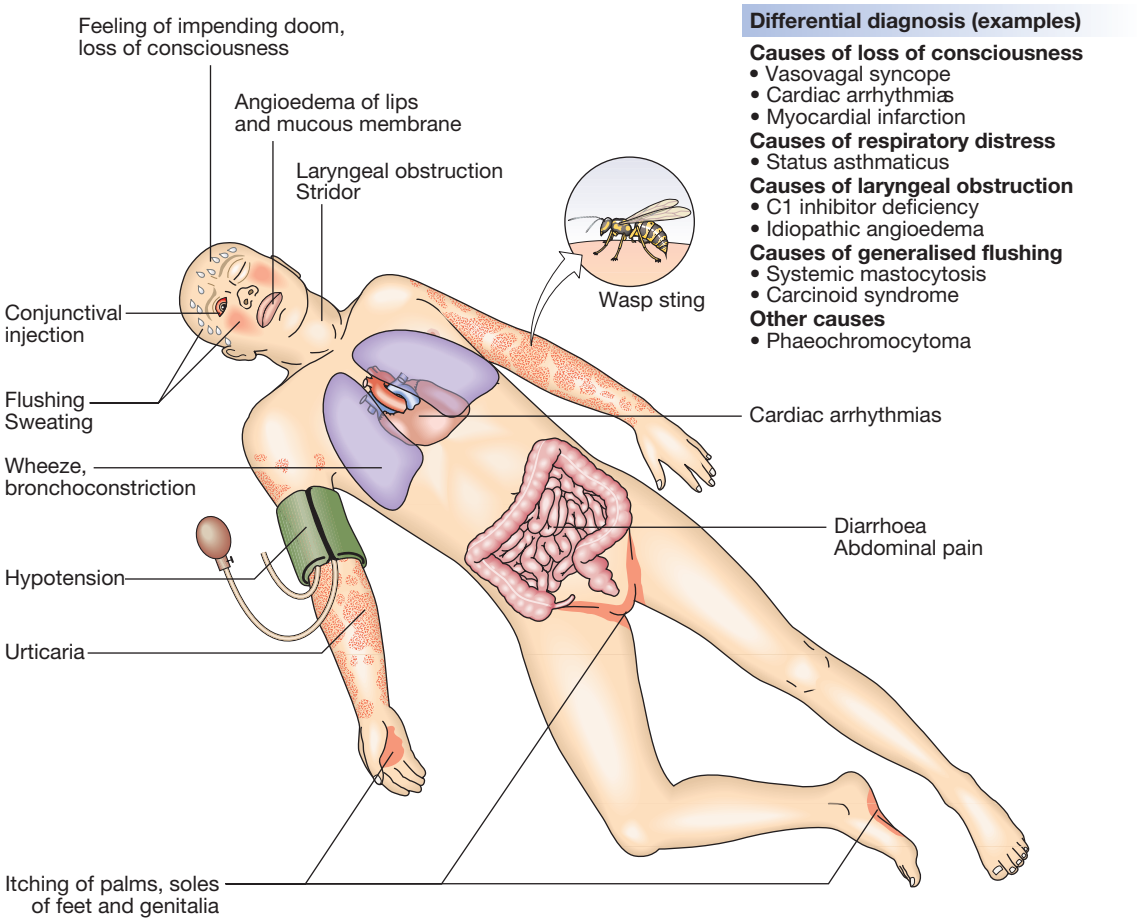

Fig. 4.10 Clinical manifestations of anaphylaxis. In this example, the response is to an insect sting containing venom to which the patient is allergic.

4.18 Common causes of systemic allergic reactions

Anaphylaxis: IgE-mediated mast cell degranulation

Foods
- Peanuts
- Tree nuts
- Fish and shellfish
- Milk
- Eggs
- Soy products

Insect stings
- Bee venom
- Wasp venom

Chemicals, drugs and other foreign proteins
- Intravenous anaesthetic agents, e.g. suxamethonium
- Penicillin and other antibiotics
- Latex

Anaphylactoid: non-IgE-mediated mast cell degranulation

Drugs
- Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs)
- Opiates
- Radiocontrast media

Physical
- Exercise
- Cold

Idiopathic
- No cause is identified in 20% of patients with anaphylaxis

exercise or alcohol, can lower the threshold for an anaphylactic event.

A number of conditions may mimic anaphylaxis (see Fig. 4.10). Anaphylactoid reactions result from the non-specific degranulation of mast cells by drugs, chemicals or other triggers (see Box 4.18), and do not involve IgE antibodies. The clinical presentations are indistinguishable, and in the acute situation discriminating between them is unnecessary. However, this may be important in identifying precipitating factors and appropriate avoidance measures.

Investigations

Measurement of serum mast cell tryptase concentrations is useful to confirm the diagnosis. Specific IgE tests may be preferable to skin prick tests when investigating patients with a history of anaphylaxis.

Management

Anaphylaxis is an acute medical emergency (Box 4.19).

Individuals who have recovered from an anaphylactic event should be referred for specialist assessment. The aim is to identify the trigger factor, to educate the patient regarding avoidance and management of subsequent episodes, and to identify whether specific treatment, such as immunotherapy, is indicated. If the trigger factor cannot be identified or cannot be avoided, recurrence is common. Patients who have previously experienced an anaphylactic event should be prescribed self-injectable adrenaline (epinephrine), and they and their families or carers should be instructed on its use (Box 4.20). The use of a MedicAlert (or similar) bracelet will increase the likelihood that adrenaline will be administered in an emergency. Issues most pertinent to serious allergy in adolescents are shown in Box 4.21.

4.19 Emergency management of anaphylaxis

Prevent further contact with allergen
- e.g. Removal of bee sting

Ensure airway patency

Administer *intramuscular* adrenaline (epinephrine) promptly
- Adult dose: 0.3–0.5 mL 1 : 1000 solution
- Acts within minutes
- Repeat at 5–10-min intervals if initial response is inadequate

Administer antihistamines
- e.g. Chlorphenamine 10 mg IM or slow IV injection
- Directly opposes effects of histamine released by activated mast cells

Administer corticosteroids
- e.g. Hydrocortisone 200 mg IV
- Prevents rebound symptoms in severely affected patients

Provide supportive treatments
- e.g. Nebulised β_2-agonists to decrease bronchoconstriction
- Intravenous fluids to restore or maintain blood pressure
- Oxygen

4.20 How to prescribe self-injectable adrenaline (epinephrine)

Prescription of an adrenaline auto-injector is usually initiated by a specialist (e.g. immunologist or allergist)

Indications
- Anaphylaxis to allergens which are difficult to avoid, e.g. insect venom and foods
- Idiopathic anaphylactic reactions
- History of severe localised reactions with high risk of future anaphylaxis, e.g. reaction to trace allergen or likely repeated exposure to allergen
- History of severe localised reactions with high risk of adverse outcome, should anaphylaxis occur, e.g. poorly controlled asthma, lack of access to emergency care

Relative contraindications

Risk of arrhythmia or acute coronary syndrome
- Ischaemic heart disease, uncontrolled hypertension
- Tricyclic antidepressants, monoamine oxidase inhibitors, cocaine use

Key practice points

Patient and family education
- Know when and how to use the device
- Carry the device at all times
- Seek medical assistance immediately after use
- Wear an alert bracelet or necklace
- Include the school in education for young patients

Prescriptions
- Specify the brand of auto-injector, as they have different triggering mechanisms
- Always prescribe two syringes
- Avoid β-blockers, as they may increase the severity of an anaphylactic reaction and reduce the response to adrenaline

4.21 Allergy in adolescence

- **Resolution of childhood allergy**: most children affected by allergy to milk, egg, soybean or wheat will grow out of their food allergies by adolescence. However, allergies to peanuts, tree nuts, fish and shellfish are frequently life-long.
- **Risk-taking behaviour and fatal anaphylaxis**: serious allergy is increasingly common in adolescents, and this is the highest-risk group for fatal, food-induced anaphylaxis. Food-allergic teenagers are more likely than adults to eat unsafe foods, deny reaction symptoms and delay emergency treatment.
- **Emotional impact of food allergies**: some adolescents neglect to carry a prescribed adrenaline (epinephrine) auto-injector because of the associated nuisance and/or stigma. Surveys of food-allergic teenagers reveal that many take risks because they feel socially isolated by their allergy.

Angioedema

Angioedema is the episodic, localised, non-pitting swelling of submucous or subcutaneous tissues. This most frequently affects the face (Fig. 4.11), extremities and genitalia. Involvement of the larynx or tongue may cause life-threatening respiratory tract obstruction, and oedema of the intestinal mucosa may cause abdominal pain and distension.

In most cases, the underlying mechanism is degranulation of mast cells. However, angioedema may occasionally be mediated by increased local bradykinin concentration (Box 4.22). Differentiating the mechanism of angioedema is important in determining appropriate investigations and treatment.

Fig. 4.11 Angioedema. This young man has hereditary angioedema. A Normal appearance. B During an acute attack. From Helbert 2006 – see p. 96.

4.22 Types of angioedema

	Allergic reaction to specific trigger	Idiopathic angioedema	Hereditary angioedema	ACE-inhibitor associated angioedema
Pathogenesis	IgE-mediated degranulation of mast cells	Non-IgE-mediated degranulation of mast cells	C1 inhibitor deficiency, with resulting increased local bradykinin concentration	Inhibition of breakdown of bradykinin
Key mediator	Histamine	Histamine	Bradykinin	Bradykinin
Prevalence	Common	Common	Rare autosomal dominant disorder	0.1–0.2% of patients treated with ACE inhibitors
Clinical features	Usually associated with urticaria History of other allergies common Follows exposure to specific allergen, e.g. food, animal dander or insect venom	Usually associated with urticaria May be triggered by physical stimuli, such as heat, pressure or exercise Dermatographism common Occasionally associated with infection or thyroid disease	Not associated with urticaria or other features of allergy Does not cause anaphylaxis May cause life-threatening respiratory tract obstruction Can cause severe abdominal pain	Not associated with urticaria Does not cause anaphylaxis Usually affects the head and neck, and may cause life-threatening respiratory tract obstruction Can occur years after the start of treatment
Investigations	Specific IgE tests or skin prick tests	Specific IgE tests and skin prick tests often negative Exclude hypothyroidism	Complement C4 (invariably low in acute attacks) C1 inhibitor levels	No specific investigations
Treatment	Allergen avoidance Antihistamines	Antihistamines are mainstay of treatment and prophylaxis	Unresponsive to antihistamines Attenuated androgens C1 inhibitor concentrate or icatibant for acute attacks	Discontinue ACE inhibitor Avoid angiotensin II receptor blockers
Possible drug causes	Specific drug allergies, e.g. penicillin	NSAIDs Opioids Radiocontrast media		ACE inhibitors Angiotensin II receptor blockers

(ACE = angiotensin-converting enzyme; NSAIDs = non-steroidal anti-inflammatory drugs)

Specific allergies

Insect venom allergy

Local non-IgE-mediated reactions to insect stings are common and may cause extensive swelling around the site lasting as long as 7 days. These usually do not require specific treatment. Toxic reactions to venom after multiple (50–100) simultaneous stings may mimic anaphylaxis. In addition, exposure to large amounts of insect venom frequently stimulates the production of IgE antibodies, and thus may be followed by allergic reactions to single stings. Allergic IgE-mediated reactions vary from mild to life-threatening. Antigen-specific immunotherapy with bee or wasp venom reduces the incidence of recurrent anaphylaxis from 50–60% to 10% but requires treatment for several years (see Box 4.17).

Peanut allergy

Peanut allergy is the most common food-related allergy. More than 50% of patients present before the age of 3 years and some individuals react to their first known exposure to peanuts, possibly because of sensitisation by topical creams. Peanuts are ubiquitous in the Western diet, and every year up to 25% of peanut-allergic individuals will experience a reaction as a result of inadvertent exposure.

Birch oral allergy syndrome

This syndrome is characterised by a combination of birch pollen hay fever and local angioedema after contact with fresh fruit (especially apples), vegetables and nuts. Cooked fruits and vegetables are tolerated without difficulty. It is due to shared or cross-reactive allergens which are destroyed by cooking or digestion, and can be confirmed by skin prick testing using fresh fruit. Severe allergic reactions are unusual.

C1 inhibitor deficiency

Hereditary angioedema

Hereditary angioedema (HAE), also known as inherited C1 inhibitor deficiency, is an autosomal dominant disorder caused by decreased production or activity of C1 inhibitor protein. This complement regulatory protein inhibits spontaneous activation of the classical complement pathway (see Fig. 4.3, p. 75). C1 inhibitor is also a regulatory protein for the kinin cascade, activation of which increases local bradykinin levels and gives rise to local pain and swelling.

In HAE, angioedema may be spontaneous or triggered by local trauma or infection. Multiple parts of the body may be involved, especially the face, extremities, upper airway and gastrointestinal tract. Oedema of the intestinal wall causes severe abdominal pain. The most important complication is laryngeal obstruction, often associated with minor dental procedures, which can be fatal. Episodes of angioedema are self-limiting and usually resolve within 48 hours. Patients with HAE generally present in adolescence, but may go undiagnosed for many years. A family history can be identified in 80% of cases. HAE is not associated with allergic diseases and is specifically not associated with urticaria.

4.23 Immunological diseases in pregnancy

Allergic disease

- **Maternal dietary restrictions during pregnancy or lactation**: current evidence does not support these for prevention of allergic disease.
- **Breastfeeding for at least 4 mths**: prevents or delays the occurrence of atopic dermatitis, cow's milk allergy and wheezing in early childhood, as compared with feeding formula milk containing intact cow's milk protein.

Autoimmune disease

- **Suppressed T cell-mediated immune responses in pregnancy**: autoimmune diseases often improve during pregnancy but flare immediately after delivery. However, an exception is SLE, which is prone to exacerbation in pregnancy.
- **Passive transfer of maternal antibodies**: can mediate autoimmune disease in the fetus and newborn, including SLE, Graves' disease and myasthenia gravis.
- **Antiphospholipid syndrome** (p. 1055): an important cause of fetal loss, intrauterine growth restriction and pre-eclampsia.

Acute episodes are always accompanied by low C4 levels and the diagnosis can be confirmed by C1 inhibitor measurement. Prevention is with modified androgens (e.g. danazol), which increase endogenous production of complement proteins. Severe acute attacks should be treated with purified C1 inhibitor or a bradykinin receptor antagonist (icatibant).

Acquired C1 inhibitor deficiency

This rare disorder is clinically indistinguishable from HAE but presents in late adulthood. It is associated with autoimmune and lymphoproliferative diseases. Treatment of the underlying disorder may induce remission of angioedema.

TRANSPLANTATION IMMUNOLOGY

Transplantation provides the opportunity for definitive treatment of end-stage organ disease. The major complications are graft rejection, drug toxicity and infection consequent on immunosuppression. Transplant survival continues to improve, as a result of the introduction of less toxic immunosuppressive agents and increased understanding of rejection mechanisms.

Haematopoietic stem cell transplantation and its complications are discussed on page 1017.

Transplant rejection

Solid organ transplantation inevitably stimulates an aggressive immune response by the recipient, unless the transplant is between monozygotic twins. The type and severity of the rejection response are determined by the genetic disparity between the donor and recipient, the immune status of the host and the nature of the tissue

4.24 Classification of transplant rejection

Type	Time	Pathological findings	Mechanism	Treatment
Hyperacute rejection	Mins to hrs	Thrombosis, necrosis	Preformed antibody to donor antigens results in complement activation (type II hypersensitivity)	None – irreversible graft loss
Acute vascular rejection	5–30 days	Vasculitis	Antibody and complement activation	Increase immunosuppression
Acute cellular rejection	5–30 days	Cellular infiltration	$CD4^+$ and $CD8^+$ T cells (type IV hypersensitivity)	Increase immunosuppression
Chronic allograft failure	> 30 days	Fibrosis, scarring	Immune and non-immune mechanisms	Minimise drug toxicity, control hypertension and hyperlipidaemia

transplanted (Box 4.24). The most important genetic determinant is the difference between donor and recipient HLA proteins (p. 75). The extensive polymorphism of these proteins means that donor HLA antigens are almost invariably recognised as foreign by the recipient immune system, unless an active attempt has been made to minimise incompatibility.

- *Acute cellular rejection* is the most common form of graft rejection. It is mediated by activated T cells and results in deterioration in graft function. It may cause fever, pain and tenderness over the graft. It is usually amenable to increased immunosuppressive therapy.
- *Hyperacute rejection* results in rapid and irreversible destruction of the graft. It is mediated by pre-existing recipient antibodies against donor HLA antigens, which arise as a result of previous exposure through transplantation, blood transfusion or pregnancy. It is rarely seen in practice, as the use of screening for anti-HLA antibodies and pre-transplant cross-matching ensure prior identification of recipient–donor incompatibility.
- *Acute vascular rejection* is mediated by antibody formed de novo after transplantation. It is more curtailed than the hyperacute response because of the use of intercurrent immunosuppression, but it is also associated with reduced graft survival. Aggressive immunosuppressive therapy is indicated, and physical removal of antibody through plasmapheresis may be effective. Not all post-transplant anti-donor antibodies cause graft damage; their consequences are determined by specificity and ability to trigger other immune components, such as the complement cascade.
- *Chronic allograft failure*, also known as chronic rejection, is a major cause of graft loss. It is associated with proliferation of transplant vascular smooth muscle, interstitial fibrosis and scarring. The pathogenesis is poorly understood but contributing factors include immunological damage caused by subacute rejection, hypertension, hyperlipidaemia and chronic drug toxicity.

Investigations

Pre-transplantation testing

HLA typing determines an individual's HLA polymorphisms and facilitates donor–recipient matching.

Potential transplant recipients are screened for the presence of anti-HLA antibodies using either recombinant HLA proteins or a pool of lymphocytes from individuals with broadly representative HLA types. If antibodies are detected, their specificity is further characterised and the recipient is excluded from receiving a transplant which carries these alleles.

Donor–recipient cross-matching is a functional assay that directly tests whether serum from a recipient (which potentially contains anti-donor antibodies) is able to bind and/or kill donor lymphocytes. It is specific to a prospective donor–recipient pair and is done immediately prior to transplantation. A positive cross-match is a contraindication to transplantation because of the risk of hyperacute rejection.

C4d staining

C4d is a fragment of complement protein C4 (see Fig. 4.3, p. 75). Deposition of C4d in graft capillaries indicates local activation of the classical complement pathway and provides evidence for antibody-mediated damage. This is useful in diagnosis of vascular rejection.

Complications of transplant immunosuppression

The prevention of transplant rejection requires indefinite treatment with immunosuppressive agents. In general, two or more immunosuppressive drugs are used in synergistic combinations in order to minimise drug side-effects (Box 4.25). The major complications of long-term immunosuppression are infection and malignancy.

The risk of some opportunistic infections may be minimised through the use of prophylactic medication (e.g. ganciclovir for CMV prophylaxis and trimethoprim–sulfamethoxazole for *Pneumocystis* prophylaxis). Immunisation with killed vaccines is appropriate, although the immune response may be curtailed. Live vaccines should not be given.

The increased risk of malignancy arises because T-cell suppression results in failure to control viral infections. Virus-associated tumours include lymphoma (associated with EBV), Kaposi's sarcoma (associated with human herpesvirus 8) and skin tumours (associated with human papillomavirus). Immunosuppression is also associated with a small increase in the incidence of common cancers not associated with viral infection

4.25 Immunosuppressive drugs used in transplantation

Drug	Mechanism of action	Major adverse effects
Anti-proliferative agents e.g. azathioprine, mycophenolate mofetil	Inhibit lymphocyte proliferation by blocking DNA synthesis May be directly cytotoxic at high doses	Increased susceptibility to infection Leucopenia Hepatotoxicity
Calcineurin inhibitors e.g. ciclosporin, tacrolimus	Inhibit T-cell signalling; prevent lymphocyte activation and block cytokine transcription	Increased susceptibility to infection Hypertension Nephrotoxicity Diabetogenic (especially tacrolimus) Gingival hypertrophy, hirsutism (ciclosporin)
Corticosteroids	Decrease phagocytosis and release of proteolytic enzymes; decrease lymphocyte activation and proliferation; decrease cytokine production; decrease antibody production	Increased susceptibility to infection Multiple other complications (p. 776)
Anti-T-cell induction agents e.g. anti-thymocyte globulin (ATG)	Antibodies to cell surface proteins deplete or inhibit T cells	Profound non-specific immunosuppression Increased susceptibility to infection

(such as lung, breast and colon cancer), reflecting the importance of T cells in anti-cancer surveillance.

Organ donation

The major problem in transplantation is the shortage of organ donors. Cadaveric organ donors are usually previously healthy individuals who experience brainstem death (p. 1161), frequently as a result of road traffic accidents or cerebrovascular events. However, even if organs were obtained from all potential cadaveric donors, their numbers would be insufficient to meet current needs. An alternative is the use of living donors. Altruistic living donation, usually from close relatives, is widely used in renal transplantation. Living organ donation is inevitably associated with some risk to the donor, and the process is highly regulated to ensure appreciation of the dangers involved. Because of concerns about coercion and exploitation, non-altruistic organ donation (the sale of organs) is illegal in most countries.

PRINCIPLES AND INVESTIGATION OF ENVIRONMENTAL FACTORS IN DISEASE

Environmental effects on health

Health emerges from a highly complex interaction between factors intrinsic to the patient and his or her environment. Many factors within the environment influence health, including aspects of the physical environment, biological environment (bacteria, viruses), built environment and social environment, but these also encompass more distant influences such as the global ecosystem (Fig. 5.1). Environmental changes affect many physiological systems and do not respect boundaries between medical specialties. The specialty of 'public health' in the UK is concerned with the investigation and management of health in communities and populations, but the principles apply in all specialties.

Exposure to infectious agents is a major environmental determinant of health and is described in detail in Chapter 6. This chapter describes the approach to other common environmental factors that influence health.

The hierarchy of systems – from molecules to ecologies

When assessing a patient, a clinician subconsciously considers many levels at which problems may be occurring, including molecular, cellular, tissue, organ and body systems. When the environment's influence on health is being considered, this 'hierarchy of systems' extends beyond the individual to include the family, community, population and ecology. Box 5.1 shows an example of the utility of this concept in describing determinants of coronary heart disease operating at each level of a hierarchy.

Interactions between people and their environment

The hierarchy of systems demonstrates that the clinician should not focus too quickly on the disease process without considering the context. Health is an emergent quality of a complex interaction between many determinants, including genetic inheritance, the physical circumstances in which people live (e.g. housing, air quality, working environment), the social environment (e.g. levels of friendship, support and trust), personal behaviour (smoking, diet, exercise), and access to money and the other resources that give people control over their lives. Health care is not the only determinant – and is usually not the major determinant – of health status in the population.

These systems do not operate in isolation in separate communities. When one group responds to ill health by manipulating its environment, the consequences may be global. For example, an Afghan farmer who starts growing opium for money in order to feed his children influences the environment of a teenager in Europe; in turn, drug misuse in Europe has fostered higher prevalence of blood-borne infectious diseases such as human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS); in turn, these have spilled out into sexually transmitted disease. This process contributes significantly to the tragedy of the epidemic of HIV/AIDS.

The life course

The determinants of health operate over the whole lifespan. Values and behaviours acquired during childhood and adolescence have a profound influence on

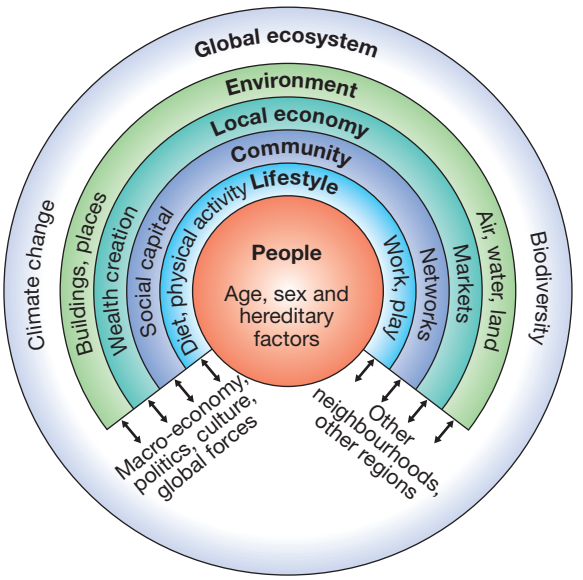

Fig. 5.1 Hierarchy of systems that influence population health. From Rao, et al. 2007 – see p. 132.

5.1 'Hierarchy of systems' applied to ischaemic heart disease

Level in the hierarchy	Example of effect
Molecular	ApoB mutation causing hypercholesterolaemia
Cellular	Foam cells accumulate in vessel wall
Tissue	Atheroma and thrombosis of coronary artery
Organ	Ischaemia and infarction of myocardium
System	Cardiac failure
Person	Limited exercise capacity, impact on employment
Family	Passive smoking, diet
Community	Shops and leisure opportunities
Population	Prevalence of obesity
Society	Policies on smoking, screening for risk factors
Ecology	Agriculture influencing fat content in diet

educational outcomes, job prospects and risk of disease. Attributes such as the ability to form empathetic relationships or assess risk have a strong influence on whether a young person takes up damaging behaviour like smoking, risky sexual activity and drug misuse. Influences on health can even operate before birth.

Individuals with low birth weight have been shown to have a higher prevalence of conditions such as hypertension and type 2 diabetes as young adults and of cardiovascular disease in middle age. It has been suggested that under-nutrition during middle to late gestation permanently 'programmes' cardiovascular and metabolic responses.

This 'life course' perspective highlights the cumulative effect on health of exposures to episodes of illness, adverse environmental conditions and behaviours that damage health. In this way, biological and social risk factors at each stage of life link to form pathways to disease and health.

Investigations in environmental health

Incidence and prevalence

The first task is to establish how common a problem is within the population. This is expressed in two ways (Box 5.2).

- If the problem is a continuing condition (e.g. enlarged spleen due to malaria), then prevalence is the appropriate measurement and is calculated by dividing the number of people with the condition at a specified time by the number of people in the population at risk at that time. Prevalence tends to be higher if the problem is common (many new cases) and/or if it is of longer duration.
- If the problem is an event that occurs at a clear point in time (e.g. fever due to malaria), then incidence is used. Incidence is a measure of the rate at which new cases occur (e.g. confirmed pyrexia with malaria parasites on a blood film) in the population at risk during a defined period of time.

5.2 Calculation of risk using descriptive epidemiology

Prevalence
• The ratio of the number of people with a longer-term disease or condition at a specified time, to the number of people in the population who are at risk
Incidence
• The number of events (new cases or episodes) occurring in the population at risk during a defined period of time
Attributable risk
• The difference between the risk (or incidence) of disease in exposed and non-exposed populations
Attributable fraction
• The ratio of the attributable risk to the incidence
Relative risk
• The ratio of the risk (or incidence) in the exposed population to the risk (or incidence) in the non-exposed population

Variability by time, person and place

The next task is to establish how the problem varies in terms of time, person and place. The incidence may fluctuate throughout the year; for example, malaria occurs in the wet season but not the dry. Observation over longer periods establishes whether a problem is becoming more or less common: malaria may re-emerge due to drug resistance. The next questions are, who are the victims? Are males or females more commonly affected? What is the age pattern? What are the occupations and social positions of those affected? In this example, symptomatic malaria is more common in poorer, rural-dwelling children. Finally, there is the question of variability by place: the prevalence of malaria is dictated by the distribution of *Anopheles* mosquitoes.

Measuring risk

Epidemiology is also concerned with the numerical estimation of risk. This is best illustrated by a simple example. In a rural African town with a population of 5000, disease 'd' is under investigation. The majority of the cases of disease 'd' (300 out of 360) occurred among women and children who use the river, which recently had its flow of water reduced because of a new irrigation scheme. A formal experiment is established to measure risk. The 1000 women and children who use the river are followed up for 1 year and compared to a cohort with a similar age and sex distribution who use standpipes as their source of water.

The incidence (new cases) of disease 'd' in the 1000 exposed to risk 'r' (river water) was 300. The incidence (new cases) of disease 'd' in the 1000 not exposed to risk 'r' was 60. The relative risk is the incidence in the exposed population (300 per 1000 per year) divided by the incidence in the non-exposed population (60 per 1000 per year); 300/60 = 5, meaning that those exposed to the river water are 5 times more likely to contract the disease – their relative risk is 5. The attributable risk of exposure 'r' for disease 'd' is the incidence in the exposed population (300) minus the incidence in the non-exposed population (60), which is 240 per 1000 per year. The fraction, or proportion, of the disease in the exposed population which can be attributed to risk (r) is called the attributable fraction, in this case (300–60)/300 = 0.8. This means that 80% of the disease can be attributed to exposure to river water.

Establishing cause and effect

Associations between a risk factor and a disease do not prove that the risk factor causes the disease. In the northern hemisphere, both multiple sclerosis and blue eyes are more common but it is implausible that having blue eyes is the cause of multiple sclerosis. Cause and effect can only be proven by more detailed investigation. In the above example, further investigation of the river water will be needed, using the criteria for causation defined in Koch's postulates (for infectious agents, p. 134) or the more generic Bradford Hill criteria.

Preventive medicine

There are many examples of epidemiological associations defining causative factors in disease, e.g. the association between cigarette smoking and lung cancer (p. 699). However, as illustrated above, the complexity of the interactions between physical, social and economic determinants of health means that successful prevention is often difficult. Moreover, the life course perspective illustrates that it may be necessary to intervene early in life or even before birth, to prevent important disease in later life. Successful prevention is likely to require many interventions across the life course and at several levels in the hierarchy of systems. The examples below illustrate this principle.

ENVIRONMENTAL DISEASES

The term 'homeostasis' describes the capacity to maintain the internal milieu by adapting to increases or decreases in a given environmental factor. However, there are limits to the coping abilities of any system, at which 'too much' or 'too little' of a given environmental factor will result in ill health. Too many calories lead to obesity, while too few lead to malnutrition. Either involuntarily or deliberately, we expose ourselves to many poisons and hazards. Examples discussed elsewhere include industrial/occupational hazards, such as asbestos (p. 718) and other carcinogens (p. 266). 'Social' poisons, such as tobacco, alcohol and drugs of misuse, also need to be considered (p. 240).

Alcohol

The World Health Organization (WHO) estimates that the harmful use of alcohol results in the death of 2.5 million people annually. Rates of alcohol-related harm vary by place and time but have risen dramatically in the UK, with Scotland showing the highest rates. (Fig. 5.2 demonstrates the climbing rates during the 1990s, since when rates have stabilised at very high levels.) Why did Scotland experience this dramatic increase in alcohol deaths? The most likely explanation is that the environment changed. The price of alcohol fell in real terms and availability increased (more supermarkets sold alcohol and the opening times of public houses were extended). Also, the culture changed in a way that fostered higher levels of consumption and more binge drinking. These changes have caused a trebling of male and a doubling of female deaths due to alcohol. Public, professional and governmental concern has now led to a minimum price being charged for a unit of alcohol, tightening of licensing regulations and curtailment of some promotional activity (e.g. two-for-one offers in bars). Many experts judge that even more aggressive public health measures will be needed to reverse the levels of harm in the community. The approach for individual patients suffering adverse effects of alcohol is described on pages 240 and 252.

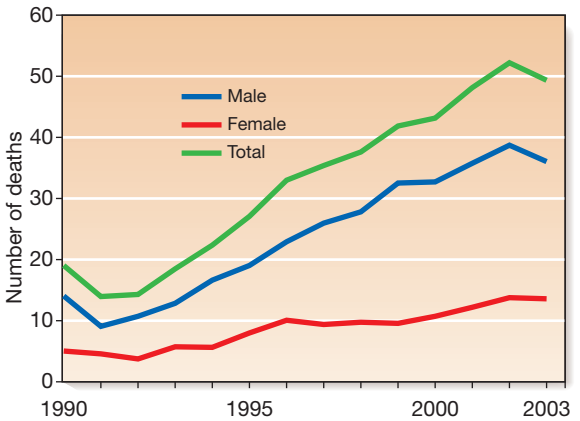

Fig. 5.2 Alcohol-related deaths in Scotland by year and sex (1990–2003). Principal ('underlying') and secondary ('contributing') causes of death. (Source: General Register Office (Scotland))

Smoking

Smoking tobacco dramatically increases the risk of developing many diseases. It is responsible for a substantial majority of cases of lung cancer and chronic obstructive pulmonary disease, and most smokers die either from these respiratory diseases or from ischaemic heart disease. Smoking also causes cancers of the upper respiratory and gastrointestinal tracts, pancreas, bladder and kidney, and increases risks of peripheral vascular disease, stroke and peptic ulceration. Maternal smoking is an important cause of fetal growth retardation. Moreover, there is increasing evidence that passive (or 'secondhand') smoking has adverse effects on cardiovascular and respiratory health.

When the ill-health effects of smoking were first discovered, doctors imagined that warning people about the dangers of smoking would result in them giving up. However, it also took increased taxation of tobacco, banning of advertising and support for smoking cessation to maintain a decline in smoking rates. In several European countries (including the UK), this has culminated in a complete ban on smoking in all public places – legislation that only became possible as the public became convinced of the dangers of secondhand smoke. However, smoking rates remain high in many poorer areas and are increasing amongst young women. In many developing countries, tobacco companies have found new markets and rates are rising. Worldwide, there are approximately 1 billion smokers, and it is estimated by WHO that 6 million die prematurely each year as a result of their habit.

In reality, there is a complex hierarchy of systems that interact to cause smokers to initiate and maintain their habit. At the molecular and cellular levels, nicotine acts on the nervous system to create dependence, so that smokers experience unpleasant effects when they attempt to quit. So, even if they know it is harmful, the role of addiction in maintaining the habit is important. Influences at the personal and social level are just as important. Many individuals bolster their denial of the harmful effects of smoking by focusing on someone they knew personally who smoked until he or she was very old and died peacefully in bed. Such strong counter-examples help smokers to maintain internal beliefs that comfort them when presented with statistical evidence.

5.3 Methods for smoking cessation*

Smokers who are not motivated to try to stop smoking

- Record smoking status at regular intervals
- Anti-smoking advice
- Encourage change in attitude towards smoking to improve motivation

Motivated light smokers (< 10/day)

- Anti-smoking advice
- Anti-smoking support programme

Motivated heavy smokers (10–15/day)

- As above plus nicotine replacement therapy (NRT) (minimum 8 weeks)

Motivated heavy smokers (> 15/day)

- As above plus bupropion if NRT and behavioural support are unsuccessful and patient remains motivated

*Based on Coleman T. Smoking cessation: integrating recent advances with clinical practice. Thorax 2001; 56:579–582, with permission from the BMJ Publishing Group.

EBM 5.4 Smoking cessation

'Placebo or will-power alone has a ~2% chance of abstinence for ≥ 6 months. This can be increased by the percentage shown by:

- written self-help materials: 1%
- opportunistic advice from doctor: 2%
- face-to-face behavioural support from specialist: 4–7%
- proactive telephone counselling: 2%
- NRT with limited or intensive behavioural support: 5–12%
- bupropion with intensive behavioural support: 9%.'

- Health Education Board for Scotland, Edinburgh; 2000.

Young female smokers are often motivated more by the desire to 'stay thin' or 'look cool' than to avoid an illness in middle life.

Even if a smoker decides to quit, there are a variety of influences in the wider environment that reduce the chances of sustained success, including peer pressure, cigarette advertising, and finding oneself in circumstances where one previously smoked. The tobacco industry works very hard to maintain and expand the smoking habit, and its advertising budget is much greater than that available to health promoters.

Strategies to help individuals quit smoking are outlined in Boxes 5.3 and 5.4. Although the success rates are modest, these interventions are cost-effective and form an important part of the overall anti-tobacco strategy.

Obesity

Obesity is a condition characterised by an excess of body fat. In its simplest terms, obesity can be considered to result from an imbalance between the amount of energy consumed in the diet and the amount of energy expended through exercise and bodily functions. People who are obese are more likely to develop a range of chronic conditions. In 2006, the number of obese and overweight people in the world overtook the numbers who are malnourished and underweight. It would, however, be wrong to focus only on those who are obese because, in countries like the USA and the UK, fat deposition is affecting almost the entire population. The weight distribution of almost the whole population is shifting upwards – the slim are becoming less slim while the fat are getting fatter. In the UK, this translates into a 1-kilogram increase in weight per adult per year (on average over the adult population). It is now widely accepted that we cannot blame the current obesity epidemic on individual behaviour and poor choice, although many current approaches still focus on individuals. The best way, therefore, to understand the current obesity epidemic is to consider humans as 'obesogenic organisms' who, for the first time in their history, find themselves in an obesogenic environment – that is, one where people's circumstances encourage them to eat more and exercise less. This includes the availability of cheap and heavily marketed energy-rich foods, the increase in labour-saving devices (e.g. lifts and remote controls) and the increase in passive transport (cars as opposed to walking, cycling, or walking to public transport hubs). Our physiology was formed a long time ago when food was scarce and we needed large amounts of energy in order to find food and stay alive. We are stuck with the metabolic and behavioural legacy of our evolutionary history – we are organisms that are programmed to eat when we can and preserve energy whenever possible. It is not surprising that we have problems coping with an environment that exerts constant pressure to increase energy intake and to decrease energy expenditure. The rise in obesity suggests that the effects of our obesogenic environment are overriding the biological regulatory mechanisms in more and more people. To combat the health impact of obesity, therefore, we need to help those who are already obese but also develop strategies that impact on the whole population and reverse the obesogenic environment.

Poverty and affluence

The adverse health and social consequences of poverty are well documented: high birth rates, high death rates and short life expectancy (Box 5.5). Typically, with

5.5 Examples of effects of financial resources on health

Poverty

- Respiratory disease exacerbated or caused by air pollution
- Exposure to unnecessary hazards in the workplace or living environment
- Poor hygiene causing diarrhoeal diseases and debilitating intestinal parasitic infections
- Malnutrition
- Cardiovascular disease

Affluence

- Physical inactivity
- Alcohol and drug consumption
- High rates of suicide, depression, anxiety and stress
- Sexually transmitted infection
- Obesity

industrialisation, the pattern changes: low birth rates, low death rates and longer life expectancy (Box 5.6). Instead of infections, chronic conditions such as heart disease dominate in an older population. Adverse health consequences of excessive affluence are also becoming apparent. Despite experiencing sustained economic growth for the last 50 years, people in many industrialised countries are not growing any happier and the litany of socioeconomic problems – crime, congestion, inequality – persists. Living in societies that give pride of place to economic growth means that there is constant pressure to contribute by performing ever harder at work and by consuming as much as – or more than – we can afford. As a result, people become stressed and may adopt unhealthy strategies to mitigate their discomfort; they overeat, overshop, or use sex or drugs (legal and illegal) as 'pain-killers'. These behaviours often lead to the problems listed in Box 5.5.

Many countries are now experiencing a 'double burden'. They have large populations still living in poverty who are suffering from problems such as diarrhoea and malnutrition, alongside affluent populations (often in cities) who suffer from chronic illness such as diabetes and heart disease. Recent research suggests that uneven distribution of wealth is a more important determinant of health than the absolute level of wealth; countries with a more even distribution of wealth enjoy longer life expectancies than countries with similar or higher gross domestic products (GDPs) but wider distributions of wealth.

Atmospheric pollution

Emissions from industry, power plants and motor vehicles of sulphur oxides, nitrogen oxides, respirable particles and metals are severely polluting cities and towns in Asia, Africa, Latin America and Eastern Europe. Increased death rates from respiratory and cardiovascular disease occur in vulnerable adults, such as those with established respiratory disease and the elderly, while children experience an increase in bronchitic symptoms. In nations like the UK that have reduced their primary emissions, the new issue of greenhouse gases has emerged. Developing countries also suffer high rates of respiratory disease as a result of indoor pollution caused mainly by heating and cooking combustion.

5.6 Environmental factors in disease in old age

- **Quality of life**: the major goal of public health policy in the young is to prolong lifespan; in old age, quality of life may be more important than its duration.
- **Life course**: the environmental factors that determine life expectancy operate throughout the lifespan and begin before birth.
- **Susceptibility to risk**: decline in many physiological functions increases risks from, for example, extremes of temperature, poverty, pollution and accidents in the home.
- **Reliance on support**: in many societies, financial, family and community support for older people is declining, with increasing risks of social isolation, poverty, malnutrition and neglect.

Carbon dioxide and global warming

Climate change is arguably the world's most important environmental health issue. A combination of increased production of carbon dioxide and habitat destruction, both caused primarily by human activity, seems to be the main cause. The temperature of the globe is rising, climate is being affected, and if the trend continues, sea levels will rise and rainfall patterns will be altered so that both droughts and floods will become more common. These have already claimed millions of lives during the past 20 years and have adversely affected the lives of many more. The economic costs of property damage and the impact on agriculture, food supplies and prosperity have also been substantial. The health impacts of global warming will also include changes in the geographical range of some vector-borne infectious diseases.

Currently, politicians cannot agree on an effective framework of actions to tackle the problem. Meanwhile, the industrialised world continues with lifestyles and levels of waste that are beyond the planet's ability to sustain. Rapidly growing economies in the world's two most populous states, India and China, are going to be a vital part of the unfolding problem or solution.

Radiation exposure

Radiation includes ionising (Box 5.7) and non-ionising radiations (ultraviolet (UV), visible light, laser, infrared and microwave). Whilst global industrialisation and the generation of fluorocarbons have raised concerns about loss of the ozone layer, leading to an increased exposure to UV rays, and disasters such as the Chernobyl and Fukushima nuclear power station explosions have demonstrated the harm of ionising radiation, it is important to remember that it can be harnessed for medical benefit. Ionising radiation is used in X-rays, computed tomography (CT), radionucleotide scans and radiotherapy, and non-ionising UV for therapy in skin diseases and laser therapy for diabetic retinopathy.

Types of ionising radiation

These include charged subatomic alpha and beta particles, uncharged neutrons or high-energy electromagnetic

5.7 Properties of ionising radiations

	Range in air	Range in tissue	Protection
Alpha particles	Few centimetres	No penetration	Paper
Beta particles	Few metres	Few millimetres	Aluminium sheet
X-rays/ gamma rays	Kilometres	Passes through	Lead
Neutrons	Kilometres	Passes through	Concrete or thick polythene

radiations such as X-rays and gamma rays. When they interact with atoms, energy is released and the resulting ionisation can lead to molecular damage. The clinical effects of different forms of radiation depend upon their range in air and tissue penetration (see Box 5.7).

Dosage and exposure

The dose of radiation is based upon the energy absorbed by a unit mass of tissue and is measured in grays (Gy), with 1 Gy representing 1 J/kg. To take account of different types of radiation and variations in the sensitivity of various tissues, weighting factors are used to produce a unit of effective dose, measured in sieverts (Sv). This value reflects the absorbed dose weighted for the damaging effects of a particular form of radiation and is most valuable in evaluating the long-term effects of exposure.

'Background radiation' refers to our exposure to naturally occurring radioactivity (e.g. radon gas and cosmic radiation). This produces an average annual individual dose of approximately 2.6 mSv per year, although this varies according to local geology.

Effects of radiation exposure

Effects on the individual are classified as either deterministic or stochastic.

Deterministic effects

Deterministic (threshold) effects occur with increasing severity as the dose of radiation rises above a threshold level. Tissues with actively dividing cells, such as bone marrow and gastrointestinal mucosa, are particularly sensitive to ionising radiation. Lymphocyte depletion is the most sensitive marker of bone marrow injury, and after exposure to a fatal dose, marrow aplasia is a common cause of death. However, gastrointestinal mucosal toxicity may cause earlier death due to profound diarrhoea, vomiting, dehydration and sepsis. The gonads are highly radiosensitive and radiation may result in temporary or permanent sterility. Eye exposure can lead to cataracts and the skin is susceptible to radiation burns. Irradiation of the lung and central nervous system may induce acute inflammatory reactions, pulmonary fibrosis and permanent neurological deficit respectively. Bone necrosis and lymphatic fibrosis are characteristic following regional irradiation, particularly for breast cancer. The thyroid gland is not inherently sensitive but its ability to concentrate iodine makes it susceptible to damage after exposure to relatively low doses of radioactive iodine isotopes, such as were released from Chernobyl.

Stochastic effects

Stochastic (chance) effects occur with increasing probability as the dose of radiation increases. Carcinogenesis represents a stochastic effect. With acute exposures, leukaemias may arise after an interval of around 2–5 years and solid tumours after an interval of about 10–20 years. Thereafter the incidence rises with time. An individual's risk of developing cancer depends on the dose received, the time to accumulate the total dose and the interval following exposure.

Management of radiation exposure

The principal problems after large-dose exposures are maintenance of adequate hydration, control of sepsis and the management of marrow aplasia. Associated injuries such as thermal burns need specialist management within 48 hours of active resuscitation. Internal exposure to radioisotopes should be treated with chelating agents (such as Prussian blue used to chelate ^{137}-caesium after ingestion). White cell colony stimulation and haematopoietic stem cell transplantation may need to be considered for marrow aplasia.

Extremes of temperature

Thermoregulation

Body heat is generated by basal metabolic activity and muscle movement, and lost by conduction (which is more effective in water than in air), convection, evaporation and radiation (most important at lower temperatures when other mechanisms conserve heat) (Box 5.8). Body temperature is controlled in the hypothalamus, which is directly sensitive to changes in core temperature and indirectly responds to temperature-sensitive neurons in the skin. The normal 'set-point' of core

5.8 Thermoregulation: responses to hot and cold environments

	Mechanism	Hot environment	Cold environment
Heat production	Basal metabolic rate	→	↓ in hypothermia
	Muscle activity	↓ by lethargy	↑ by shivering ↓ in severe hypothermia
Heat loss	Conduction*	↑ by vasodilatation	↓ by vasoconstriction ↑↑ in water < 31°C
	Convection*	↑ by vasodilatation ↓ by lethargy	↓ by vasoconstriction ↑ by wind and movement
	Evaporation*	↑↑ by sweating ↓ by high humidity	↑ by hyperventilation
	Radiation	↑ by vasodilatation	↓ by vasoconstriction (but is the major heat loss in dry cold)

*These losses are dependent on the relative ambient and skin temperatures.

temperature is tightly regulated within 37 ± 0.5°C, which is necessary to preserve the normal function of many enzymes and other metabolic processes. The temperature set-point is increased in response to infection (p. 296).

In a cold environment, protective mechanisms include cutaneous vasoconstriction and shivering; however, any muscle activity that involves movement may promote heat loss by increasing convective loss from the skin, and respiratory heat loss by stimulating ventilation. In a hot environment, sweating is the main mechanism for increasing heat loss. This usually occurs when the ambient temperature rises above 32.5°C or during exercise.

Hypothermia

Hypothermia exists when the body's normal thermal regulatory mechanisms are unable to maintain heat in a cold environment and core temperature falls below 35°C (Fig. 5.3).

Whilst infants are susceptible to hypothermia because of their poor thermoregulation and high body surface area to weight ratio, it is the elderly who are at highest risk (Box 5.9). Hypothyroidism is often a contributory factor in old age, while alcohol and other drugs (e.g. phenothiazines) commonly impede the thermoregulatory response in younger people. More rarely, hypothermia is secondary to glucocorticoid insufficiency, stroke, hepatic failure or hypoglycaemia.

Hypothermia also occurs in healthy individuals whose thermoregulatory mechanisms are intact but insufficient to cope with the intensity of the thermal stress. Typical examples include immersion in cold water, when core temperature may fall rapidly (acute hypothermia), exposure to extreme climates such as during hill walking (subacute hypothermia), and slow-onset hypothermia, as develops in an immobilised older individual (subchronic hypothermia). This classification is important, as it determines the method of rewarming.

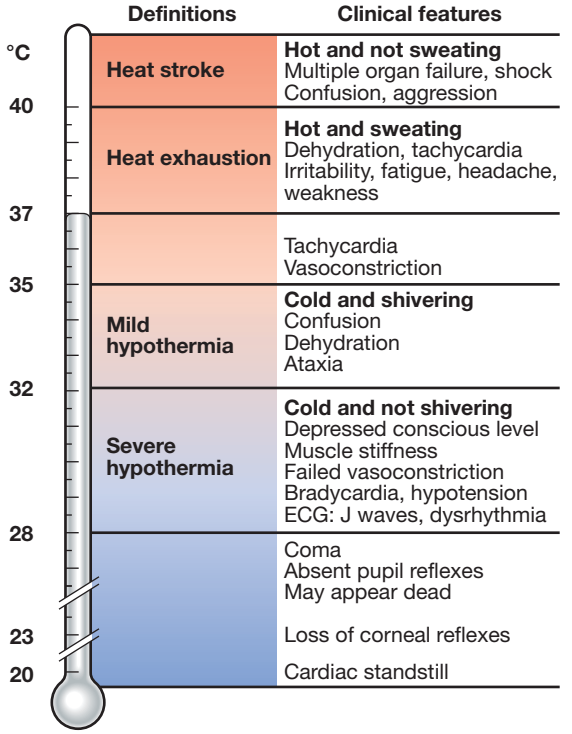

Fig. 5.3 Clinical features of abnormal core temperature. The hypothalamus normally maintains core temperature at 37°C, but this set-point is altered – for example, in fever (pyrexia, p. 296) – and may be lost in hypothalamic disease (p. 785). In these circumstances, the clinical picture at a given core temperature may be different.

Clinical features

Diagnosis is dependent on recognition of the environmental circumstances and measurement of core (rectal) body temperature. Clinical features depend on the degree of hypothermia (see Fig. 5.3).

In a cold patient, it is very difficult to diagnose death reliably by clinical means. It has been suggested that, in extreme environmental conditions, irreversible hypothermia is probably present if there is asystole (no carotid pulse for 1 minute), the chest and abdomen are rigid, the core temperature is below 13°C and serum potassium is > 12 mmol/L. However, in general, resuscitative measures should continue until the core temperature is normal and only then should a diagnosis of brain death be considered (p. 1161).

Investigations

Blood gases, a full blood count, electrolytes, chest X-ray and electrocardiogram (ECG) are all essential investigations. Haemoconcentration and metabolic acidosis are common, and the ECG may show characteristic J waves, which occur at the junction of the QRS complex and the ST segment (Fig. 5.4). Cardiac dysrhythmias, including ventricular fibrillation, may occur. Although the arterial oxygen tension may be normal when measured at room

5.9 Thermoregulation in old age

- **Age-associated changes**: impairments in vasomotor function, skeletal muscle response and sweating mean that older people react more slowly to changes in temperature.
- **Increased comorbidity**: thermoregulatory problems are more likely in the presence of pathology such as atherosclerosis and hypothyroidism, and medication such as sedatives and hypnotics.
- **Hypothermia**: may arise as a primary event, but more commonly complicates other acute illness, e.g. pneumonia, stroke or fracture.
- **Ambient temperature**: financial pressures and older equipment may result in inadequate heating during cold weather.

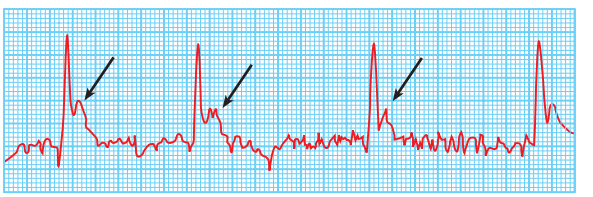

Fig. 5.4 Electrocardiogram showing J waves (arrows) in a hypothermic patient.

temperature, the arterial PO_2 in the blood falls by 7% for each 1°C fall in core temperature. Serum aspartate aminotransferase and creatine kinase may be elevated secondary to muscle damage and the serum amylase is often high due to subclinical pancreatitis. If the cause of hypothermia is not obvious, additional investigations for thyroid and pituitary dysfunction (p. 737), hypoglycaemia (p. 807) and the possibility of drug intoxication (p. 209) should be performed.

Management

Following resuscitation, the objectives of management are to rewarm the patient in a controlled manner while treating associated hypoxia (by oxygenation and ventilation if necessary), fluid and electrolyte disturbance, and cardiovascular abnormalities, particularly dysrhythmias. Careful handling is essential to avoid precipitating the latter. The method of rewarming is dependent not on the absolute core temperature, but on haemodynamic stability and the presence or absence of an effective cardiac output.

Mild hypothermia

Outdoors, continued heat loss is prevented by sheltering the patient from the cold, replacing wet clothing, covering the head and insulating him or her from the ground. Once in hospital, even in the presence of profound hypothermia, if there is an effective cardiac output then forced-air rewarming, heat packs placed in axilla, groin and around the abdomen, inhaled warmed air and correction of fluid and electrolyte disturbances are usually sufficient. Rewarming rates of 1–2°C per hour are effective in leading to a gradual and safe return to physiological normality. Underlying conditions should be treated promptly (e.g. hypothyroidism with triiodothyronine 10 µg IV 3 times daily; p. 743).

Severe hypothermia

In the case of severe hypothermia with cardiopulmonary arrest (non-perfusing rhythm), the aim is to restore perfusion, and rapid rewarming at a rate greater than 2°C per hour is required. This is best achieved by cardiopulmonary bypass or extracorporeal membrane oxygenation. If these are unavailable, then veno–veno haemofiltration, and pleural, peritoneal, thoracic or bladder lavage with warmed fluids are alternatives. Monitoring of cardiac rhythm and arterial blood gases, including H^+ (pH) is essential. Significant acidosis may require correction (p. 445).

Cold injury

Freezing cold injury (frostbite)

This represents the direct freezing of body tissues and usually affects the extremities: in particular, the fingers, toes, ears and face. Risk factors include smoking, peripheral vascular disease, dehydration and alcohol consumption. The tissues may become anaesthetised before freezing and, as a result, the injury often goes unrecognised at first. Frostbitten tissue is initially pale and doughy to the touch and insensitive to pain (Fig. 5.5). Once frozen, the tissue is hard.

Rewarming should not occur until it can be achieved rapidly in a water bath. Give oxygen and aspirin 300 mg as soon as possible. Frostbitten extremities should be rewarmed in warm water at 37–39°C, with antiseptic added. Adequate analgesia is necessary, as rewarming is very painful. Vasodilators such as pentoxifylline (a phosphodiesterase inhibitor) have been shown to improve tissue survival. Once it has thawed, the injured part must not be re-exposed to the cold, and should be dressed and rested. Whilst wound débridement may be necessary, amputations should be delayed for 60–90 days, as good recovery may occur over an extended period.

Fig. 5.5 Frostbite in a female Everest sherpa.

Non-freezing cold injury (trench or immersion foot)

This results from prolonged exposure to cold, damp conditions. The limb (usually the foot) appears cold, ischaemic and numb, but there is no freezing of the tissue. On rewarming, the limb appears mottled and thereafter becomes hyperaemic, swollen and painful. Recovery may take many months, during which there may be chronic pain and sensitivity to cold. The pathology remains uncertain but probably involves endothelial injury. Gradual rewarming is associated with less pain than rapid rewarming. The pain and associated paraesthesia are difficult to control with conventional analgesia and may require amitriptyline (50 mg nocte), best instituted early. The patient is at risk of further damage on subsequent exposure to the cold.

Chilblains

Chilblains are tender, red or purplish skin lesions that occur in the cold and wet. They are often seen in horse riders, cyclists and swimmers, and are more common in women than men. They are short-lived, and although painful, not usually serious.

Heat-related illness

When generation of heat exceeds the body's capacity for heat loss, core temperature rises. Non-exertional heat illness (NEHI) occurs with high environmental temperature in those with attenuated thermoregulatory control mechanisms: the elderly, the young, those with comorbidity or those taking drugs that affect thermoregulation (particularly phenothiazines, diuretics and alcohol). Exertional heat illness (EHI), on the other hand, typically develops in athletes when heat production exceeds the body's ability to dissipate it.

5.10 Differential diagnosis in patients with elevated core body temperature

- Heat illness (heat exhaustion, heat stroke)
- Sepsis, including meningitis
- Malaria
- Drug overdose
- Malignant hyperpyrexia
- Thyroid storm (p. 742)

Acclimatisation mechanisms to environmental heat include stimulation of the sweat mechanism with increased sweat volume, reduced sweat sodium content and secondary hyperaldosteronism to maintain body sodium balance. The risk of heat-related illness falls as acclimatisation occurs. Heat illness can be prevented to a large extent by adequate replacement of salt and water, although excessive water intake alone should be avoided because of the risk of dilutional hyponatraemia (p. 437).

A spectrum of illnesses occurs in the heat (see Fig. 5.3). The cause is usually obvious but the differential diagnosis should be considered (Box 5.10).

Heat cramps

These painful muscle contractions occur following vigorous exercise and profuse sweating in hot weather. There is no elevation of core temperature. The mechanism is considered to be extracellular sodium depletion as a result of persistent sweating, exacerbated by replacement of water but not salt. Symptoms usually respond rapidly to rehydration with oral rehydration salts or intravenous saline.

Heat syncope

This is similar to a vasovagal faint (p. 555) and is related to peripheral vasodilatation in hot weather.

Heat exhaustion

Heat exhaustion occurs with prolonged exertion in hot and humid weather, profuse sweating and inadequate salt and water replacement. There is an elevation in core (rectal) temperature to between 37°C and 40°C, leading to the clinical features shown in Figure 5.3. Blood analyses may show evidence of dehydration with mild elevation of the blood urea, sodium and haematocrit. Treatment involves removal of the patient from the heat, and active evaporative cooling using tepid sprays and fanning (strip–spray–fan). Fluid losses are replaced with either oral rehydration mixtures or intravenous isotonic saline. Up to 5 L positive fluid balance may be required in the first 24 hours. Untreated, heat exhaustion may progress to heat stroke.

Heat stroke

Heat stroke occurs when the core body temperature rises above 40°C and is a life-threatening condition. The symptoms of heat exhaustion progress to include headache, nausea and vomiting. Neurological manifestations include a coarse muscle tremor and confusion, aggression or loss of consciousness. The patient's skin feels very hot, and sweating is often absent due to failure of thermoregulatory mechanisms. Complications include hypovolaemic shock, lactic acidosis, disseminated intravascular coagulation, rhabdomyolysis, hepatic and renal failure, and pulmonary and cerebral oedema.

The patient should be resuscitated with rapid cooling by spraying with water, fanning and ice packs in the axillae and groins. Cold crystalloid intravenous fluids are given but solutions containing potassium should be avoided. Over-aggressive fluid replacement must be avoided, as it may precipitate pulmonary oedema or further metabolic disturbance. Appropriate monitoring of fluid balance, including central venous pressure, is important. Investigations for complications include routine haematology and biochemistry, coagulation screen, hepatic transaminases (aspartate aminotransferase and alanine aminotransferase), creatine kinase and chest X-ray. Once emergency treatment is established, heat stroke patients are best managed in intensive care.

With appropriate treatment, recovery from heat stroke can be rapid (within 1–2 hours) but patients who have had core temperatures higher than 40°C should be monitored carefully for later onset of rhabdomyolysis, renal damage and other complications before discharge from hospital. Clear advice to avoid heat and heavy exercise during recovery is important.

High altitude

The physiological effects of high altitude are significant. On Everest, the barometric pressure of the atmosphere falls from sea level by approximately 50% at base camp (5400 m) and approximately 70% at the summit (8848 m). The proportions of oxygen, nitrogen and carbon dioxide in air do not change with the fall in pressure but their partial pressure falls in proportion to barometric pressure (Fig. 5.6). Oxygen tension within the pulmonary alveoli is further reduced at altitude because the partial pressure of water vapour is related to body temperature and not barometric pressure, and so is proportionately greater at altitude, accounting for only 6% of barometric pressure at sea level, but 19% at 8848 m.

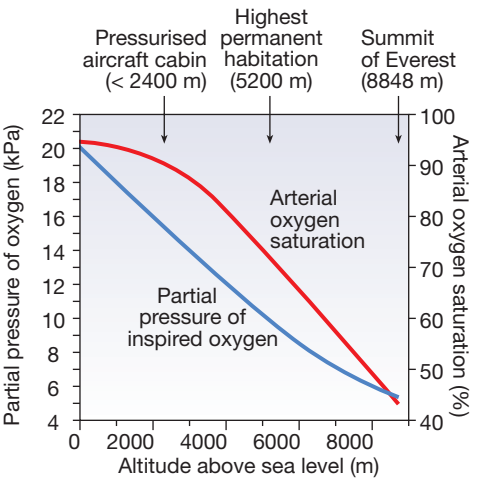

Fig. 5.6 Change in inspired oxygen tension and blood oxygen saturation at altitude. The blue curve shows changes in oxygen availability at altitude and the red curve shows the typical resultant changes in arterial oxygen saturation in a healthy person. Oxygen saturation varies between individuals according to the shape of the oxygen–haemoglobin dissociation curve and the ventilatory response to hypoxaemia. (To convert kPa to mmHg, multiply by 7.5.)

Physiological effects of high altitude

Reduction in oxygen tension results in a fall in arterial oxygen saturation (see Fig. 5.6). This varies widely between individuals, depending on the shape of the sigmoid oxygen–haemoglobin dissociation curve (see Fig. 8.3, p. 183) and the ventilatory response. Acclimatisation to hypoxaemia at high altitude involves a shift in this dissociation curve (dependent on 2,3-diphosphoglycerate (DPG)), erythropoiesis, haemoconcentration, and hyperventilation resulting from hypoxic drive (which is then sustained despite hypocapnia by restoration of cerebrospinal fluid pH to normal in prolonged hypoxia). This process takes several days, so travellers need to plan accordingly.

Illnesses at high altitude

Ascent to altitudes up to 2500 m or travel in a pressurised aircraft cabin is harmless to healthy people. Above 2500 m high-altitude illnesses may occur in previously healthy people, and above 3500 m these become common. Sudden ascent to altitudes above 6000 m, as experienced by aviators, balloonists and astronauts, may result in decompression illness with the same clinical features as seen in divers (see below), or even loss of consciousness. However, most altitude illness occurs in travellers and mountaineers.

Acute mountain sickness

Acute mountain sickness (AMS) is a syndrome comprised principally of headache, together with fatigue, anorexia, nausea and vomiting, difficulty sleeping or dizziness. Ataxia and peripheral oedema may be present. Its aetiology is not fully understood but it is thought that hypoxaemia increases cerebral blood flow and hence intracranial pressure. Symptoms occur within 6–12 hours of an ascent and vary in severity from trivial to completely incapacitating. The incidence in travellers to 3000 m may be 40–50%, depending on the rate of ascent.

Treatment of mild cases consists of rest and simple analgesia; symptoms usually resolve after 1–3 days at a stable altitude, but may recur with further ascent. Occasionally there is progression to cerebral oedema. Persistent symptoms indicate the need to descend but may respond to acetazolamide, a carbonic anhydrase inhibitor that induces a metabolic acidosis and stimulates ventilation; acetazolamide may also be used as prophylaxis if a rapid ascent is planned.

High-altitude cerebral oedema

The cardinal symptoms of high-altitude cerebral oedema (HACE) are ataxia and altered consciousness. This is rare, life-threatening and usually preceded by AMS. In addition to features of AMS, the patient suffers confusion, disorientation, visual disturbance, lethargy and ultimately loss of consciousness. Papilloedema and retinal haemorrhages are common and focal neurological signs may be found.

Treatment is directed at improving oxygenation. Descent is essential and dexamethasone (8 mg immediately and 4 mg 4 times daily) should be given. If descent is impossible, oxygen therapy in a portable pressurised bag may be helpful.

High-altitude pulmonary oedema

High-altitude pulmonary oedema (HAPE) is a life-threatening condition that usually occurs in the first 4 days after ascent above 2500 m. Unlike HACE, HAPE may occur de novo without the preceding signs of AMS. Presentation is with symptoms of dry cough, exertional dyspnoea and extreme fatigue. Later, the cough becomes wet and sputum may be blood-stained. Tachycardia and tachypnoea occur at rest and crepitations may often be heard in both lung fields. There may be profound hypoxaemia, pulmonary hypertension and radiological evidence of diffuse alveolar oedema. It is not known whether the alveolar oedema is a result of mechanical stress on the pulmonary capillaries associated with the high pulmonary arterial pressure, or an effect of hypoxia on capillary permeability. Reduced arterial oxygen saturation is not diagnostic but is a marker for disease progression.

Treatment is directed at reversal of hypoxia with immediate descent and oxygen administration. Nifedipine (20 mg 4 times daily) should be given to reduce pulmonary arterial pressure, and oxygen therapy in a portable pressurised bag should be used if descent is delayed.

Chronic mountain sickness (Monge's disease)

This occurs on prolonged exposure to altitude and has been reported in residents of Colorado, South America and Tibet. Patients present with headache, poor concentration and other signs of polycythaemia. They are cyanosed and often have finger clubbing.

High-altitude retinal haemorrhage

This occurs in over 30% of trekkers at 5000 m. The haemorrhages are usually asymptomatic and resolve spontaneously. Visual defects can occur with haemorrhage involving the macula, but there is no specific treatment.

Venous thrombosis

This has been reported at altitudes over 6000 m. Risk factors include dehydration, inactivity and the cold. The use of the oral contraceptive pill at high altitude should be considered carefully, as this is an additional risk factor.

Refractory cough

A cough at high altitude is common and usually benign. It may be due to breathing dry, cold air and increased mouth breathing, with consequent dry oral mucosa. This may be indistinguishable from the early signs of HAPE.

Air travel

Commercial aircraft usually cruise at 10000–12000 m, with the cabin pressurised to an equivalent of around 2400 m. At this altitude, the partial pressure of oxygen is 16 kPa (120 mmHg), leading to a PaO_2 in healthy people of 7.0–8.5 kPa (53–64 mmHg). Oxygen saturation is also reduced, but to a lesser degree (see Fig. 5.6). Although well tolerated by healthy people, this degree of hypoxia may be dangerous in patients with respiratory disease.

Advice for patients with respiratory disease

The British Thoracic Society has published guidance on the management of patients with respiratory disease who want to fly. Specialist pre-flight assessment is advised for all patients who have hypoxaemia (oxygen saturation < 95%) at sea level, and includes spirometry and a hypoxic challenge test with 15% oxygen (performed in hospital). Air travel may have to be avoided or undertaken only with inspired oxygen therapy during the flight. Asthmatic patients should be advised to carry their inhalers in their hand baggage. Following pneumothorax, flying should be avoided while air remains in the pleural cavity, but can be considered after proven resolution or definitive (surgical) treatment.

Advice for other patients

Other circumstances in which patients are more susceptible to hypoxia require individual assessment. These include cardiac dysrhythmia, sickle-cell disease and ischaemic heart disease. Most airlines decline to carry pregnant women after the 36th week of gestation. In complicated pregnancies it may be advisable to avoid air travel at an earlier stage. Patients who have had recent abdominal surgery, including laparoscopy, should avoid flying until all intraperitoneal gas is reabsorbed. Divers should not fly for 24 hours after a dive requiring decompression stops.

Ear and sinus pain due to changes in gas volume are common but usually mild, although patients with chronic sinusitis and otitis media may need specialist assessment. A healthy mobile tympanic membrane visualised during a Valsalva manœuvre usually suggests a patent Eustachian tube.

On long-haul flights, patients with diabetes mellitus may need to adjust their insulin or oral hypoglycaemic dosing according to the timing of in-flight and subsequent meals (p. 825). Advice is available from Diabetes UK and other websites. Patients should be able to provide documentary evidence of the need to carry needles and insulin.

Deep venous thrombosis

Air travellers have an increased risk of venous thrombosis (p. 1008), due to a combination of factors, including loss of venous emptying because of prolonged immobilisation (lack of muscular activity) and reduced barometric pressure on the tissues, together with haemoconcentration as a result of oedema and perhaps a degree of hypoxia-induced diuresis.

Venous thrombosis can probably be prevented by avoiding dehydration and excess alcohol, and exercising muscles during the flight. Without a clear cost–benefit analysis, prophylaxis with aspirin or heparin cannot be recommended routinely, but may be considered in high-risk cases.

Under water

Drowning and near-drowning

Drowning is defined as death due to asphyxiation following immersion in a fluid, whilst near-drowning is defined as survival for longer than 24 hours after suffocation by immersion. Drowning remains a common cause of accidental death throughout the world and is particularly common in young children (Box 5.11). In about 10% of cases, no water enters the lungs and death follows intense laryngospasm ('dry' drowning). Prolonged immersion in cold water, with or without water inhalation, results in a rapid fall in core body temperature and hypothermia (p. 104).

5.11 Most common causes of drowning by age

Infants/young children	
• Domestic baths	• Garden pools
Adolescents	
• Swimming pools	• Rivers, sea, etc.
Adults	
• Water sports, boating, fishing	• Occupational
Older people	
• Domestic baths	

Following inhalation of water, there is a rapid onset of ventilation–perfusion imbalance with hypoxaemia, and the development of diffuse pulmonary oedema. Fresh water is hypotonic and, although rapidly absorbed across alveolar membranes, impairs surfactant function, which leads to alveolar collapse and right-to-left shunting of unoxygenated blood. Absorption of large amounts of hypotonic fluid can result in haemolysis. Salt water is hypertonic and inhalation provokes alveolar oedema, but the overall clinical effect is similar to that of freshwater drowning.

Clinical features

Those rescued alive (near-drowning) are often unconscious and not breathing. Hypoxaemia and metabolic acidosis are inevitable features. Acute lung injury usually resolves rapidly over 48–72 hours, unless infection occurs (Fig. 5.7). Complications include dehydration, hypotension, haemoptysis, rhabdomyolysis, renal failure and cardiac dysrhythmias. A small number of patients, mainly the more severely ill, progress to develop the acute respiratory distress syndrome (ARDS; p. 192).

Survival is possible after immersion for up to 30 minutes in very cold water, as the rapid development of hypothermia after immersion may be protective, particularly in children. Long-term outcome depends on the severity of the cerebral hypoxic injury and is predicted by the duration of immersion, delay in resuscitation, intensity of acidosis and the presence of cardiac arrest.

Management

Initial management requires cardiopulmonary resuscitation with administration of oxygen and maintenance of the circulation (p. 558). It is important to clear the airway of foreign bodies and protect the cervical spine. Continuous positive airways pressure (CPAP; p. 193) should be considered for spontaneously breathing patients with oxygen saturations below 94%. Observation is required for a minimum of 24 hours. Prophylactic antibiotics are only required if exposure was to obviously contaminated water.

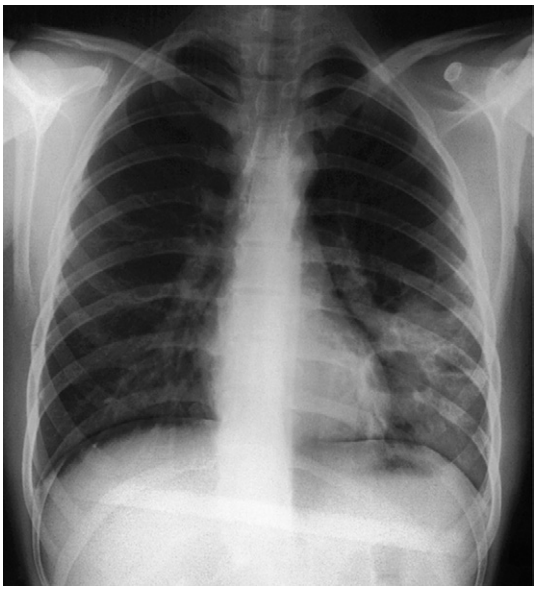

Fig. 5.7 Near-drowning. Chest X-ray of a 39-year-old farmer, 2 weeks after immersion in a polluted freshwater ditch for 5 minutes before rescue. Airspace consolidation and cavities in the left lower lobe reflect secondary staphylococcal pneumonia and abscess formation.

Diving-related illness

The underwater environment is extremely hostile. Other than drowning, most diving illness is related to changes in barometric pressure and its effect on gas behaviour.

Ambient pressure under water increases by 101 kPa (1 atmosphere) for every 10 metres of seawater (msw) depth. As divers descend, the partial pressures of the gases they are breathing increase (Box 5.12), and the blood and tissue concentrations of dissolved gases rise accordingly. Nitrogen is a weak anaesthetic agent, and if the inspiratory pressure of nitrogen is allowed to increase above –320 kPa (i.e. a depth of approximately 30 msw), it produces 'narcosis', resulting in impairment of cognitive function and manual dexterity, not unlike alcohol intoxication. For this reason, compressed air can only be used for shallow diving. Oxygen is also toxic at inspired pressures above approximately 40 kPa (inducing apprehension, muscle twitching, euphoria, sweating, tinnitus, nausea and vertigo), so 100% oxygen cannot be used as an alternative. For dives deeper than approximately 30 msw, mixtures of oxygen with nitrogen and/or helium are used.

Whilst drowning remains the most common diving-related cause of death, another important group of disorders usually present once the diver returns to the surface: decompression illness (DCI) and barotrauma.

5.12 Physics of breathing compressed air while diving in sea water

Depth	Lung volume	Barometric pressure	PiO_2	PiN_2
Surface	100%	101 kPa (1 atmos)	21 kPa	79 kPa
10 m	50%	202 kPa (2 atmos)	42 kPa	159 kPa
20 m	33%	303 kPa (3 atmos)	63 kPa	239 kPa
30 m	25%	404 kPa (4 atmos)	84 kPa	319 kPa

5.13 Assessment of a patient with decompression illness*

Evolution

- Progressive
- Static
- Relapsing
- Spontaneously improving

Manifestations

- Pain: often large joints, e.g. shoulder ('the bends')
- Neurological: any deficit is possible
- Audiovestibular: vertigo, tinnitus, nystagmus; may mimic inner ear barotrauma
- Pulmonary: chest pain, cough, haemoptysis, dyspnoea; may be due to arterial gas embolism
- Cutaneous: itching, erythematous rash
- Lymphatic: tender lymph nodes, oedema
- Constitutional: headache, fatigue, general malaise

Dive profile

- Depth
- Type of gas used
- Duration of dive

*Information required by diving specialists to decide appropriate treatment. See contact details on page 132.

Clinical features

Decompression illness

This includes decompression sickness (DCS) and arterial gas embolism (AGE). Whilst the vast majority of symptoms of decompression illness present within 6 hours of a dive, they can also be provoked by flying and thus patients may present to medical services at sites far removed from the dive.

Exposure of individuals to increased partial pressures of nitrogen results in additional nitrogen being dissolved in body tissues; the amount dissolved depends on the depth/pressure and on the duration of the dive. On ascent, the tissues become supersaturated with nitrogen, and this places the diver at risk of producing a critical quantity of gas (bubbles) in tissues if the ascent is too fast. The gas so formed may cause symptoms locally, by bubbles passing through the pulmonary vascular bed (Box 5.13) or by embolisation elsewhere. Arterial embolisation may occur if the gas load in the venous system exceeds the lungs' abilities to excrete nitrogen, or when bubbles pass through a patent foramen ovale (present asymptomatically in 25–30% of adults; p. 528). Although DCS and AGE can be indistinguishable, their early treatment is the same.

Barotrauma

During the ascent phase of a dive, the gas in the diver's lungs expands due to the decreasing pressure. The diver must therefore ascend slowly and breathe regularly; if ascent is rapid or the diver holds his/her breath, the expanding gas may cause lung rupture (pulmonary barotrauma). This can result in pneumomediastinum, pneumothorax or AGE due to gas passing directly into the pulmonary venous system. Other air-filled body cavities may be subject to barotrauma, including the ear and sinuses.

Management

The patient is nursed horizontally, and airway, breathing and circulation are assessed. Treatment includes the following:

- *High-flow oxygen* is given by a tight-fitting mask using a rebreathing bag. This assists in the washout of excess inert gas (nitrogen) and may reduce the extent of local tissue hypoxia resulting from focal embolic injury.
- *Fluid replacement* (oral or intravenous) corrects the intravascular fluid loss from endothelial bubble injury and the dehydration associated with immersion. Maintenance of an adequate peripheral circulation is important for the excretion of excess dissolved gas.
- *Recompression* is the definitive therapy. Transfer to a recompression chamber facility may be by surface or air, provided that the altitude remains low (< 300 m) and the patient continues to breathe 100% oxygen. Recompression reduces the volume of gas within tissues and puts nitrogen back into solution.

The majority of patients make a complete recovery with treatment, although a small but significant proportion are left with neurological disability.

NUTRITIONAL FACTORS AND DISEASE

Obtaining adequate nutrition is a fundamental requirement for survival of every individual and species. The politics of food provision for humans are complex, and constitute a prominent factor in wars, natural disasters and the global economy. In recent decades, economic success has been rewarded by plentiful nutrition unknown to previous generations, which has led to a pandemic of obesity and its serious consequences for health. Yet, in many parts of the world, famine and under-nutrition still represent a huge burden. Quality, as well as quantity, of food influences health, with governmental advice on healthy diets maximising fruit and vegetable intakes (Fig. 5.8). Inappropriate diets have been linked with diseases such as coronary heart disease and cancer. Deficiencies of simple vitamins or minerals lead to avoidable conditions such as anaemia due to iron deficiency or blindness due to severe vitamin A deficiency. A proper understanding of nutrition is therefore essential in dealing with the needs of individual patients and to inform the planning of public policy.

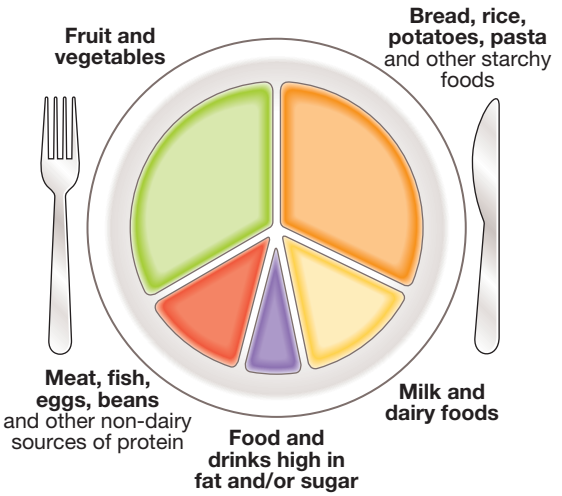

Fig. 5.8 Proportion of key food groups recommended for a healthy, well-balanced diet. Crown copyright – see p. 132.

Physiology of nutrition

Nutrients in the diet can be classified into 'macronutrients', which are eaten in relatively large amounts to provide fuel for energy, and 'micronutrients' (e.g. vitamins and minerals), which do not contribute to energy balance but are required in small amounts because they are not synthesised in the body.

Energy balance

The laws of thermodynamics dictate that energy balance is achieved when energy intake = energy expenditure (Fig. 5.9).

Energy expenditure has several components. The basal metabolic rate (BMR) describes the obligatory energy expenditure required to maintain metabolic functions in tissues and hence sustain life. It is most closely predicted by fat-free mass (i.e. total body mass minus fat mass), which is lower in females and older people (Fig. 5.9B). Extra metabolic energy is consumed during growth, pregnancy and lactation, and when febrile. Metabolic energy is also required for thermal regulation, and expenditure is higher in cold or hot environments. The energy required for digestion of food (diet-induced thermogenesis (DIT); Fig. 5.9D) accounts for approximately 10% of total energy expenditure, with protein requiring more energy than other macronutrients. Another component of energy expenditure is governed by the level of muscular activity, which can vary considerably with occupation and lifestyle (Fig. 5.9C). Physical activity levels are usually defined as multiples of BMR.

Energy intake is determined by the 'macronutrient' content of food. Carbohydrates, fat, protein and alcohol provide fuel for oxidation in the mitochondria to generate energy (as adenosine triphosphate (ATP); p. 45). The energy provided by each of these elements differs:

- carbohydrates (16 kJ/g)
- fat (37 kJ/g)
- protein (17 kJ/g)
- alcohol (29 kJ/g).

Regulation of energy balance

Energy intake and expenditure are highly regulated (Fig. 5.10). A link with reproductive function ensures that pregnancy is most likely to occur during times of nutritional plenty when both mother and baby have a better chance of survival. Improved nutrition is thought to be the reason for the increasingly early onset of puberty in many societies. At the other extreme, anorexia nervosa and excessive exercise can lead to amenorrhoea (p. 255).

Regulation of energy balance is coordinated in the hypothalamus, which receives afferent signals that indicate nutritional status in the short term (e.g. the stomach

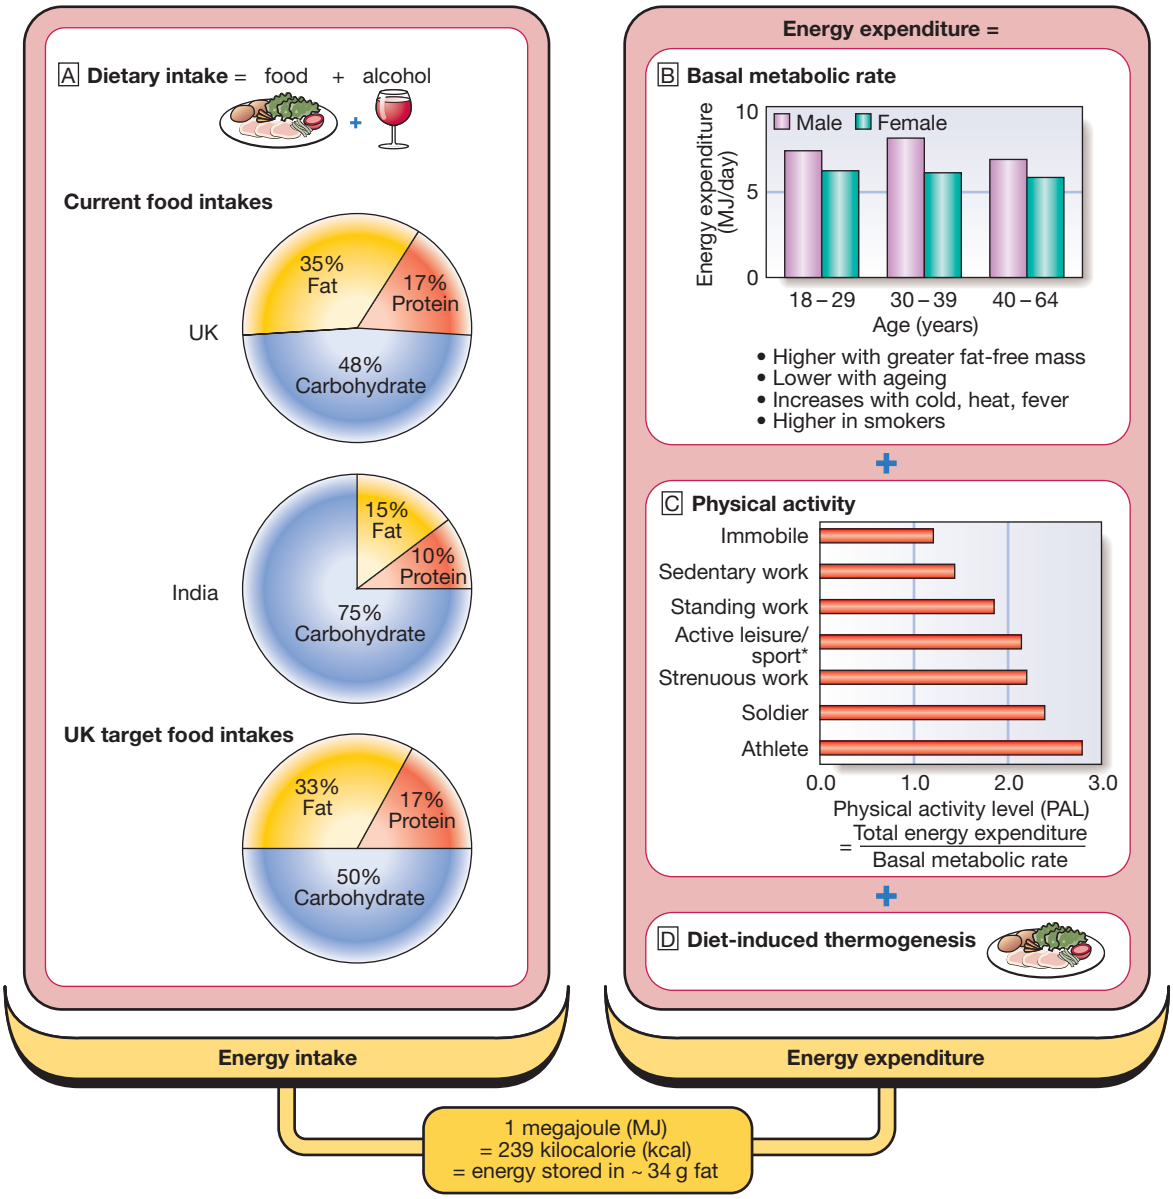

Fig. 5.9 Determinants of energy balance. A Energy intake is shown as national averages, highlighting the differences in sources of energy in different countries (but obscuring substantial regional variations). The targets are recommendations as a percentage of food energy only (Source: Dept of Health 1991). For WHO target, see Box 5.17 (p. 114). In the UK, it is assumed that 5% of energy intake will be derived from alcohol. B Data for normal basal metabolic rate (BMR) were obtained from healthy men and women in various countries. BMR declines from middle age and is lower in women, even after adjustment for body size because of differences in fat-free mass. C Energy is required for movement and activity. Physical activity level (PAL) is the multiple of BMR by which total energy expenditure is increased by activity. D Energy is consumed in order to digest food. Leisure or sport activity increases PAL by –0.3 for each 30–60 minutes of moderate exercise performed 4–5 times per week. The UK population median for PAL is 1.6, with estimates of 1.5 for the 'less active' and 1.8 for the 'more active'.

hormone ghrelin, which falls immediately after eating and rises gradually thereafter, to suppress satiety and signal that it is time for the next meal) and the long term (e.g. the adipose hormone leptin, which increases with growing fat mass and may also link fat mass to reproductive function). The hypothalamus responds with changes in many local neurotransmitters that alter activity in a number of pathways that influence energy balance (see Fig. 5.10), including hormones acting on the pituitary gland (see Fig. 20.2, p. 737), and neural control circuits that connect with the cerebral cortex and autonomic nervous system.

Responses to under- and over-nutrition

These complex regulatory pathways allow adaptation to variations in nutrition. In response to starvation, reproductive function is suppressed, BMR is reduced, and there are profound psychological effects, including energy conservation through lethargy. These adjustments can 'defend' body weight within certain limits.

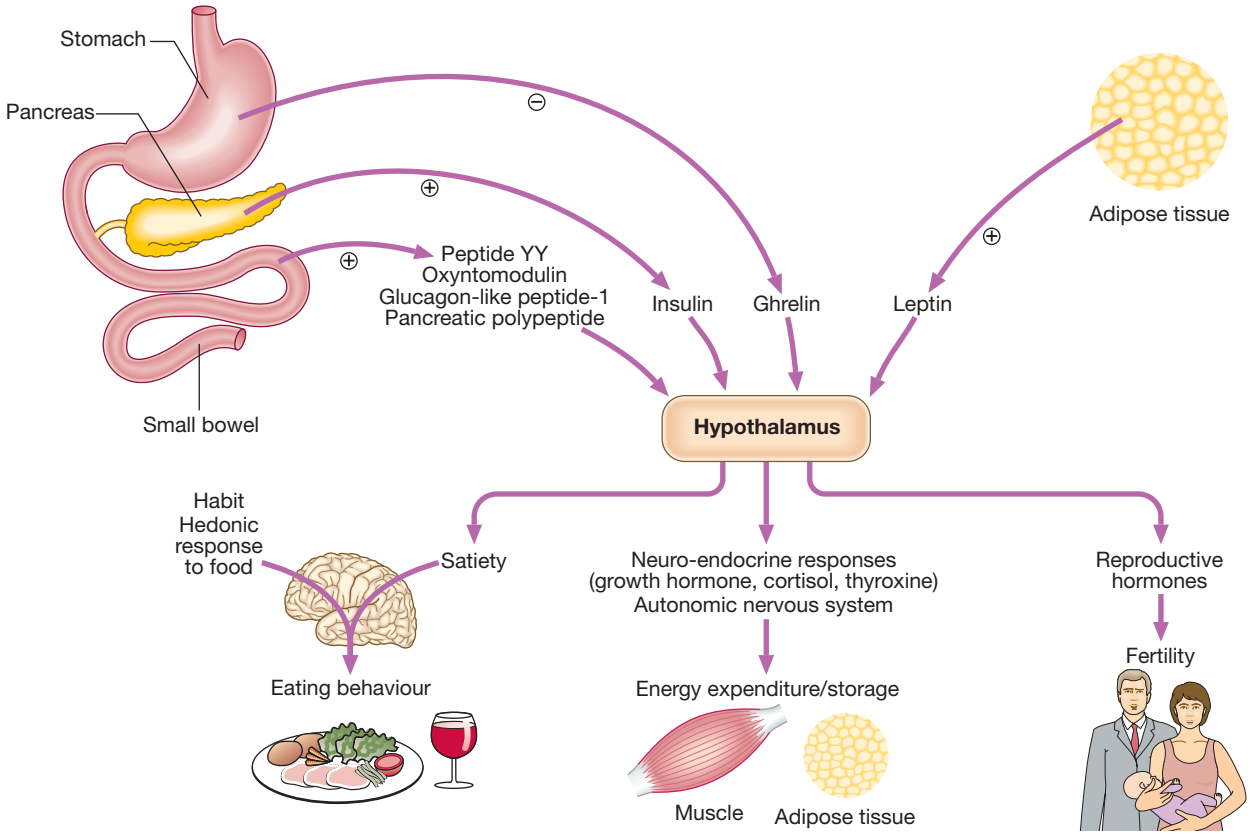

Fig. 5.10 Regulation of energy balance and its link with reproduction. ⊕ indicates factors that are stimulated by eating and induce satiety. ⊖ indicates factors that are suppressed by eating and inhibit satiety.

However, in the low-insulin state of starvation (see Fig. 21.2, p. 801), fuels are liberated from stores initially in glycogen (in liver and muscle), then in triglyceride (lipolysis in adipose tissue, with excess free fatty acid supply to the liver leading to ketosis) and finally in protein (proteolysis in muscle).

In response to over-nutrition, BMR is increased, and extra energy is consumed in the work of carrying increased fat stores, so that body weight is again 'defended' within certain limits. In the high-insulin state of over-nutrition, excess energy is invested in fatty acids and stored as triglycerides; these are deposited principally in adipose tissue but they may also accumulate in the liver (non-alcoholic fatty liver disease; p. 959) and skeletal muscle. In the absence of hypothalamic function (e.g. in those with craniopharyngioma; see Fig. 20.30, p. 794) or in rare patients with mutations in relevant genes (e.g. in leptin or melanocortin-4 receptors), loss of response to satiety signals, together with loss of adaptive changes in energy expenditure, result in relentless weight gain.

Macronutrients (energy-yielding nutrients)

Carbohydrates

Types of carbohydrate and their dietary sources are listed in Box 5.14. The 'available' carbohydrates (starches and sugars) are broken down to monosaccharides before absorption from the gut (p. 842), and supply over half the energy in a normal, well-balanced diet (see Fig. 5.9A). No individual carbohydrate is an essential nutrient, as carbohydrates can be synthesised de novo from glycerol or protein. However, if the available carbohydrate intake is less than 100 g per day, increased lipolysis leads to ketosis (see Fig. 21.5, p. 804).

Dietary guidelines do not restrict the intake of intrinsic sugars in fruit and vegetables or the sugars in milk. However, intake of non-milk extrinsic sugars (sucrose, maltose, fructose), which increase the risk of dental caries and diabetes mellitus, should be limited. Individuals who do not produce lactase ('lactose-intolerant') are advised to avoid or limit dairy products and foods with added lactose. Starches in cereal foods, root foods and legumes provide the largest proportion of energy in most diets around the world. All starches are polymers of glucose, linked by the same 1–4 glycosidic linkages. However, some starches are digested promptly by salivary and then pancreatic amylase, producing rapid delivery of glucose to the blood. Other starches are digested more slowly, either because they are protected in the structure of the food, because of their crystal structure, or because the molecule is unbranched (amylose). These differences are the basis for the 'glycaemic index' of foods. This is the area under the curve of the rise in blood glucose concentration in the 2 hours following ingestion of 50 g carbohydrate, expressed as a percentage of the response to 50 g anhydrous glucose. There is emerging evidence linking high glycaemic index foods with obesity and type 2 diabetes (p. 806).

5.14 Dietary carbohydrates

Class	Components	Examples	Source
Free sugars	Monosaccharides Disaccharides	Glucose, fructose Sucrose, lactose, maltose	Intrinsic: fruits, milks, vegetables Extrinsic (extracted, refined): beet or cane sucrose, high-fructose corn syrup
Short-chain carbohydrates	Oligosaccharides	Maltodextrins, fructo-oligosaccharides	
Starch polysaccharides	Rapidly digestible Slowly digestible Resistant		Cereals (wheat, rice), root vegetables (potato), legumes (lentils, beans, peas)
Non-starch polysaccharides (NSP, dietary fibre)	Fibrous Viscous	Cellulose Hemicellulose Pectins Gums	Plants
Sugar alcohols		Sorbitol, xylitol	Sorbitol: stone fruits (apples, peaches, prunes) Xylitol: maize, berry fruits Both used as low-calorie sugar alternatives

Sugar alcohols (e.g. sorbitol) that are used as replacement sweeteners can cause diarrhoea if eaten in large amounts.

Dietary fibre

Dietary fibre is plant food that is not digested by human enzymes in the gastrointestinal tract. Most dietary fibre is known as the 'non-starch polysaccharides' (NSP) (see Box 5.14). A small percentage of 'resistant' dietary starch may also pass unchanged into the large intestine. Dietary fibre can be broken down by the resident bacteria in the colon to produce short-chain fatty acids. This is essential fuel for the enterocytes and contributes to bowel health. The extent of flatus formed is dependent on the food source.

Some types of NSP, notably the hemicellulose of wheat, increase the water-holding capacity of colonic contents and the bulk of faeces. They relieve simple constipation, appear to prevent diverticulosis and may reduce the risk of cancer of the colon. Other viscous, indigestible polysaccharides like pectin and guar gum are important in the upper gastrointestinal tract, where they slow gastric emptying, contribute to satiety, and reduce bile salt absorption and hence plasma cholesterol concentration.

Fats

Fat has the highest energy density of the macronutrients (37 kJ/g) and excessive consumption may be an insidious cause of obesity (see Fig. 5.9A). Free fatty acids are absorbed in chylomicrons (pp. 450 and 841; see Fig. 22.5, p. 842), allowing access of complex molecules into the circulation. Fatty acid structures are shown in Figure 5.11. The principal polyunsaturated fatty acid (PUFA) in plant seed oils is linoleic acid (18:2 ω6). This and alpha-linolenic acid (18:3 ω3) are the 'essential' fatty acids, which humans cannot synthesise de novo. They undergo further desaturation and elongation, to produce, for example, γ-linolenic acid (18:3 ω6) and arachidonic acid (20:4 ω6). These are precursors of prostaglandins and eicosanoids, and form part of the structure of lipid membranes in all cells. Fish oils are rich in ω3 PUFA (e.g. eicosapentaenoic (20:5 ω3) and docosahexaenoic (22:6 ω3), which promote the anti-inflammatory cascade of prostaglandin production and occur in the lipids of the human brain and retina. They inhibit thrombosis by competitively antagonising thromboxane A_2 formation. Substituting saturated fat (i.e. from animal sources: butter, ghee or lard) with PUFA in the diet can lower the concentration of circulating low-density lipoprotein (LDL) cholesterol and may help prevent coronary heart disease. High intakes of *trans* fatty acids (TFA) (isomers of the natural *cis* fatty acids) reflect the use of oils that have been partially hydrogenated in the food industry. It is recommended that TFAs are limited to < 2% of the dietary fat intake, as they are associated with cardiovascular disease. Changes in industrial practice in the UK and US have meant that TFA intake is now below 1%, with the residual amounts coming from milk as a result of ruminant digestion.

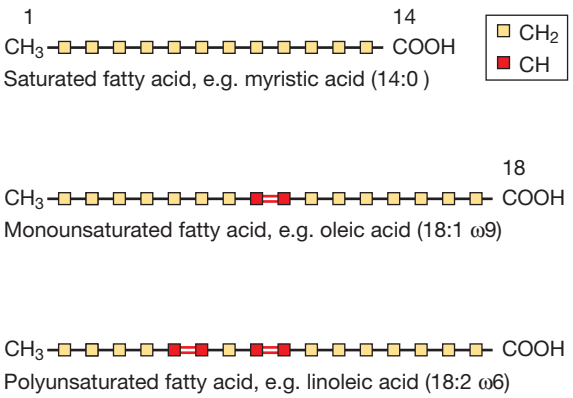

Fig. 5.11 Schematic representation of fatty acids. Standard nomenclature specifies the number of carbon atoms and indicates the number and position of the double bond(s) relative to the methyl ($-CH_3$, ω) end of the molecule after a colon.

Cholesterol is also absorbed directly from food in chylomicrons and is an important substrate for steroid and sterol synthesis, but not an important source of energy.

5.15 Amino acids

Essential amino acids

- Tryptophan
- Histidine
- Methionine
- Threonine
- Isoleucine
- Valine
- Phenylalanine
- Lysine
- Leucine

Conditionally essential amino acids and their precursors

- Cysteine: methionine, serine
- Tyrosine: phenylalanine
- Arginine: glutamine/glutamate, aspartate
- Proline: glutamate
- Glycine: serine, choline

Proteins

Proteins are made up of some 20 different amino acids, of which nine are 'essential' (Box 5.15), i.e. they cannot be synthesised in humans but are required for synthesis of important proteins. Another group of five amino acids are termed 'conditionally essential', meaning that they can be synthesised from other amino acids, provided there is an adequate dietary supply. The remaining amino acids can be synthesised in the body by transamination, provided there is a sufficient supply of amino groups.

The nutritive or 'biological' value of different proteins depends on the relative proportions of essential amino acids they contain. Proteins of animal origin, particularly from eggs, milk and meat, are generally of higher biological value than proteins of vegetable origin, which are low in one or more of the essential amino acids. However, when two different vegetable proteins are eaten together (e.g. a cereal and a legume), their amino acid contents are complementary and produce an adequate mix, an important principle in vegan diets.

Dietary recommendations for macronutrients

Recommendations for energy intake (Box 5.16) and proportions of macronutrients (Box 5.17) have been calculated to provide a balance of essential nutrients and minimise the risks of excessive refined sugar (dental caries, high glycaemic index/diabetes mellitus), saturated fat or *trans* fat (obesity, coronary heart disease). Recommended dietary fibre intake is based on avoiding risks of colonic disease. The usual recommended protein intake for a healthy man doing light work is 65–100 g/day. The minimum requirement is around 40 g of protein with a high proportion of essential amino acids or a high biological value.

5.16 Daily adult energy requirements in health

Circumstances	Daily requirements* Females	Males
At rest (basal metabolic rate)	5.4 MJ (1300 kcal)	6.7 MJ (1600 kcal)
Less active	8.0 MJ (1900 kcal)	9.9 MJ (2400 kcal)
Population median	8.8 MJ (2100 kcal)	10.8 MJ (2600 kcal)
More active	9.6 MJ (2300 kcal)	11.8 MJ (2800 kcal)

*These are based on a healthy target body mass index (BMI) of 22.5 kg/m^2. For a female, height is 162 cm and weight 59.0 kg; for a male, height is 175 cm and weight 68.8 kg. Previous average recommendations of 8.1 MJ (1950 kcal, usually rounded up to 2000 kcal) for females and 10.7 MJ (2500 kcal) for males should continue to be used, as these fall within experimental error.

5.17 WHO recommended population macronutrient goals

Nutrient (% of total energy unless indicated)	Target limits for average population intakes Lower	Upper
Total fat	15	30
Saturated fatty acids	0	10
Polyunsaturated fatty acids	6	10
Trans fatty acids	0	2
Dietary cholesterol (mg/day)	0	300
Total carbohydrate	55	75
Free sugars	0	10
Complex carbohydrate	50	70
Dietary fibre (g/day)		
As non-starch polysaccharides	16	24
As total dietary fibre	27	40
Protein	10	15

Clinical assessment and investigation of nutritional status

The diverse manifestations of inadequate nutrition dictate that its clinical assessment and investigation involve many systems. Energy balance is reflected in body composition, which is most readily assessed by clinical anthropometric measurements. It can also be tested non-invasively by the measurement of body fat by bio-impedance or dual energy X-ray absorptiometry (DEXA) scanning. Abnormal micronutrient status is commonly manifest in clinical signs in the skin and mucous membranes, or in other systems.

A dietary history provides useful information, especially when obtained by a dietitian. A weighed food diary is considered to be the gold standard dietary assessment but is rarely conducted in clinical practice.

Anthropometric measurements

Body mass index (BMI) is useful for categorising under- and over-nutrition. It is the weight in kilograms divided by the height in metres, squared. For example, an adult weighing 70 kg with a height of 1.75 m has a BMI of $70/1.75^2 = 22.9$ kg/m^2. If height cannot be determined (e.g. in older people with kyphosis or in those who cannot stand), a surrogate measure is:

- *the demispan*: measured from the sternal notch to the middle finger; height = 0.73 × (2 × demispan) + 0.43
- *knee height*:

females (60–80 years): height (cm) = (knee height (cm) × 1.91) – (age (years) × 0.17) + 75.00

males (60–80 years): height (cm) = (knee height (cm) × 2.05) + 59.01.

BMI does not discriminate between fat mass and lean body mass and can be increased by muscle mass (e.g. in athletes). Moreover, there are ethnic differences in body fat content; at the same BMI, Asians have more body fat than Europeans. For optimal health, the BMI should be 18.5–24.9 kg/m^2.

An indication of the degree of abdominal obesity is the waist circumference, measured at the level of the umbilicus. Hip circumference can be measured at the level of the greater trochanters; waist:hip ratios show whether the distribution of fat is android or gynoid (see below). Skinfold measurements can be used to calculate body fat content, whereas relative loss of muscle and subcutaneous fat can be estimated by measuring mid-arm circumference (at the middle of the humerus) and skinfold thickness over the triceps (using special callipers); muscle mass is estimated by subtracting triceps skinfold thickness from mid-arm circumference.

DISORDERS OF ALTERED ENERGY BALANCE

Obesity

Obesity is widely regarded as a pandemic, with potentially disastrous consequences for human health. Over one-quarter of adults in the UK were obese (i.e. BMI ≥ 30 kg/m^2) in 2010, compared with 7% prevalence in 1980 and 16% in 1995. Moreover, almost two-thirds of the UK adult population are overweight (BMI ≥ 25 kg/m^2), although there is considerable regional and age group variation. In developing countries, average national rates of obesity are low, but these figures may disguise high rates of obesity in urban communities; for example, nearly one-quarter of women in urban India are overweight.

There is increasing public awareness of the health implications of obesity. Many patients will seek medical help for their obesity, others will present with one of the complications of obesity, and increasing numbers are being identified during health screening examinations.

Complications of obesity

Obesity has adverse effects on both mortality and morbidity (Box 5.18). Changes in mortality are difficult to analyse due to the confounding effects of lower body weight in cigarette smokers and those with other illnesses (such as cancer). However, it is clear that the lowest mortality rates are seen in Europeans in the BMI range 18.5–24 kg/m^2 (and at lower BMI in Asians). It is suggested that obesity at age 40 years can reduce life expectancy by up to 7 years for non-smokers and by 13 years for smokers. Coronary heart disease (Fig. 5.12) is the major cause of death but cancer rates are also increased in the overweight, especially colorectal cancer in males and cancer of the gallbladder, biliary tract, breast, endometrium and cervix in females. Obesity has little effect on life expectancy above 70 years of age, but the obese do spend a greater proportion of their active life disabled. Epidemic obesity has been accompanied by an epidemic of type 2 diabetes (p. 806) and osteoarthritis, particularly of the knee. Although an increased body size results in greater bone density through increased mechanical stress, it is not certain whether this translates to a lower incidence of osteoporotic fractures (p. 1120). Obesity may have profound psychological consequences, compounded by stigmatisation of the obese in many societies.

5.18 Complications of obesity

Risk factors	Outcomes
'Metabolic syndrome' Type 2 diabetes Hypertension Hyperlipidaemia	 Coronary heart disease Stroke Diabetes complications
Liver fat accumulation	Non-alcoholic steatohepatitis Cirrhosis
Restricted ventilation	Exertional dyspnoea Obstructive sleep apnoea Obesity hypoventilation syndrome (Pickwickian syndrome)
Mechanical effects of weight	Urinary incontinence Osteoarthritis Varicose veins
Increased peripheral steroid interconversion in adipose tissue	Hormone-dependent cancers (breast, uterus) Polycystic ovarian syndrome (infertility, hirsutism; p. 764)
Others	Psychological morbidity (low self-esteem, depression) Socioeconomic disadvantage (lower income, less likely to be promoted) Gallstones Colorectal cancer Skin infections (groin and submammary candidiasis; hidradenitis)

Body fat distribution

For some complications of obesity, the distribution rather than the absolute amount of excess adipose tissue appears to be important. Increased intra-abdominal fat causes 'central' ('abdominal', 'visceral', 'android' or 'apple-shaped') obesity, which contrasts with subcutaneous fat accumulation causing 'generalised' ('gynoid' or 'pear-shaped') obesity; the former is more common in men and is more closely associated with type 2 diabetes, the metabolic syndrome and cardiovascular disease (see Box 5.18). The key difference between these depots of fat may lie in their vascular anatomy, with intra-abdominal fat draining into the portal vein and thence directly to the liver. Thus many factors that are released from adipose tissue (including free fatty acids; 'adipokines', such as tumour necrosis factor-α, adiponectin and resistin; and steroid hormones) may be at higher concentration in the liver and hence induce insulin resistance and promote type 2 diabetes (p. 805). Recent research has also highlighted the importance of fat deposition within specific organs, especially the

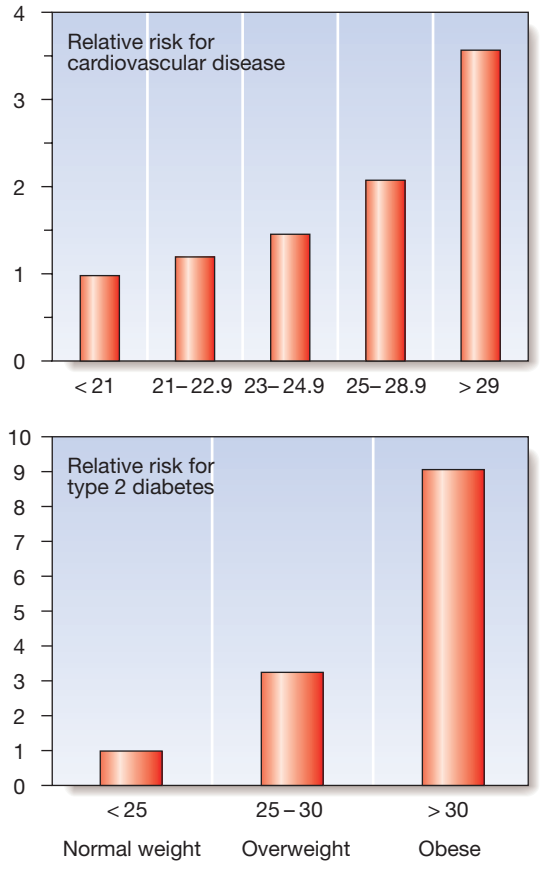

Fig. 5.12 Risks of diabetes and cardiovascular disease in overweight and obese women. Data are from the Nurses' Health Study in the USA, mostly of Caucasian women. In some ethnic groups (e.g. South Asians, Native Americans) and in people with higher waist circumference, the metabolic complications are even more severe at a given level of BMI.

liver, as an important determinant of metabolic risk in the obese.

Aetiology

Accumulation of fat results from a discrepancy between energy consumption and energy expenditure that is too large to be defended by the hypothalamic regulation of BMR. A continuous small daily positive energy balance of only 0.2–0.8 MJ (50–200 kcal; < 10% of intake) would lead to weight gain of 2–20 kg over a period of 4–10 years. Given the cumulative effects of subtle energy excess, body fat content shows 'tracking' with age such that obese children usually become obese adults. Weight tends to increase throughout adult life, as BMR and physical activity decrease (see Fig. 5.9).

The pandemic of obesity reflects changes in both energy intake and energy expenditure (Box 5.19), although both are difficult to measure reliably. The estimated average global daily supply of food energy per person increased from approximately 9.8 MJ (2350 kcal) in the 1960s to approximately 11.7 MJ (2800 kcal) in the 1990s, but its delivery is unequal. For example, in India it is estimated that 5% of the population receives 40% of

5.19 Some reasons for the increasing prevalence of obesity – the 'obesogenic' environment

Increasing energy intake

- ↑ Portion sizes
- ↑ Snacking and loss of regular meals
- ↑ Energy-dense food (mainly fat)
- ↑ Affluence

Decreasing energy expenditure

- ↑ Car ownership
- ↓ Walking to school/work
- ↑ Automation; ↓ manual labour
- ↓ Sports in schools
- ↑ Time spent on computer games and watching TV
- ↑ Central heating

the available food energy, leading to obesity in the urban population in parallel with persisting under-nutrition in some rural communities. In affluent societies, a significant proportion of this food supply is discarded. In the US, the average daily energy intake of men reportedly rose from 10.2 MJ (2450 kcal) in 1971 to 11.0 MJ (2618 kcal) in 2000. Portion sizes, particularly of energy-dense foods such as drinks with highly refined sugar content and salty snacks, have increased. However, data in the UK suggest that energy intakes have declined (which may in part be due to deliberate restriction or 'dieting'), but this is apparently insufficient to compensate for the decrease in physical activity levels in recent years. Obesity is correlated positively with the number of hours spent watching television, and inversely with levels of physical activity (e.g. stair climbing). It is suggested that minor activities such as fidgeting and chewing gum may contribute to energy expenditure and protect against obesity.

Susceptibility to obesity

Susceptibility to obesity and its adverse consequences undoubtedly varies between individuals. It is not true that obese subjects have a 'slow metabolism', since their BMR is higher than that of lean subjects. Twin and adoption studies confirm a genetic influence on obesity. The pattern of inheritance suggests a polygenic disorder, with small contributions from a number of different genes, together accounting for 25–70% of variation in weight. Recent results from 'genome-wide' association studies of polymorphisms in large numbers of people (p. 53) have identified a handful of genes that influence obesity, some of which encode proteins known to be involved in the control of appetite or metabolism and some of which have unknown function. However, these genes account for less than 5% of the variation in body weight.

A few rare single-gene disorders have been identified that lead to severe childhood obesity. These include mutations of the melanocortin-4 receptor (MC4R), which account for approximately 5% of severe early-onset obesity; defects in the enzymes processing propiomelanocortin (POMC, the precursor for adrenocorticotrophic hormone (ACTH)) in the hypothalamus; and mutations in the leptin gene (see Fig. 5.9). The latter can be treated by leptin injections. Additional genetic conditions in which obesity is a feature include the Prader–Willi (see Box 3.3, p. 54) and Lawrence–Moon–Biedl syndromes.

5.20 Potentially reversible causes of weight gain

Endocrine factors	
• Hypothyroidism • Cushing's syndrome • Insulinoma	• Hypothalamic tumours or injury
Drug treatments	
• Atypical antipsychotics (e.g. olanzapine) • Sulphonylureas, thiazolidinediones, insulin	• Pizotifen • Corticosteroids • Sodium valproate • β-blockers

Reversible causes of obesity and weight gain

In a small minority of patients presenting with obesity, specific causal factors can be identified and treated (Box 5.20). These patients are distinguished from those with idiopathic obesity by their short history, with a recent marked change in the trajectory of their adult weight gain.

Clinical assessment and investigations

In assessing an individual presenting with obesity, the aims are to:

- quantify the problem
- exclude an underlying cause
- identify complications
- reach a management plan.

Severity of obesity can be quantified using the BMI (Box 5.21). A waist circumference of > 102 cm in men or > 88 cm in women indicates that the risk of metabolic and cardiovascular complications of obesity is high.

A dietary history may be helpful in guiding dietary advice, but is notoriously susceptible to under-reporting of food consumption. It is important to consider 'pathological' eating behaviour (such as binge eating, nocturnal eating or bulimia; p. 255), which may be the most important issue to address in some patients. Alcohol is an important source of energy intake and should be considered in detail.

The history of weight gain may help diagnose underlying causes. A patient who has recently gained substantial weight or has gained weight at a faster rate than previously, and is not taking relevant drugs (see Box 5.20), is more likely to have an underlying disorder such as hypothyroidism (p. 743) or Cushing's syndrome (p. 773). All obese patients should have thyroid function tests performed on one occasion, and an overnight dexamethasone suppression test or 24-hour urine free cortisol if Cushing's syndrome is suspected. Monogenic and 'syndromic' causes of obesity are usually only relevant in children presenting with severe obesity.

Assessment of the diverse complications of obesity (see Box 5.18) requires a thorough history, examination and screening investigations. The impact of obesity on the patient's life and work is a major consideration. Assessment of other cardiovascular risk factors is important. Blood pressure should be measured with a large cuff, if required (p. 608). Associated type 2 diabetes and dyslipidaemia are detected by measuring blood glucose or HbA_{1c} and a serum lipid profile, ideally in a fasting morning sample. Elevated serum transaminases occur in patients with non-alcoholic fatty liver disease (p. 959).

5.21 Quantifying obesity with body mass index (weight/height^2)

BMI (kg/m^2)	Classification*	Risk of obesity comorbidity
18.5–24.9	Reference range	Negligible
25.0–29.9	Overweight	Mildly increased
> 30.0	**Obese**	
30.0–34.9	Class I	Moderate
35.0–39.9	Class II	Severe
> 40.0	Class III	Very severe

*Classification of the WHO and International Obesity Task Force. The Western Pacific Region Office of WHO recommends that, amongst Asians, BMI > 23.0 is overweight and > 25.0 is obese.

Management

The health risks of obesity are largely reversible. Interventions proven to reduce weight in obese patients also ameliorate cardiovascular risk factors. Lifestyle advice that lowers body weight and increases physical exercise reduces the incidence of type 2 diabetes (p. 820). Given the high prevalence of obesity and the large magnitude of its risks, population strategies to prevent and reverse obesity are high on the public health priority list for many countries. Initiatives include promoting healthy eating in schools, enhancing walking and cycling options for commuters, and liaising with the food industry to reduce energy and fat content and to label foods appropriately. Unfortunately, 'low-fat' foods are often still energy-dense, and current lifestyles with labour-saving devices, sedentary work and passive leisure activities have much lower energy requirements than the manual labour and household duties of previous generations.

Most patients seeking assistance with obesity are motivated to lose weight but have attempted to do so previously without long-term success. Often weight will have oscillated between periods of successful weight loss and then regain of weight ('recidivism'). These patients may hold misconceptions that they have an underlying disease, inaccurate perceptions of their energy intake and expenditure, and an unrealistic view of the target weight that they would regard as a 'success'. An empathetic explanation of energy balance, which recognises that some individuals are more susceptible to obesity than others and may find it more difficult to lose and sustain body weight loss, is important. Exclusion of underlying 'hormone imbalance' with simple tests is reassuring and shifts the focus on to consideration of energy balance. Appropriate goals for weight loss should be agreed, recognising that the slope of the relationship between obesity and many of its complications becomes steeper with increasing BMI, so that a given amount of weight loss achieves greater risk reduction at higher levels of BMI. A reasonable goal for most patients is to lose 5–10% of body weight.

The management plan will vary according to the severity of the obesity (see Box 5.21) and the associated risk factors and complications. It will also be influenced by availability of resources; health-care providers and regulators have generally been careful not to recommend expensive interventions (especially long-term drug therapy and surgery) for everyone who is overweight. Instead, most guidelines focus resources on short-term interventions in those who have high health risks and comorbidities associated with their obesity, and who have demonstrated their capacity to alter their lifestyle to achieve weight loss (Fig. 5.13).

Lifestyle advice

Behavioural modification to avoid some of the effects of the 'obesogenic' environment (see Box 5.19) is the cornerstone of long-term control of weight. Regular eating patterns and maximising physical activity are advised, with reference to the modest extra activity required to increase physical activity level (PAL) ratios (see Fig. 5.9C, p. 111). Where possible, this should be incorporated in the daily routine (e.g. walking rather than driving to work), since this is more likely to be sustained. Alternative exercise (e.g. swimming) may be considered if musculoskeletal complications prevent walking. Changes in eating behaviour (including food selection, portion size control, avoidance of snacking, regular meals to encourage satiety, and substitution of sugar with artificial sweeteners) should be discussed. Regular support from a dietitian or attendance at a weight loss group may be helpful.

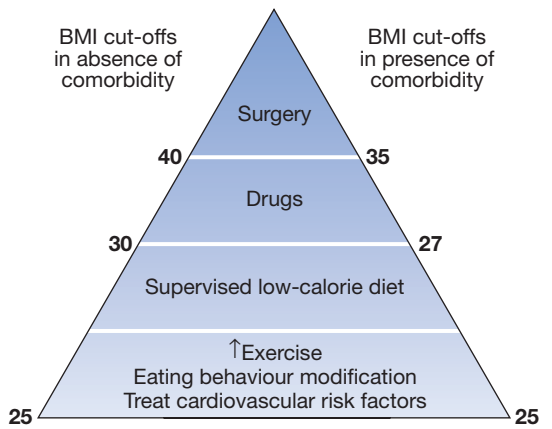

Fig. 5.13 Therapeutic options for obesity. Relevant comorbidities include type 2 diabetes, hypertension, cardiovascular disease, sleep apnoea, and waist circumference > 102 cm in men or 88 cm in women. This is an approximate consensus of the numerous national guidelines, which vary slightly in their recommendations and are revised every few years.

Weight loss diets

In overweight people, adherence to the lifestyle advice given above may gradually induce weight loss. In obese patients, more active intervention is usually required to lose weight before conversion to the 'weight maintenance' advice given above. A significant industry has developed in marketing diets for weight loss. These vary substantially in their balance of macronutrients (Box 5.22), but there is little evidence that they vary in their medium-term (1-year) efficacy. Most involve recommending a reduction of daily total energy intake of –2.5 MJ (600 kcal) from the patient's normal consumption. Modelling data that take into account the reduced energy expenditure as weight is lost suggest that a reduction of energy intake of 100 kJ per day will lead to an eventual bodyweight change of about 1 kg, with half of the weight change being achieved in about 1 year and 95% of the weight change in about 3 years. Weight loss is highly variable, with patient compliance being the major determinant of success. There is some evidence that weight loss diets are most effective in their early weeks, and that compliance is improved by novelty of the diet; this provides some justification for switching to a different dietary regimen when weight loss slows on the first diet. Vitamin supplementation is wise in those diets in which macronutrient balance is markedly disturbed.

In some patients, more rapid weight loss is required, e.g. in preparation for surgery. There is no role for starvation diets, which risk profound loss of muscle mass and the development of arrhythmias (and even sudden death) secondary to elevated free fatty acids, ketosis and deranged electrolytes. Very-low-calorie diets (VLCDs) are recommended for short-term rapid weight loss, producing losses of 1.5–2.5 kg/week, compared to 0.5 kg/week on conventional regimens, but require the supervision of an experienced physician and nutritionist. The composition of the diet should ensure a minimum of 50 g of protein each day for men and 40 g for women to minimise muscle degradation. Energy content should be a minimum of 1.65 MJ (400 kcal) for women of height < 1.73 m, and 2.1 MJ (500 kcal) for all men and for women taller than 1.73 m. Side-effects are a problem in

5.22 Low-calorie diet therapy for obesity

Diet	% carbohydrate	% fat	% protein	Comments
Normal (typical developed country)	50	30	15	
Moderate fat (e.g. Weight Watchers)	60	25	15	Maintains balance in macronutrients and micronutrients while reducing energy-dense fats
Low carbohydrate (e.g. Atkins)	10	60	30	Induction of ketosis may suppress hunger
High protein (e.g. Zone)	43	30	27	Protein has greater satiety effect than other macronutrients
Low fat (e.g. Ornish)	70	13	17	

the early stages and include orthostatic hypotension, headache, diarrhoea and nausea.

Drugs

A huge investment has been made by the pharmaceutical industry in finding drugs for obesity. The side-effect profile has limited the use of many agents, with notable withdrawals from clinical use of sibutramine (increased cardiovascular events) and rimonabant (psychiatric side-effects) in recent years; only one drug, orlistat, is currently licensed for long-term use. A number of other agents are in development, so the situation could change rapidly over the next few years. There is no role for diuretics, or for thyroxine therapy without biochemical evidence of hypothyroidism.

Orlistat inhibits pancreatic and gastric lipases and thereby decreases the hydrolysis of ingested triglycerides, reducing dietary fat absorption by approximately 30%. The drug is not absorbed and adverse side-effects relate to the effect of the resultant fat malabsorption on the gut: namely, loose stools, oily spotting, faecal urgency, flatus and the potential for malabsorption of fat-soluble vitamins. Orlistat is taken with each of the three main meals of the day and the dose can be adjusted (60–120 mg) to minimise side-effects. Its efficacy is shown in Figure 5.14; these effects may be explained because patients taking orlistat adhere better to low-fat diets in order to avoid unpleasant gastrointestinal side-effects.

Drug therapy is usually reserved for patients with high risk of complications from obesity (see Fig. 5.13), and its optimum timing and duration are controversial. Although life-long therapy is advocated for many drugs that reduce risk on the basis of relatively short-term research trials (e.g. drugs for hypertension and osteoporosis), some patients who continue to take anti-obesity drugs tend to regain weight with time; this may partly reflect age-related weight gain, but significant weight gain should prompt reinforcement of lifestyle advice and, if this is unsuccessful, drug therapy should be discontinued (see Fig. 5.14).

Surgery

'Bariatric' surgery is by far the most effective long-term treatment for obesity (see Fig. 5.14 and Box 5.23) and is

5.23 Effectiveness and adverse effects of laparoscopic bariatric surgical procedures

Procedure	Expected weight loss (% excess weight)	Adverse effects
Gastric banding	50–60%	Band slippage, erosion, stricture Port-site infection Mortality < 0.2% in experienced centres
Sleeve gastrectomy	50–60%	Iron deficiency Vitamin B_{12} deficiency Mortality < 0.2% in experienced centres
Roux-en-Y gastric bypass	70–80%	Internal hernia Stomal ulcer Dumping syndrome Hypoglycaemia Iron deficiency Vitamin B_{12} deficiency Vitamin D deficiency Mortality 0.5%
Duodenal switch	Up to 100%	Steatorrhoea Protein-calorie malnutrition Iron deficiency Vitamin B_{12} deficiency Calcium, zinc, copper deficiency Mortality 1%

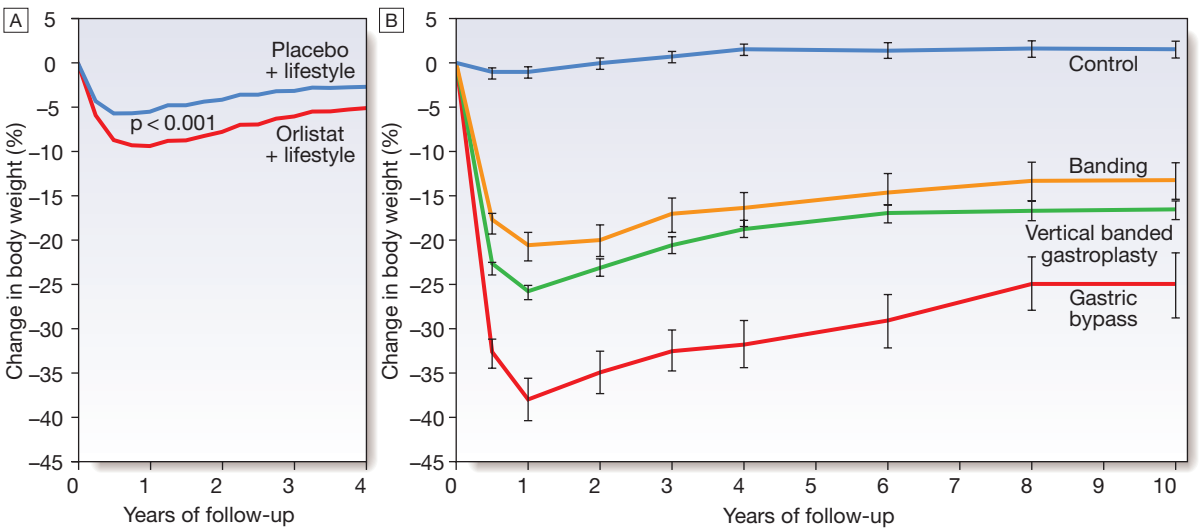

Fig. 5.14 Effects of orlistat and bariatric surgery on weight loss. A Data are from Torgerson JS, et al. Diabetes Care 2004; 27:155–161. B Data for surgery are from Sjostrom L, et al. New Engl J Med 2004; 351:2683–2693. Each obese subject undergoing surgery was matched with a control subject whose obesity was 'treated' by standard non-operative interventions. Note that the maximum weight loss achieved with orlistat was approximately 11 %; surgery achieves much more substantial and prolonged weight loss.

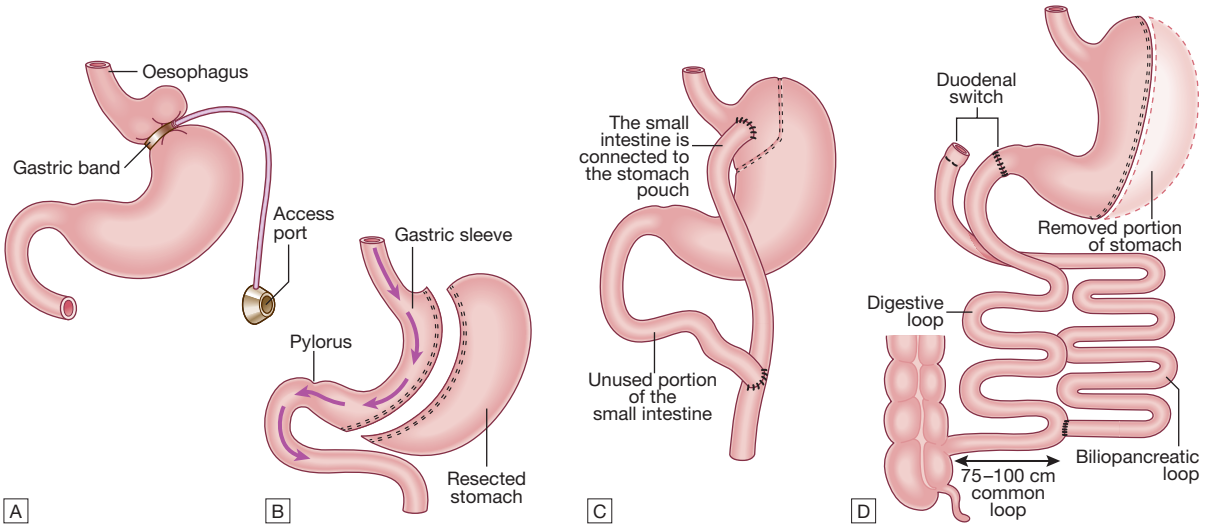

Fig. 5.15 Bariatric surgical procedures. A Laparoscopic banding, with the option of a reservoir band and subcutaneous access to restrict the stomach further after compensatory expansion has occurred. B Sleeve gastrectomy. C Roux-en-Y gastric bypass. D Biliopancreatic diversion with duodenal switch.

the only anti-obesity intervention that has been associated with reduced mortality. Bariatric surgery should be contemplated in motivated patients who have very high risks of complications of obesity (see Fig. 5.13), in whom extensive dietary and drug therapy has been insufficiently effective. It is usually reserved for those with severe obesity (BMI > 40 kg/m^2), or those with a BMI > 35 kg/m^2 and significant complications, such as type 2 diabetes or obstructive sleep apnoea. Only experienced specialist surgeons should undertake these procedures, in collaboration with a multidisciplinary team. Several approaches are used (Fig. 5.15) and all can be performed laparoscopically. The mechanism of weight loss may not simply relate to limiting the stomach or absorptive capacity, but rather in disrupting the release of ghrelin from the stomach or promoting the release of other peptides from the small bowel, thereby enhancing satiety signalling in the hypothalamus. Diabetes may improve rapidly after surgery, particularly after gastric bypass, and although this may be attributed to severe energy restriction in the perioperative period, it is possible that increased release of incretin hormones such as glucagon-like peptide (GLP)-1 may contribute to the improvement in glucose control. Complications depend upon the approach. Mortality is low in experienced centres, but post-operative respiratory problems, wound infection and dehiscence, staple leaks, stomal stenosis, marginal ulcers and venous thrombosis may occur. Additional problems may arise at a later stage, such as pouch and distal oesophageal dilatation, persistent vomiting, 'dumping' (p. 875) and micronutrient deficiencies, particularly of folate, vitamin B_{12} and iron, which are of concern especially to women contemplating pregnancy.

Cosmetic surgical procedures may be considered in obese patients after successful weight loss. Apronectomy is usually advocated to remove an overhang of abdominal skin, especially if infected or ulcerated. This operation is of no value for long-term weight reduction if food intake remains unrestricted.

Treatment of additional risk factors

Obesity must not be treated in isolation and other risk factors must be addressed, including smoking, excess alcohol consumption, diabetes mellitus, hyperlipidaemia, hypertension and obstructive sleep apnoea. Treatment of these is discussed in the relevant chapters.

Under-nutrition

Starvation and famine

There remain regions of the world, particularly rural Africa, where under-nutrition due to famine is endemic, the prevalence of BMI < 18.5 kg/m^2 (Box 5.24) in adults is as high as 20%, and growth retardation due to under-nutrition affects 50% of children.

WHO reports that chronic under-nutrition is responsible for more than half of all childhood deaths worldwide. Starvation is manifest as marasmus (malnutrition with marked muscle-wasting), or, when additional complicating mechanisms, such as oxidative stress, come into play, malnourished children can develop kwashiorkor (malnutrition with oedema). Growth retardation is due to deficiency of key nutrients, e.g. protein, zinc, potassium, phosphorus and sulphur. Treatment of these

5.24 Classification of under-nutrition in adults by body mass index (weight/height^2)

BMI (kg/m^2)	Classification
> 20	Adequate nutrition
18.5–20	Marginal
< 18.5	**Under-nutrition**
17–18.4	Mild
16–17	Moderate
< 16	Severe

5.25 Causes of under-nutrition and weight loss in adults

Decreased energy intake

- Famine
- Persistent regurgitation or vomiting
- Anorexia, including depression and anorexia nervosa
- Malabsorption (e.g. small intestinal disease)
- Maldigestion (e.g. pancreatic exocrine insufficiency)

Increased energy expenditure

- Increased BMR (thyrotoxicosis, trauma, fever, cancer, cachexia)
- Excessive physical activity (e.g. marathon runners)
- Energy loss (e.g. glycosuria in diabetes)
- Impaired energy storage (e.g. Addison's disease, phaeochromocytoma)

childhood conditions is not discussed in this adult medicine textbook.

In adults, starvation is the result of chronic under-nutrition, i.e. sustained negative energy (calorie) balance. Causes are shown in Box 5.25. Causes of weight loss are considered further on page 859.

Clinical assessment

In starvation, the severity of malnutrition can be assessed by anthropometric measurements, such as BMI (see Box 5.24). Demispan and mid-arm circumference measurements (p. 114) are most useful in monitoring progress during treatment. The clinical features of severe under-nutrition in adults include:

- weight loss
- thirst, craving for food, weakness and feeling cold
- nocturia, amenorrhoea or impotence
- lax, pale, dry skin with loss of turgor and, occasionally, pigmented patches
- cold and cyanosed extremities, pressure sores
- hair thinning or loss (except in adolescents)
- muscle-wasting, best demonstrated by the loss of the temporalis and periscapular muscles and reduced mid-arm circumference
- loss of subcutaneous fat, reflected in reduced skinfold thickness and mid-arm circumference
- hypothermia, bradycardia, hypotension and small heart
- oedema, which may be present without hypoalbuminaemia ('famine oedema')
- distended abdomen with diarrhoea
- diminished tendon jerks
- apathy, loss of initiative, depression, introversion, aggression if food is nearby
- susceptibility to infections (Box 5.26).

Under-nutrition often leads to vitamin deficiencies, especially of thiamin, folate and vitamin C (see below).

5.26 Infections associated with starvation

- Gastroenteritis and Gram-negative septicaemia
- Respiratory infections, especially bronchopneumonia
- Certain viral diseases, especially measles and herpes simplex
- Tuberculosis
- Streptococcal and staphylococcal skin infections
- Helminthic infestations

Diarrhoea can lead to depletion of sodium, potassium and magnesium. The high mortality rate in famine situations is often due to outbreaks of infection, e.g. typhus or cholera, but the usual signs of infection may not be apparent. In advanced starvation, patients become completely inactive and may assume a flexed, fetal position. In the last stage of starvation, death comes quietly and often quite suddenly. The very old are most vulnerable. All organs are atrophied at necropsy, except the brain, which tends to maintain its weight.

Investigations

In a famine, laboratory investigations may be impractical, but will show that plasma free fatty acids are increased and there is ketosis and a mild metabolic acidosis. Plasma glucose is low but albumin concentration is often maintained because the liver still functions normally. Insulin secretion is diminished, glucagon and cortisol tend to increase, and reverse T_3 replaces normal triiodothyronine (p. 738). The resting metabolic rate falls, partly because of reduced lean body mass and partly because of hypothalamic compensation (see Fig. 5.9, p. 111). The urine has a fixed specific gravity and creatinine excretion becomes low. There may be mild anaemia, leucopenia and thrombocytopenia. The erythrocyte sedimentation rate is normal unless there is infection. Tests of delayed skin hypersensitivity, e.g. to tuberculin, are falsely negative. The electrocardiogram shows sinus bradycardia and low voltage.

Management

Whether in a famine or in wasting secondary to disease, the severity of under-nutrition is graded according to BMI (see Box 5.24). People with mild starvation are in no danger; those with moderate starvation need extra feeding; those who are severely underweight need hospital care.

In severe starvation, there is atrophy of the intestinal epithelium and of the exocrine pancreas, and the bile is dilute. It is critical that the condition is managed by experts. When food becomes available, it should be given by mouth in small, frequent amounts at first, using a suitable formula preparation (Box 5.27). Individual energy requirements can vary by 30%. During rehabilitation, more concentrated formula can be given with additional food that is palatable and similar to the usual staple meal. Salt should be restricted and micronutrient supplements may be essential (e.g. potassium, magnesium, zinc and multivitamins). Between 6.3 and 8.4 MJ/day (1500–2000 kcal/day) will arrest progressive under-nutrition, but additional energy may be required for regain of weight. During refeeding, a weight gain of 5% body weight per month indicates satisfactory progress. Other care is supportive, and includes attention to the skin, adequate hydration, treatment of infections, and careful monitoring of body temperature since thermoregulation may be impaired.

Circumstances and resources are different in every famine, but many problems are non-medical and concern organisation, infrastructure, liaison, politics, procurement, security and ensuring that food is distributed on the basis of need. Lastly, plans must be made for the future for prevention and/or earlier intervention if similar circumstances prevail.

5.27 WHO recommended diets for refeeding

Nutrient (per 100 mL)	F-75 diet[1]	F-100 diet[2]
Energy	315 kJ (75 kcal)	420 kJ (100 kcal)
Protein (g)	0.9	2.9
Lactose (g)	1.3	4.2
Potassium (mmol)	3.6	5.9
Sodium (mmol)	0.9	1.9
Magnesium (mmol)	0.43	0.73
Zinc (mg)	2.0	2.3
Copper (mg)	0.25	0.25
Percentage of energy from		
Protein	5	12
Fat	32	53
Osmolality (osmol/L)	333	419
Dose	170 kJ/kg (40 kcal/kg)	630–920 kJ/kg (150–220 kcal/kg)
Rate of feeding by mouth	2.2 (mL/kg/hr)	Gradual increase in volume, 6 times daily

[1]F-75 is prepared from milk powder (25 g), sugar (70 g), cereal flour (35 g), vegetable oil (27 g) and vitamin and mineral supplements, made up to 1 L with water.
[2]F-100 (1 L) contains milk powder (80 g), sugar (50 g), vegetable oil (60 g) and vitamin and mineral supplements (no cereal).

5.28 Energy balance in old age

- **Body composition**: muscle mass is decreased and percentage body fat increased.
- **Energy expenditure**: with the fall in lean body mass, BMR is decreased and energy requirements are reduced.
- **Weight loss**: after weight gain throughout adult life, weight often falls beyond the age of 70 years. This may reflect decreased appetite, loss of smell and taste, and decreased interest in and financial resources for food preparation, especially after loss of a partner.
- **BMI**: less reliable in old age as height is lost (due to kyphosis, osteoporotic crush fractures, loss of intervertebral disc spaces). Alternative measurements include arm demispan and knee height (p. 114), which can be extrapolated to estimate height.

Under-nutrition in hospital

Under-nutrition is a common problem in the hospital setting. In the UK, approximately one-third of patients are affected by moderate or severe under-nutrition on admission. The elderly are particularly at risk (Box 5.28). Once in hospital, many patients lose weight due to factors such as poor appetite, poor dental health, concurrent illness and even being kept 'nil by mouth' for investigations. Under-nutrition is poorly recognised in hospital and has serious consequences. Physical effects include impaired immunity and muscle weakness, which in turn affect cardiac and respiratory function, and delayed wound healing after surgery with increased risks of post-operative infection. The undernourished patient is often apathetic and withdrawn, which may be mistaken for a depressive illness and can affect cooperation with treatment and rehabilitation.

This can be averted with proper monitoring and involvement of an appropriate multidisciplinary team. As a minimum standard, all patients should be weighed on admission to hospital and at least weekly until discharge. A scoring system for identifying patients at nutritional risk is shown in Figure 5.16.

Nutritional support of the hospital patient

Normal diet

As a first step, patients should be encouraged to eat a normal and adequate diet. This is often neglected and there is evidence of substantial wastage in hospital food. In patients at risk of under-nutrition (see Fig. 5.16), quantities eaten should be recorded on a food chart. Hospital staff must identify and overcome barriers to adequate food intake, such as unpalatability of food, cultural and religious factors influencing acceptability of

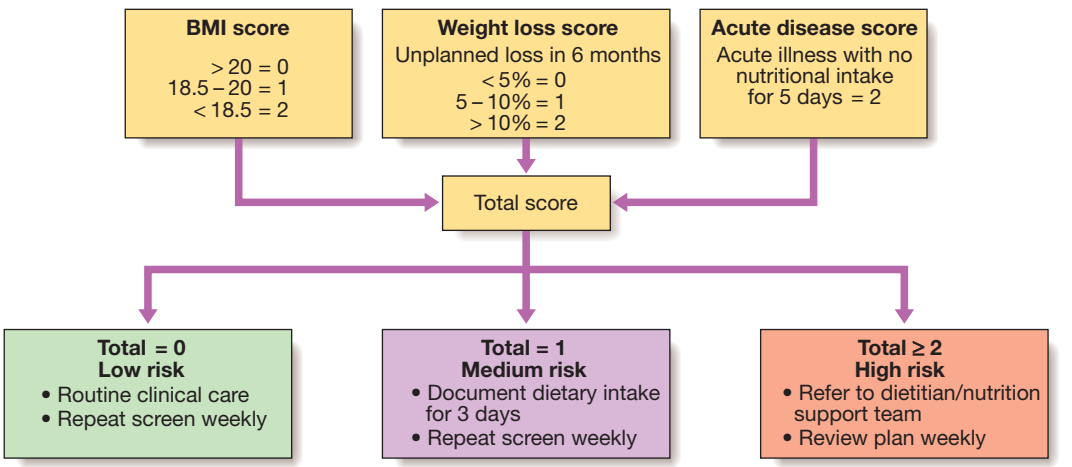

Fig. 5.16 Screening hospitalised patients for risk of malnutrition. Acute illnesses include decompensated liver disease, cancer cachexia or being kept 'nil by mouth'. Adapted from the British Association of Parenteral and Enteral Nutrition Malnutrition Universal Screening Tool' (www.bapen.org.uk).

food, difficulty with hand dexterity (arthritis, stroke), immobility in bed, or poor oral health. Hospital catering departments have an important role in providing acceptable and adequate meals.

Dietary supplements

If sufficient nutritional intake cannot be achieved from normal diet alone, then dietary supplements should be used. These are drinks with high energy and protein content, and are available in cartons as manufactured, flavoured products or are made in the hospital kitchen from milk products and egg. They should be prescribed, and administered by nursing staff, to ensure that they are taken regularly. Dietary supplements do not significantly affect the patient's consumption of normal food.

Enteral tube feeding

Patients who are unable to swallow may require artificial nutritional support: for example, after acute stroke or throat surgery, or when there are long-term neurological problems such as motor neuron disease and multiple sclerosis. The enteral route should always be used if possible, since feeding via the gastrointestinal tract preserves the integrity of the mucosal barrier. This prevents bacteraemia and, in intensive care patients, reduces the risk of multi-organ failure (p. 198).

If the need for artificial nutritional support is thought to be short-term, then feeding is instituted using a fine-bore nasogastric tube. The position of the tube in the stomach must be confirmed before any fluid is administered, as severe respiratory complications can occur if fluid is inadvertently infused into a bronchus (Box 22.48, p. 879). Thereafter, specially prepared liquid feeds are administered either by continuous infusion or using a bolus technique. If the patient fails to absorb the administered feed or vomits it, this may indicate gastric outlet obstruction or gastric stasis, which can be overcome by placing a nasojejunal tube.

If long-term artificial enteral feeding is needed, a percutaneous endoscopic gastrostomy (PEG) should be sited (Fig. 5.17). A PEG tube is more comfortable for the patient, since there is no irritation to the nasal mucosa. The tube is less likely to become displaced or to be pulled out, so the feed can be given more reliably. However, inserting a gastrostomy is an invasive procedure, especially in frail patients with significant comorbidities. It may be complicated by local infection (30%) and inadvertent puncture of other intra-abdominal organs, causing peritonitis and bleeding, so the indication for placement must be carefully considered. It takes approximately 10 days for a fibrous tract to form around the PEG tube. If the PEG is displaced or removed during that time, there is a high risk of peritonitis. If a problem occurs with food absorption, a jejunal extension can be placed through the PEG tube and liquid feed administered directly into the small bowel.

Parenteral nutrition

Intravenous feeding should only be used when enteral feeding is impossible. Parenteral feeding is expensive and carries higher risks of complications. There is little benefit if parenteral feeding is required for less than 1 week.

There are a number of possible routes for parenteral nutrition:

- *Peripheral venous cannula*. This can only be used for low-osmolality solutions due to the development of thrombophlebitis, and is unsuitable for patients with high nutritional requirements.
- *Peripherally inserted cannula (PIC)*. A 20 cm cannula is placed in a mid-arm vein. Once again, hyperosmolar solutions cannot be used.

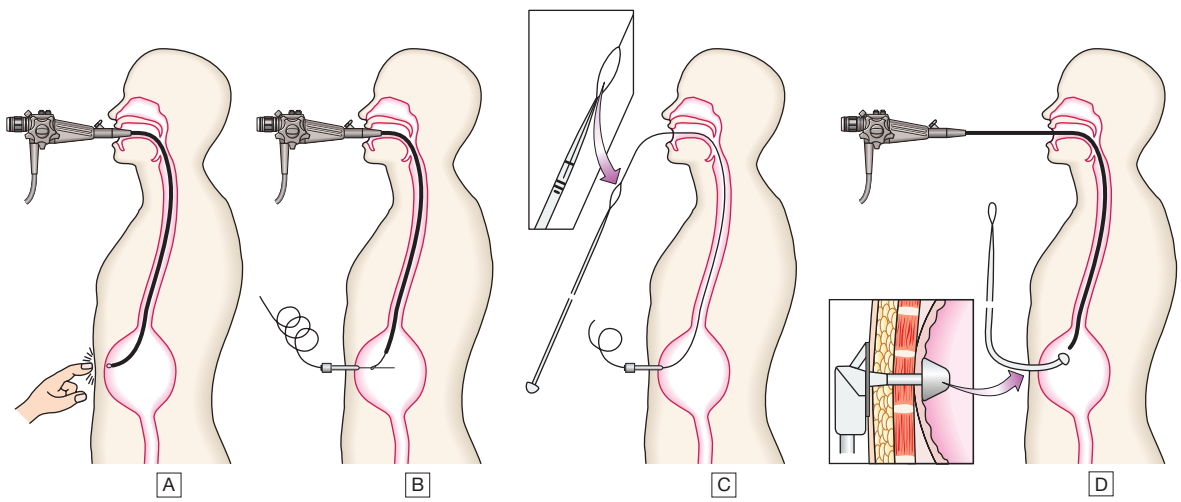

Fig. 5.17 Percutaneous endoscopic gastrostomy (PEG) placement. A Finger pressure on the anterior abdominal wall is noted by the endoscopist. B Following insertion of a cannula through the anterior abdominal wall into the stomach, a guidewire is threaded through the cannula and grasped by the endoscopic forceps or snare. C The endoscope is withdrawn with the guidewire. The gastrostomy tube is then attached to the guidewire. D The guidewire and tube are pulled back through the mouth, oesophagus and stomach to exit on the anterior abdominal wall, and the endoscope is repassed to confirm the site of placement of the retention device. The latter closely abuts the gastric mucosa; its position is maintained by an external fixation device (see inset). It is also possible to place PEG tubes using fluoroscopic guidance in patients in whom endoscopy is difficult (radiologically inserted gastrostomy (RIG)).

- *Peripherally inserted central catheter (PICC).* A 60 cm cannula is inserted into a vein in the antecubital fossa. The distal end lies in a central vein, allowing hyperosmolar solutions to be used.
- *Central line.* The subclavian route is preferred to the internal jugular vein, due to lower infection rates. Hyperosmolar solutions can be used without difficulty. Lines need to be handled with strict aseptic technique, and a single-lumen tube is preferred, to prevent infection.

If access has been gained to a central vein, nutritional support is usually given as an 'all-in-one' mixture. The main energy source is provided by carbohydrate, usually as glucose. The solution also contains amino acids, lipid emulsion, electrolytes, trace elements and vitamins. These are mixed as a large bag in a sterile environment, with the constituents adjusted according to the results of regular blood monitoring. Relevant tests include:

- *daily*: urea and electrolytes, glucose
- *twice* weekly: liver function tests, calcium, phosphate, magnesium
- *weekly*: full blood count, zinc, triglycerides
- *monthly*: copper, selenium, manganese.

If the patient develops fever or other features of septicaemia, it should be assumed to be due to a line infection (p. 200). Blood cultures should be taken, the existing line removed, the tip sent for bacteriological analysis, and a new line inserted.

Refeeding syndrome

When nutritional support is given to an under-nourished patient, there is a rapid conversion from a catabolic to an anabolic state. Administration of carbohydrates stimulates release of insulin, leading to cellular uptake of phosphate, potassium and magnesium, which may provoke significant falls in serum levels. The resulting electrolyte imbalance can have serious consequences, such as cardiac arrhythmias, so careful monitoring is essential. In patients who are thiamin-deficient, Wernicke's encephalopathy can be precipitated by refeeding with carbohydrates (p. 253); this is prevented by administering thiamin before starting nutritional support.

Legal and ethical aspects of artificial nutritional support

The ability to intervene with artificial nutritional support raises many legal and ethical dilemmas (pp. 9 and 291). Starvation will inevitably lead to death, but inability to eat may be part of the terminal stages of a disease process. Difficult decisions are raised by situations such as strokes, which affect swallowing. The instigation of feeding may speed recovery and lead to better functional outcome; on the other hand, feeding might prolong the process of dying in severe stroke. There will be different approaches to these decisions, depending on the local availability of resources as well as legal, cultural and religious influences. Some guidelines are given in Box 5.29.

5.29 Ethical and legal considerations in the management of artificial nutritional support*

- Care of the sick involves the duty of providing adequate fluid and nutrients
- Food and fluid should not be withheld from a patient who expresses a desire to eat and drink, unless there is a medical contraindication (e.g. risk of aspiration)
- A treatment plan should include consideration of nutritional issues and should be agreed by all members of the health-care team
- In the situation of palliative care, tube feeding should only be instituted if it is needed to relieve symptoms
- Tube feeding is usually regarded in law as a medical treatment. Like other treatments, the need for such support should be reviewed on a regular basis and changes made in the light of clinical circumstances
- A competent adult patient must give consent for any invasive procedures, including the passage of a nasogastric tube or the insertion of a central venous cannula
- If a patient is unable to give consent, the health-care team should act in that person's best interests, taking into account any wishes previously expressed by the patient and the views of family
- Under certain specified circumstances (e.g. anorexia nervosa), it will be appropriate to provide artificial nutritional support to the unwilling patient

*Based on British Association for Parenteral and Enteral Nutrition guidelines (www.bapen.org.uk).

Cachexia

Cachexia is the weight loss and muscle-wasting associated with chronic illness, which is characteristic of chronic infections such as HIV-AIDS, end-stage organ failure and certain cancers (especially of the lung and upper gastrointestinal tract). Although there is decreased energy intake with loss of appetite, the main cause is thought to be increased metabolic rate through the production of key cytokines and other proteolytic factors.

MICRONUTRIENTS, MINERALS AND THEIR DISEASES

Vitamins

Vitamins are organic substances with key roles in certain metabolic pathways, and are categorised into those that are fat-soluble (vitamins A, D, E and K) and those that are water-soluble (vitamins of the B complex group and vitamin C).

Recommended daily intakes of micronutrients (Box 5.30) vary between countries and the nomenclature has become potentially confusing. In the UK, the 'reference nutrient intake' (RNI) has been calculated as the mean plus two standard deviations (SD) of daily intake in the population, which therefore describes normal intake for 97.5% of the population. The lower reference nutrient intake (LRNI) is the mean minus 2 SD, below which would be considered deficient in most of the population. These dietary reference values (DRV) have superseded the terms RDI (recommended daily intakes) and RDA (recommended daily amounts). Other countries use different terminology. Additional amounts of some micronutrients may be required in pregnancy and lactation (Box 5.31).

Vitamin deficiency diseases are most prevalent in developing countries but still occur in developed

5.30 Summary of clinically important vitamins

Vitamin	Sources* Rich	Sources* Important	Reference nutrient intake (RNI)
Fat-soluble			
A (retinol)	Liver	Milk and milk products, eggs, fish oils	700 μg men 600 μg women
D (cholecalciferol)	Fish oils	UV exposure to skin Egg yolks, margarine, fortified cereals	10 μg if > 65 yrs or no sunlight exposure
E (tocopherol)	Sunflower oil	Vegetables, nuts, seed oils	No RNI. Safe intake: 4 mg men 3 mg women
K (phylloquinone, menaquinone)	Green vegetables	Soya oil, menaquinones produced by intestinal bacteria	No RNI. Safe intake: 1 μg/kg
Water-soluble			
B_1 (thiamin)	Pork	Cereals, grains, beans	0.8 mg per 9.68 MJ (2000 kcal) energy intake
B_2 (riboflavin)	Milk	Milk and milk products, breakfast cereals, bread	1.3 mg men 1.1 mg women
B_3 (niacin, nicotinic acid, nicotinamide)	Meat, cereals		17 mg men 13 mg women
B_6 (pyridoxine)	Meat, fish, potatoes, bananas	Vegetables, intestinal microflora synthesis	1.4 mg men 1.2 mg women
Folate	Liver	Green leafy vegetables, fortified breakfast cereals	200 μg
B_{12} (cobalamin)	Animal products	Bacterial colonisation	1.5 μg
Biotin	Egg yolk	Intestinal flora	No RNI. Safe intake: 10–200 μg
C (ascorbic acid)	Citrus fruit	Fresh fruit, fresh and frozen vegetables	40 mg

*Rich sources contain the nutrient in high concentration but are not generally eaten in large amounts; important sources contain less but contribute most because larger amounts are eaten.

5.31 Nutrition in pregnancy and lactation

- **Energy requirements**: increased in both the mother and fetus, but can be met through reduced maternal energy expenditure.
- **Micronutrient requirements**: adaptive mechanisms ensure increased uptake of minerals in pregnancy, but extra increments of some are required during lactation (see Box 5.33). Additional increments of some vitamins are recommended during pregnancy and lactation:
  - — Vitamin A: for growth and maintenance of the fetus, and to provide some reserve (important in some countries to prevent blindness associated with vitamin A deficiency). Teratogenic in excessive amounts.
  - — Vitamin D: to ensure bone and dental development in the infant. Higher incidences of hypocalcaemia, hypoparathyroidisim and defective dental enamel have been seen in infants of women not taking vitamin D supplements at > 50° latitude.
  - — Folate: to avoid neural tube defects (see Box 5.32).
  - — Vitamin B_{12}: in lactation only.
  - — Thiamin: to meet increased fetal energy demands.
  - — Riboflavin: to meet extra demands.
  - — Niacin: in lactation only.
  - — Vitamin C: for the last trimester to maintain maternal stores as fetal demands increase.
  - — Iodine: in countries with high consumption of staple foods (e.g. brassicas, maize, bamboo shoots) that contain goitrogens (thiocyanates or perchlorates) that interfere with iodine uptake, supplements prevent infants being born with cretinism.

countries. Older people (and alcoholics) are at risk of deficiencies in B vitamins and in vitamins D and C. Nutritional deficiencies in pregnancy can affect either the mother or the developing fetus, and extra increments of vitamins are recommended in the UK (see Boxes 5.31 and 5.32). Darker-skinned individuals living at higher latitude, and those who cover up or do not go outside are at increased risk of vitamin D deficiency due to inadequate sunlight exposure. Dietary supplements are recommended for these 'at-risk' groups. Some nutrient deficiencies are induced by diseases or drugs.

EBM 5.32 Periconceptual folate supplementation and neural tube defects

'Folate supplementation in advance of conception and during the first trimester reduces the incidence of neural tube defects by –70%.'

- De-Regil LM, et al. Effects and safety of periconceptional folate supplementation for preventing birth defects. Cochrane Database of Systematic Reviews, 2010, issue 4. Art. no. CD001056.

For further information: www.cochrane.org/cochrane-reviews

5.33 Biochemical assessment of vitamin status

Nutrient	Biochemical assessments of deficiency or excess
Vitamin A	Serum retinol may be low in deficiency Serum retinyl esters: when vitamin A toxicity is suspected
Vitamin D	Plasma/serum 25-hydroxy vitamin D (25(OH)D): reflects body stores (liver and adipose tissue) Plasma/serum $1,25(OH)_2D$: difficult to interpret
Vitamin E	Serum tocopherol : cholesterol ratio
Vitamin K	Coagulation assays (e.g. prothrombin time) Plasma vitamin K
Vitamin B_1 (thiamin)	Red blood cell transketolase activity or whole-blood vitamin B_1
Vitamin B_2 (riboflavin)	Red blood cell glutathione reductase activity or whole-blood vitamin B_2
Vitamin B_3 (niacin)	Urinary metabolites: 1-methyl-2-pyridone-5-carboxamide, 1-methylnicotinamide
Vitamin B_6	Plasma pyridoxal phosphate or erythrocyte transaminase activation coefficient
Vitamin B_{12}	Plasma B_{12}: poor measure of overall vitamin B_{12} status but will detect severe deficiency Alternatives (methylmalonic acid and holotranscobalamin) are not used routinely
Folate	Red blood cell folate Plasma folate: reflects recent intake but also detects unmetabolised folic acid from foods and supplements
Vitamin C	Leucocyte ascorbic acid: assesses vitamin C tissue stores Plasma ascorbic acid: reflects recent (daily) intake

Deficiencies of fat-soluble vitamins are seen in conditions of fat malabsorption (e.g. biliary obstruction).

Some vitamins also have pharmacological actions when given at supraphysiological doses, e.g. the use of vitamin A (p. 1282) for acne. Taking vitamin supplements is fashionable in many countries, although there is no evidence of benefit. Toxic effects are most serious with high dosages of vitamins A, B_6 and D.

Investigation of suspected vitamin deficiency or excess may involve biochemical assessment of body stores (Box 5.33). However, measurements in blood should be interpreted carefully in conjunction with the clinical presentation.

Fat-soluble vitamins

Vitamin A (retinol)

Pre-formed retinol is found only in foods of animal origin. Vitamin A can also be derived from carotenes, which are present in green and coloured vegetables and some fruits. Carotenes provide most of the total vitamin A in the UK, and constitute the only supply in vegans. Retinol is converted to several other important molecules:

- *11-cis retinaldehyde* is part of the photoreceptor complex in rods of the retina.
- *Retinoic acid* induces differentiation of epithelial cells by binding to specific nuclear receptors, which induce responsive genes. In vitamin A deficiency, mucus-secreting cells are replaced by keratin-producing cells.
- *Retinoids* are necessary for normal growth, fetal development, fertility, haematopoiesis and immune function.

Globally, the most important consequence of vitamin A deficiency is irreversible blindness in young children. Asia is most notably affected and the problem is being addressed through widespread vitamin A

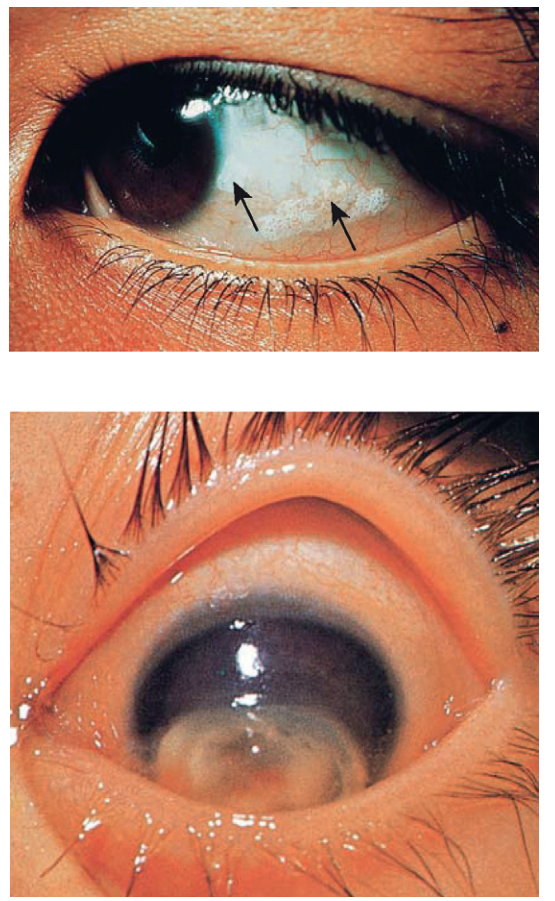

Fig. 5.18 Eye signs of vitamin A deficiency. A Bitot's spots in xerophthalmia, showing the white triangular plaques (arrows). B Keratomalacia in a 14-month-old child. There is liquefactive necrosis affecting the greater part of the cornea, with typical sparing of the superior aspect. (B) From WHO 1976 – see p. 132.

supplementation programmes. Adults are not usually at risk because liver stores can supply vitamin A when foods containing vitamin A are unavailable.

Early deficiency causes impaired adaptation to the dark (night blindness). Keratinisation of the cornea (xerophthalmia) gives rise to characteristic Bitot's spots, and progresses to keratomalacia, with corneal ulceration, scarring and irreversible blindness (Fig. 5.18). In countries where vitamin A deficiency is endemic, pregnant women should be advised to eat dark-green, leafy vegetables and yellow fruits (to build up stores of retinol in the fetal liver), and infants should be fed the same. WHO is according high priority to prevention in communities where xerophthalmia occurs, giving single prophylactic oral doses of 60 mg retinyl palmitate (providing 200 000 U retinol) to pre-school children. This also reduces mortality from gastroenteritis and respiratory infections.

Repeated moderate or high doses of retinol can cause liver damage, hyperostosis and teratogenicity. Women in countries where deficiency is not endemic are therefore advised not to take vitamin A supplements in pregnancy. Retinol intake may also be restricted in those at risk of osteoporosis. Acute overdose leads to nausea and headache, increased intracranial pressure and skin desquamation. Excessive intake of carotene can cause pigmentation of the skin (hypercarotenosis); this gradually fades when intake is reduced.

Vitamin D

The natural form of vitamin D, cholecalciferol or vitamin D_3, is formed in the skin by the action of UV light on 7-dehydrocholesterol, a metabolite of cholesterol. Few foods contain vitamin D naturally and skin exposure to sunlight is the main source. Moving away from the equator, the intensity of UV light decreases, so that at a latitude above 50° (including northern Europe), vitamin D is not synthesised in winter, and even above 30° there is seasonal variation. The body store accumulated during the summer is consumed during the winter. Vitamin D is converted in the liver to 25-hydroxy vitamin D (25(OH)D), which is further hydroxylated in the kidneys to 1,25-dihydroxy-vitamin D (1,25 $(OH)_2D$), the active form of the vitamin (see Fig. 25.55, p. 1127). $1,25(OH)_2D$ activates specific intracellular receptors which influence calcium metabolism, bone mineralisation and tissue differentiation. The synthetic form, ergocalciferol, or vitamin D_2, is considered to be less potent than the endogenous D_3.

Recommended dietary intakes aim to prevent rickets and osteomalacia. There is increasing evidence that vitamin D is important for immune and muscle function, and may reduce falls in the elderly (p. 172). Margarines are fortified with vitamin D in the UK, and milk is fortified in some parts of Europe and in North America.

The effects of vitamin D deficiency (calcium deficiency, rickets and osteomalacia) are described on page 1125. An analogue of vitamin D (calcipotriol) is used for treatment of skin conditions such as psoriasis. Excessive doses of cholecalciferol, ergocalciferol or the hydroxylated metabolites cause hypercalcaemia (p. 767).

Vitamin E

There are eight related fat-soluble substances with vitamin E activity. The most important dietary form is α-tocopherol. Vitamin E has many direct metabolic actions:

- It prevents oxidation of polyunsaturated fatty acids in cell membranes by free radicals.
- It helps maintain cell membrane structure.
- It affects DNA synthesis and cell signalling.
- It is involved in the anti-inflammatory and immune systems.

Human deficiency is rare and has only been described in premature infants and in malabsorption. It can cause a mild haemolytic anaemia, ataxia and visual scotomas. Vitamin E intakes are considered safe up to 3200 mg/day (1000-fold greater than recommended intakes). Diets rich in vitamin E are consumed in countries with lower rates of coronary heart disease. However, randomised controlled trials have not demonstrated cardioprotective effects of vitamin E or other antioxidants.

Vitamin K

Vitamin K is supplied in the diet mainly as vitamin K_1 (phylloquinone) in the UK, or as vitamin K_2 (menaquinone) from fermented products in parts of Asia. Vitamin K_2 is also synthesised by bacteria in the colon. Vitamin K is a co-factor for carboxylation reactions: in particular, the production of γ-carboxyglutamate (gla). Gla residues are found in four of the coagulation factor proteins (II, VII, IX and X; p. 997), conferring their capacity to bind to phospholipid surfaces in the presence of calcium. Other important gla proteins are osteocalcin and matrix gla protein, which are important in bone mineralisation.

Vitamin K deficiency leads to delayed coagulation and bleeding. In obstructive jaundice, dietary vitamin K is not absorbed and it is essential to administer the vitamin in parenteral form before surgery. Warfarin and related anticoagulants (p. 1019) act by antagonising vitamin K. Vitamin K is given routinely to newborn babies to prevent haemorrhagic disease. Symptoms of excess have been reported only in infants, with synthetic preparations linked to haemolysis and liver damage.

5.34 Vitamin deficiency in old age

- **Requirements**: although energy requirements fall with age, those for micronutrients do not. If dietary intake falls, a vitamin-rich diet is required to compensate.
- **Vitamin D**: levels are commonly low due to reduced dietary intake, decreased sun exposure and less efficient skin conversion. This leads to bone loss and fractures. Supplements should be given to those in institutional care and those with recurrent falls.
- **Vitamin B_{12} deficiency**: a causal relationship with dementia has not been identified, but it does produce neuropsychiatric effects and should be checked in all those with declining cognitive function.

Water-soluble vitamins

Thiamin (vitamin B_1)

Thiamin is widely distributed in foods of both vegetable and animal origin. Thiamin pyrophosphate (TPP) is a co-factor for enzyme reactions involved in the

metabolism of macronutrients (carbohydrate, fat and alcohol), including:

- decarboxylation of pyruvate to acetyl-co-enzyme A, which bridges between glycolysis and the tricarboxylic acid (Krebs) cycle
- transketolase activity in the hexose monophosphate shunt pathway
- decarboxylation of α-ketoglutarate to succinate in the Krebs cycle.

In thiamin deficiency, cells cannot metabolise glucose aerobically to generate energy as ATP. Neuronal cells are most vulnerable, since they depend almost exclusively on glucose for energy requirements. Impaired glucose oxidation also causes an accumulation of pyruvic and lactic acids, which produce vasodilatation and increased cardiac output.

Deficiency – beri-beri

In the developed world, thiamin deficiency is mainly encountered in chronic alcoholics. Poor diet, impaired absorption, storage and phosphorylation of thiamin in the liver, and the increased requirements for thiamin to metabolise ethanol all contribute. In the developing world, deficiency usually arises as a consequence of a diet based on polished rice. The body has very limited stores of thiamin, so deficiency is manifest after only 1 month on a thiamin-free diet. There are two forms of the disease in adults:

- *Dry (or neurological) beri-beri* manifests with chronic peripheral neuropathy and with wrist and/or foot drop, and may cause Korsakoff's psychosis and Wernicke's encephalopathy (p. 253).
- *Wet (or cardiac) beri-beri* causes generalised oedema due to biventricular heart failure with pulmonary congestion.

In dry beri-beri, response to thiamin administration is not uniformly good. However, multivitamin therapy seems to produce some improvement, suggesting that other vitamin deficiencies may be involved. Wernicke's encephalopathy and wet beri-beri should be treated without delay with intravenous vitamin B and C mixture ('Pabrinex', p. 253). Korsakoff's psychosis is irreversible and does not respond to thiamin treatment.

Riboflavin (vitamin B_2)

Riboflavin is required for the flavin co-factors involved in oxidation–reduction reactions. It is widely distributed in animal and vegetable foods. Levels are low in staple cereals but germination increases its content. It is destroyed under alkaline conditions by heat and by exposure to sunlight.

Deficiency is rare in developed countries. It mainly affects the tongue and lips and manifests as glossitis, angular stomatitis and cheilosis. The genitals may be affected, as well as the skin areas rich in sebaceous glands, causing nasolabial or facial dyssebacea. Rapid recovery usually follows administration of riboflavin 10 mg daily by mouth.

Niacin (vitamin B_3)

Niacin encompasses nicotinic acid and nicotinamide. Nicotinamide is an essential part of the two pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which play a key role as hydrogen acceptors and donors for many enzymes. Niacin can be synthesised in the body in limited amounts from the amino acid tryptophan.

Deficiency – pellagra

Pellagra was formerly endemic among poor people who subsisted chiefly on maize, which contains niacytin, a form of niacin that the body is unable to utilise. Pellagra can develop in only 8 weeks in individuals eating diets that are very deficient in niacin and tryptophan. It remains a problem in parts of Africa, and is occasionally seen in alcoholics and in patients with chronic small intestinal disease in developed countries. Pellagra can occur in Hartnup's disease, a genetic disorder characterised by impaired absorption of several amino acids, including tryptophan. It is also seen occasionally in carcinoid syndrome (p. 784), when tryptophan is consumed in the excessive production of 5-hydroxytryptamine (5-HT). Pellagra has been called the disease of the three Ds:

- *Dermatitis*. Characteristically, there is erythema resembling severe sunburn, appearing symmetrically over the parts of the body exposed to sunlight, particularly the limbs and especially on the neck, but not the face (Casal's necklace, Fig. 5.19). The skin lesions may progress to vesiculation, cracking, exudation and secondary infection.
- *Diarrhoea*. This is often associated with anorexia, nausea, glossitis and dysphagia, reflecting the presence of a non-infective inflammation that extends throughout the gastrointestinal tract.
- *Dementia*. In severe deficiency, delirium occurs acutely and dementia develops in chronic cases.

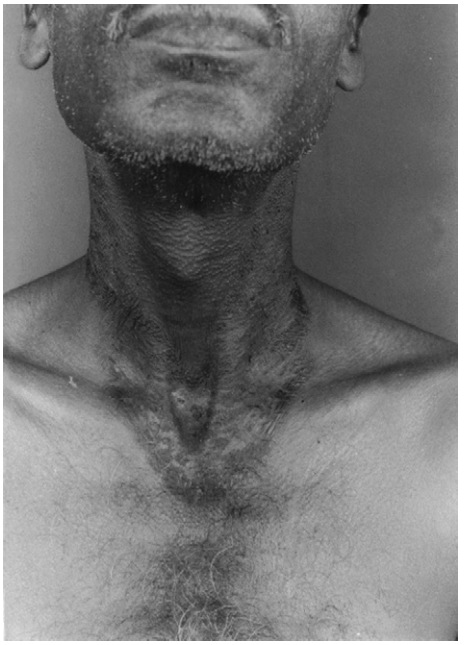

Fig. 5.19 Dermatitis due to pellagra (niacin deficiency). The lesions appear on those parts of the body exposed to sunlight. The classic 'Casal's necklace' can be seen around the neck and upper chest. From Karthikeyan and Thappa 2002 – see p. 132.

Treatment is with nicotinamide, given in a dose of 100 mg 3 times daily orally or parenterally. The response is usually rapid. Within 24 hours, the erythema diminishes, the diarrhoea ceases and a striking improvement occurs in the patient's mental state.

Toxicity

Excessive intakes of niacin may lead to reversible hepatotoxicity. Nicotinic acid is a lipid-lowering agent, but at doses above 200 mg a day gives rise to vasodilatory symptoms ('flushing' and/or hypotension).

Pyridoxine (vitamin B_6)

Pyridoxine, pyridoxal and pyridoxamine are different forms of vitamin B_6 that undergo phosphorylation to produce pyridoxal 5-phosphate (PLP). PLP is the co-factor for a large number of enzymes involved in the metabolism of amino acids. Vitamin B_6 is available in most foods.

Deficiency is rare, although certain drugs, such as isoniazid and penicillamine, act as chemical antagonists to pyridoxine. Pyridoxine administration is effective in isoniazid-induced peripheral neuropathy and some cases of sideroblastic anaemia. Large doses of vitamin B_6 have an antiemetic effect in radiotherapy-induced nausea. Although vitamin B_6 supplements have become popular in the treatment of nausea in pregnancy, carpal tunnel syndrome and premenstrual syndrome, there is no convincing evidence of benefit. Very high doses of vitamin B_6 taken for several months can cause a sensory polyneuropathy.

Biotin

Biotin is a co-enzyme in the synthesis of fatty acids, isoleucine and valine and is also involved in gluconeogenesis. Deficiency results from consuming very large quantities of raw egg whites (> 30% energy intake) because the avidin they contain binds to and inactivates biotin in the intestine. It may also be seen after long periods of total parenteral nutrition. The clinical features of deficiency include scaly dermatitis, alopecia and paraesthesia.

Folate (folic acid)

Folates exist in many forms. The main circulating form is 5-methyltetrahydrofolate. The natural forms are prone to oxidation. Folic acid is the stable synthetic form. Folate works as a methyl donor for cellular methylation and protein synthesis. It is directly involved in DNA and RNA synthesis, and requirements increase during embryonic development.

Folate deficiency may cause three major birth defects (spina bifida, anencephaly and encephalocele) resulting from imperfect closure of the neural tube, which takes place 3–4 weeks after conception. The UK Department of Health advises that women who have experienced a pregnancy affected by a neural tube defect should take 5 mg of folic acid daily from before conception and throughout the first trimester (see Box 5.32, p. 125). All women planning a pregnancy are advised to include good sources of folate in their diet, and to take folate supplements throughout the first trimester. Liver is the richest source of folate but an alternative source (e.g. leafy vegetables) is advised in early pregnancy because of the high vitamin A content of liver (p. 126). Folate deficiency has also been associated with heart disease, dementia and cancer. There is mandatory fortification of flour with folic acid in the US and voluntary fortification of many foods across Europe. There are now concerns that this may contribute to the increased incidence of colon cancer through promotion of the growth of polyps.

Hydroxycobalamin (vitamin B_{12})

Vitamin B_{12} is a co-factor in folate co-enzyme recycling and nerve myelination. Vitamin B_{12} and folate are particularly important in DNA synthesis in red blood cells (p. 1024). The haematological disorders (macrocytic or megaloblastic anaemias) due to their deficiency are discussed on pages 1024–1026. Vitamin B_{12}, but not folate, is needed for the integrity of myelin, so that vitamin B_{12} deficiency is also associated with neurological disease (see Box 24.35, p. 1024).

Neurological consequences of vitamin B_{12} deficiency

In older people and chronic alcoholics, vitamin B_{12} deficiency arises from insufficient intake and/or from malabsorption. Several drugs, including neomycin, can render vitamin B_{12} inactive. Adequate intake of folate maintains erythropoiesis and there is a concern that fortification of foods with folate may mask underlying vitamin B_{12} deficiency. In severe deficiency there is insidious, diffuse and uneven demyelination. It may be clinically manifest as peripheral neuropathy or spinal cord degeneration affecting both posterior and lateral columns ('subacute combined degeneration of the spinal cord'; p. 1222), or there may be cerebral manifestations (resembling dementia) or optic atrophy. Vitamin B_{12} therapy improves symptoms in most cases.

Vitamin C (ascorbic acid)

Ascorbic acid is the most active reducing agent in the aqueous phase of living tissues and is involved in intracellular electron transfer. It takes part in the hydroxylation of proline and lysine in protocollagen to hydroxyproline and hydroxylysine in mature collagen. It is very easily destroyed by heat, increased pH and light, and is very soluble in water; hence many traditional cooking methods reduce or eliminate it. Claims that high-dose vitamin C improves immune function (including resistance to the common cold) and cholesterol turnover remain unsubstantiated.

Deficiency – scurvy

Vitamin C deficiency causes defective formation of collagen with impaired healing of wounds, capillary haemorrhage and reduced platelet adhesiveness (normal platelets are rich in ascorbate) (Fig. 5.20). Precipitants and clinical features of scurvy are shown in Box 5.35. A dose of 250 mg vitamin C 3 times daily by mouth should saturate the tissues quickly. The deficiencies of the patient's diet also need to be corrected and other vitamin supplements given if necessary. Daily intakes of more than 1 g/day have been reported to cause diarrhoea and the formation of renal oxalate stones.

Other dietary organic compounds

There are a number of non-essential organic compounds with purported health benefits such as reducing risk of heart disease or cancer. Groups of compounds such as the flavonoids and phytoestrogens show bioactivity

Fig. 5.20 **Scurvy.** A Gingival swelling and bleeding. B Perifollicular hyperkeratosis. From Ho, et al. 2007 – see p. 132.

5.35 Scurvy – vitamin C deficiency

Precipitants

Increased requirement
- Trauma, surgery, burns, infections
- Smoking
- Drugs (corticosteroids, aspirin, indometacin, tetracycline)

Dietary deficiency
- Lack of dietary fruit and vegetables for > 2 mths
- Infants fed exclusively on boiled milk

Clinical features
- Swollen gums which bleed easily
- Perifollicular and petechial haemorrhages
- Ecchymoses
- Haemarthrosis
- Gastrointestinal bleeding
- Anaemia
- Poor wound healing

through their respective antioxidant and oestrogenic or anti-oestrogenic activities. Flavonoids (of which there are a number of different classes of compound) are found in fruit and vegetables, tea and wine; phytoestrogens are found in soy products (with higher intakes in parts of Asia compared to Europe and the US) and pulses. Caffeine from tea and coffee and carbonated beverages affects the nervous system and can improve mental performance in the short term, with adverse effects seen at higher intakes. Intake of non-carbonic organic acids (which are not metabolised to carbon dioxide), e.g. oxalates, may be restricted in individuals prone to kidney stones.

Inorganic micronutrients

A number of inorganic elements are essential dietary constituents for humans (Box 5.36). Deficiency is seen when there is inadequate dietary intake of minerals or excessive loss from the body. Toxic effects have also been observed from self-medication and disordered absorption or excretion. Examples of clinical toxicity include excess of iron (haemochromatosis or haemosiderosis), fluoride (fluorosis; p. 223), copper (Wilson's disease) and selenium (selenosis, seen in parts of China). For most minerals, the available biochemical markers do not accurately reflect dietary intake and dietary assessment is required.

Calcium and phosphorus

Calcium is the most abundant cation in the body and powerful homeostatic mechanisms control circulating ionised calcium levels (pp. 766 and 1126). WHO's dietary guidelines for calcium differ between countries, with higher intakes usually recommended in places with higher fracture prevalence. Between 20 and 30% of calcium in the diet is absorbed, depending on vitamin D status and food source. Calcium requirements depend on phosphorus intakes, with an optimum molar ratio (Ca:P) of 1:1. Excessive phosphorus intakes (e.g. 1–1.5 g/day) with a Ca:P of 1:3 have been shown to cause hypocalcaemia and secondary hyperparathyroidism (p. 768).

Calcium absorption may be impaired in vitamin D deficiency (pp. 766 and 1126) and in malabsorption secondary to small intestinal disease. Calcium deficiency causes impaired bone mineralisation and can lead to osteomalacia in adults. The potential benefits of high calcium intake in osteoporosis are discussed on page 1124. Too much calcium can lead to constipation and toxicity has been observed in 'milk-alkali syndrome' (p. 767).

Dietary deficiency of phosphorus is rare (except in older people with limited diets) since it is present in nearly all foods and phosphates are added to a number of processed foods. Phosphate deficiency in adults occurs:
- in patients with renal tubular phosphate loss (p. 448)
- due to prolonged high dosage of aluminium hydroxide (p. 488)
- sometimes when alcoholics are fed with high-carbohydrate foods
- in patients receiving parenteral nutrition if inadequate phosphate is provided.

Deficiency causes hypophosphataemia (p. 448) and muscle weakness secondary to ATP deficiency.

Iron

Iron is involved in the synthesis of haemoglobin, and is required for the transport of electrons within cells and in a number of enzyme reactions. Non-haem iron in cereals and vegetables is poorly absorbed but makes the greater contribution to overall intake, compared to the well-absorbed haem iron from animal products. Fruits and vegetables containing vitamin C enhance iron absorption, while the tannins in tea reduce it. Dietary calcium reduces iron uptake from the same meal, which

5.36 Summary of clinically important minerals

Mineral	Sources[1] Rich	Important	Reference nutrient intake (RNI)
Calcium	Milk and milk products, tofu	Milk, boned fish, green vegetables, beans	700 mg[2]
Phosphorus	Most foods contain phosphorus		550 mg[2]
	Marmite® and dry-roasted peanuts	Milk, cereal products, bread and meat	
Magnesium	Whole grains, nuts	Unprocessed and wholegrain foods	300 mg men 270 mg women[2]
Iron	Liver, red meat (haem iron)	Non-haem iron from vegetables, wholemeal bread	8.7 mg 14.8 mg women < 50 yrs
Zinc	Red meat, seafood	Dairy produce, wholemeal bread	9.5 mg men 7 mg women[2]
Iodine	Edible seaweeds	Milk and dairy products	140 μg
Selenium	Fish, wheat grown in selenium-rich soils	Fish	75 μg men 60 μg women[2]
Copper	Shellfish, liver	Bread, cereal products, vegetables	1.2 mg[2]
Fluoride	Drinking water, tea		No RNI. Safe intake: 0.5 mg/kg
Potassium	Dried fruit, potatoes, coffee	Fresh fruit, vegetables, milk	3500 mg
Sodium	Table salt, anchovies	Processed foods, bread, bacon	1600 mg

[1]Rich sources contain the nutrient in high concentration but are not generally eaten in large amounts; important sources contain less but contribute most because larger amounts are eaten. [2]Increased amounts are required in women during lactation.

may precipitate iron deficiency in those with borderline iron stores. There is no physiological mechanism for excretion of iron, so homeostasis depends on the regulation of iron absorption (see Fig. 24.20, p. 1022). This is regulated at the level of duodenal enterocytes by hepcidin. The expression of hepcidin (a peptide secreted by hepatocytes in the duodenum) is suppressed when body iron is low, leading to enhanced efflux of iron into the circulation. The normal daily loss of iron is 1 mg, arising from desquamated surface cells and intestinal losses. A regular loss of only 2 mL of blood per day doubles the iron requirement. On average, an additional 20 mg of iron is lost during menstruation, so pre-menopausal women require about twice as much iron as men (and more if menstrual losses are heavy).

The major consequence of iron deficiency is anaemia (p. 1021). This is one of the most important nutritional causes of ill health in all parts of the world. In the UK, it is estimated that 10% women are iron-deficient. Dietary iron overload is occasionally observed and results in iron accumulation in the liver and, rarely, cirrhosis. Haemochromatosis results from an inherited increase in iron absorption (p. 972).

Iodine

Iodine is required for synthesis of thyroid hormones (p. 738). It is present in sea fish, seaweed and most plant foods grown near the sea. The amount of iodine in soil and water influences the iodine content of most foods. Iodine is lacking in the highest mountainous areas of the world (e.g. the Alps and the Himalayas) and in the soil of frequently flooded plains (e.g. Bangladesh).

About a billion people in the world are estimated to have an inadequate iodine intake and hence are at risk of iodine deficiency disorder. Goitre is the most common manifestation, affecting about 200 million people (p. 752).

In those areas where most women have endemic goitre, 1% or more of babies are born with cretinism (characterised by mental and physical retardation). There is a higher than usual prevalence of deafness, slowed reflexes and poor learning in the remaining population. The best way of preventing neonatal cretinism is to ensure adequate levels of iodine during pregnancy. This can be achieved by intramuscular injections with 1–2 mL of iodised poppy seed oil (475–950 mg iodine) to women of child-bearing age every 3–5 years, by administration of iodised oil orally at 6-monthly or yearly intervals to adults and children, or by providing iodised salt for cooking.

Zinc

Zinc is present in most foods of vegetable and animal origin. It is an essential component of many enzymes, including carbonic anhydrase, alcohol dehydrogenase and alkaline phosphatase.

Acute zinc deficiency has been reported in patients receiving prolonged zinc-free parenteral nutrition and causes diarrhoea, mental apathy, a moist, eczematoid dermatitis, especially around the mouth, and loss of hair. Chronic zinc deficiency occurs in dietary deficiency, malabsorption syndromes, alcoholism and its associated hepatic cirrhosis. It causes the clinical features seen in the very rare congenital disorder known as acrodermatitis enteropathica (growth retardation, hair loss and chronic diarrhoea). Zinc deficiency is thought to be responsible for one-third of the world's population not reaching their optimal height. In the Middle East, chronic deficiency has been associated with dwarfism and hypogonadism. In starvation, zinc deficiency

causes thymic atrophy, and zinc supplements may accelerate the healing of skin lesions, promote general well-being, improve appetite and reduce the morbidity associated with the under-nourished state, and lower the mortality associated with diarrhoea and pneumonia in children.

Selenium

The family of seleno-enzymes includes glutathione peroxidase, which helps prevent free radical damage to cells, and monodeiodinase, which converts thyroxine to triiodothyronine (p. 738). North American soil has a higher selenium content than European and Asian soil, and the decreasing reliance of Europe on imported American food in recent decades has resulted in a decline in dietary selenium intake.

Selenium deficiency can cause hypothyroidism, cardiomyopathy in children (Keshan's disease) and myopathy in adults. Excess selenium can cause heart disease.

Fluoride

Fluoride helps prevent dental caries, since it increases the resistance of the enamel to acid attack. It is a component of bone mineral and some studies have shown anti-fracture effects at low doses, but excessive intakes may compromise bone structure.

If the local water supply contains more than 1 part per million (ppm) of fluoride, the incidence of dental caries is low. Soft waters usually contain no fluoride, whilst very hard waters may contain over 10 ppm. The benefit of fluoride is greatest when it is taken before the permanent teeth erupt, while their enamel is being laid down. The addition of traces of fluoride (at 1 ppm) to public water supplies is now a widespread practice. Chronic fluoride poisoning is occasionally seen where the water supply contains > 10 ppm fluoride. It can also occur in workers handling cryolite (aluminium sodium fluoride), used in smelting aluminium. Fluoride poisoning is described on page 223. Pitting of teeth is a result of too much fluoride as a child.

Sodium, potassium and magnesium

Western diets are high in sodium due to the sodium chloride (salt) that is added to processed food. In the UK, it is suggested that daily salt intakes are kept well below 6 g. The roles of sodium, potassium and magnesium, along with the disease states associated with abnormal intakes or disordered metabolism, are discussed in Chapter 16.

Other essential inorganic nutrients

These include chloride (a counter-ion to sodium and potassium), cobalt (required for vitamin B_{12}), sulphur (a constituent of methionine and cysteine), manganese (needed for or activates many enzymes) and chromium (necessary for insulin action). Deficiency of chromium presents as hyperglycaemia and has been reported in adults as a rare complication of prolonged parenteral nutrition.

Copper metabolism is abnormal in Wilson's disease (p. 973). Deficiency occasionally occurs but only in young children, causing microcytic hypochromic anaemia, neutropenia, retarded growth, skeletal rarefaction and dermatosis.

6

Infection is the establishment of foreign organisms, or 'infectious agents', in or on a human host. This may result in colonisation, if the microorganism exists at an anatomical site without causing harm, or infectious disease, when the interaction between the host and microorganism (pathogen) results in illness. In clinical practice, the term 'infection' is often used interchangeably with 'infectious disease'. Most pathogens are microorganisms, although some are multicellular organisms.

The host–pathogen interaction is dynamic and complex. Whilst it is rarely in the microorganism's interest to kill the host (on which it relies for nutrition and protection), the manifestations of disease may aid its dissemination (e.g. diarrhoea, sneezing). Conversely, it is in the host's interests to kill microorganisms likely to cause disease, whilst preserving colonising organisms, which may be beneficial.

Communicable diseases are caused by organisms transmitted between hosts, whereas endogenous diseases are caused by organisms already colonising the host. Cross-infection with colonising organisms (e.g. meticillin-resistant *Staphylococcus aureus*, MRSA) is both communicable and endogenous. Opportunistic infections may be communicable or endogenous and arise only in individuals with impaired host defence. The chain of infection (Fig. 6.1) describes six essential elements for communicable disease transmission.

Despite dramatic advances in hygiene, immunisation and antimicrobial therapy, infectious diseases are still a major cause of disease worldwide. Key challenges remain in tackling infection in resource-poor countries and in the emergence of new infectious agents and antimicrobial-resistant microorganisms. This chapter describes the biological and epidemiological principles of infectious diseases and the general approach to their prevention, diagnosis and treatment. Specific infectious diseases are described in Chapters 13–15 and many of the organ-based chapters.

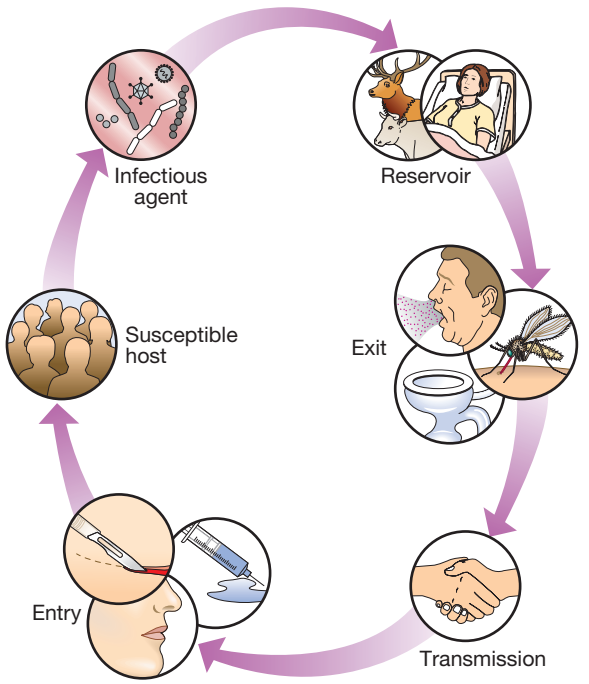

Fig. 6.1 Chain of infection. The infectious agent is the organism that causes the disease. The reservoir is the place where the population of an infectious agent is maintained. The portal of exit is the point from which the infectious agent leaves the reservoir. Transmission is the process by which the infectious agent is transferred from the reservoir to the human host, either directly or via a vector or fomite. The portal of entry is the body site that is first accessed by the infectious agent. Finally, in order for disease to ensue, the person to whom the infectious agent is transmitted must be a susceptible host.

INFECTIOUS AGENTS

The concept of an infectious agent was established by Robert Koch in the 19th century (Box 6.1). Although fulfilment of 'Koch's postulates' became the standard for the definition of an infectious agent, they do not apply to uncultivable organisms (e.g. *Mycobacterium leprae*, *Tropheryma whipplei)* or members of the normal human flora (e.g. *Escherichia coli*, *Candida* spp.). The following groups of infectious agents are now recognised.

Prions

Prions are unique amongst infectious agents in that they are devoid of any nucleic acid. They appear to be transmitted by acquisition of a normal mammalian protein (prion protein, PrP^{C}) which is in an abnormal conformation (PrP^{SC}, containing an excess of beta-sheet protein); the abnormal protein inhibits the 26S proteasome, which can degrade misfolded proteins, leading to accumulation of the abnormally configured PrP^{SC} protein instead of normal PrP^{C}. The result is accumulation of protein which forms amyloid in the central nervous system, causing a transmissible spongiform encephalopathy (see Box 13.40, p. 329, and p. 1211).

Viruses

Viruses are incapable of independent replication, instead subverting host cellular processes to ensure synthesis of their nucleic acids and proteins. A virus that infects a bacterium is a bacteriophage (phage). Viruses contain genetic material (genome), which may be single- or double-stranded DNA or RNA. Retroviruses transcribe their RNA into DNA by reverse transcription. An antigenically unique protein coat (capsid) encloses the genome, together forming the nucleocapsid. In many viruses, the nucleocapsid is packaged within a lipid envelope. Enveloped viruses are less able to survive in the environment and are spread by respiratory, sexual or blood-borne routes, including arthropod-based

6.1 Definition of an infectious agent – Koch's postulates

1. The same organism must be present in every case of the disease
2. The organism must be isolated from the diseased host and grown in pure culture
3. The isolate must cause the disease, when inoculated into a healthy, susceptible animal
4. The organism must be re-isolated from the inoculated, diseased animal

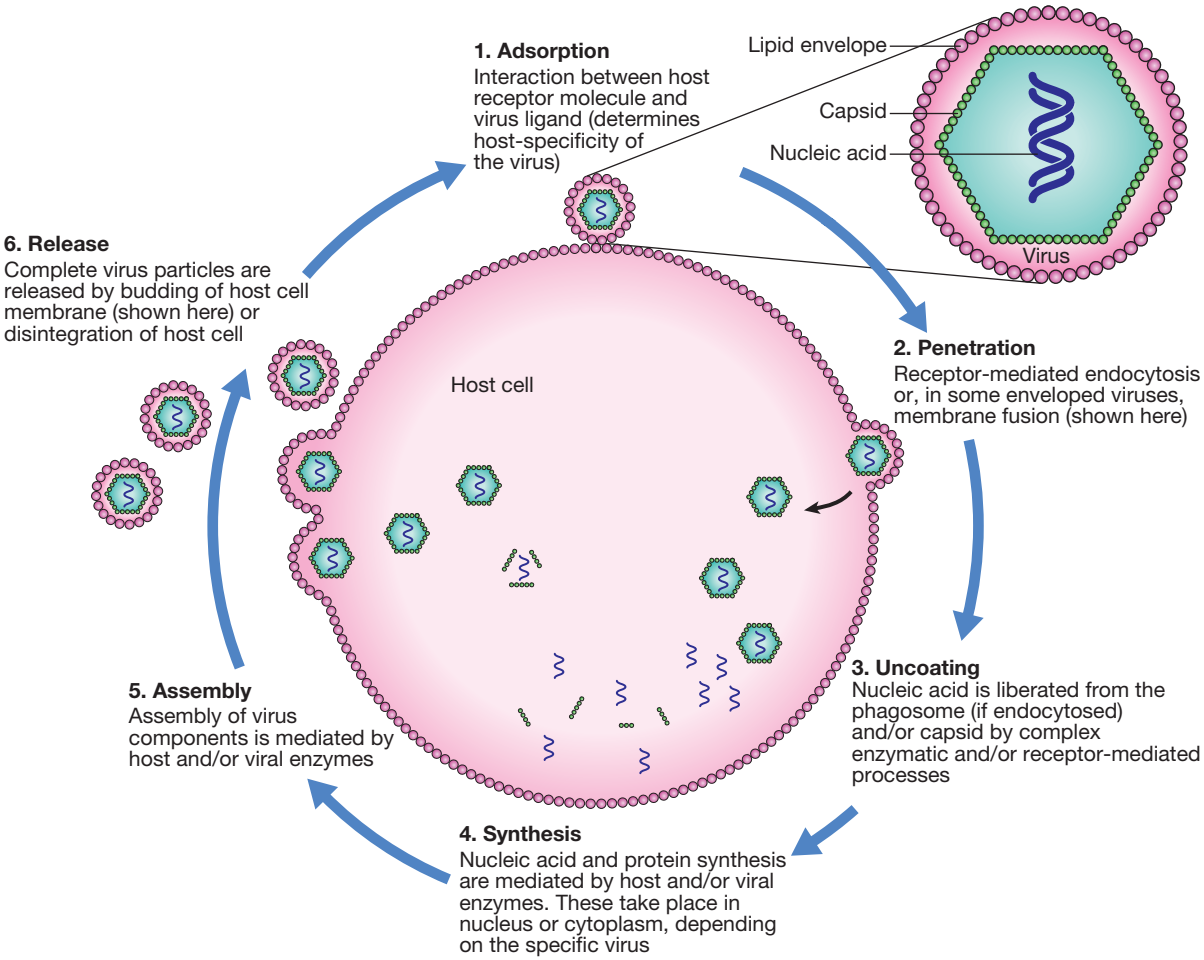

Fig. 6.2 A generic virus life cycle. Life cycle components common to most viruses are host cell attachment and penetration, virus uncoating, nucleic acid and protein synthesis, virus assembly and release. Virus release is achieved either by budding, as illustrated, or by lysis of the cell membrane. Life cycles vary between viruses.

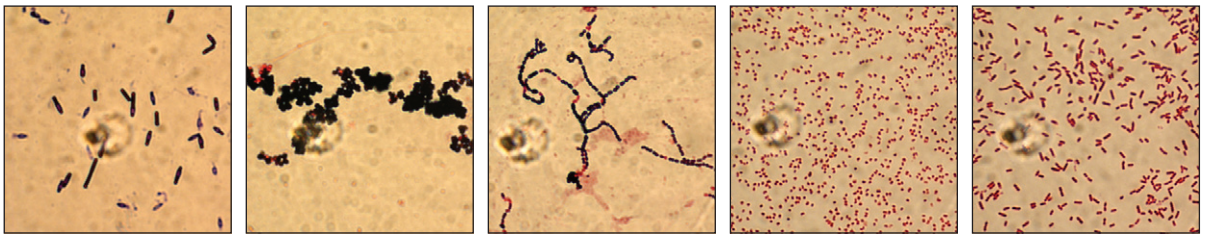
transmission. Non-enveloped viruses survive better in the environment and are predominantly transmitted by faecal–oral or, less often, respiratory routes. A generic virus life cycle is shown in Figure 6.2.

Prokaryotes: bacteria (including mycobacteria and actinomycetes)



Prokaryotic cells are capable of synthesising their own proteins and nucleic acids, and are able to reproduce autonomously, although they lack a nucleus. The bacterial cell membrane is bounded by a peptidoglycan cell wall, which is thick (20–80 nm) in Gram-positive organisms and thin (5–10 nm) in Gram-negative ones. The Gram-negative cell wall is surrounded by an outer membrane containing lipopolysaccharide. Plasmids are rings of extra-chromosomal DNA within bacteria, which can be transferred between organisms. Bacteria may be embedded in a polysaccharide capsule, and motile bacteria are equipped with flagella. Although many prokaryotes are capable of independent existence, some (e.g. *Chlamydia trachomatis*, *Coxiella burnetii*) are obligate intracellular organisms. Bacteria that replicate in artificial culture media are classified and identified using a range of characteristics (Box 6.2), with examples in Figures 6.3 and 6.4.

Eukaryotes: fungi, protozoa and helminths

Eukaryotes contain functional organelles, including nuclei, mitochondria and Golgi apparatus. Eukaryotes involved in human infection include fungi, protozoa (unicellular eukaryotes with a flexible cell membrane, p. 353) and helminths (complex multicellular organisms including nematodes, trematodes and cestodes, p. 369).

Fungi exist as either moulds (filamentous fungi) or yeasts. Dimorphic fungi exist in either form, depending on environmental conditions (see Fig. 13.57, p. 382). The fungal plasma membrane differs from the human cell membrane in that it contains the sterol, ergosterol. Fungi have a cell wall made up of polysaccharides, chitin and manno-proteins. In most fungi, the main structural component of the cell wall is β-1,3-D-glucan, a glucose polymer.

Protozoa and helminths are often referred to as parasites. Many parasites have complex multi-stage life cycles, which involve animal and/or plant hosts in addition to humans.

Gram-positive bacilli
- *Clostridium* spp. (shown here)
- *Corynebacterium* spp.
- *Bacillus* spp.

Gram-positive cocci in clusters
- Staphylococci

Gram-positive cocci in chains
- Streptococci

Gram-negative cocci
- *Neisseria* spp. (shown here)
- *Moraxella* spp.

Gram-negative bacilli
- Enterobacteriaceae (shown here)
- *Serratia* spp.
- *Acinetobacter* spp.
- *Bacteroides* spp.

Fig. 6.3 Gram film appearances of bacteria on light microscopy (×100).

6.2 How bacteria are identified

Gram stain reaction (see Fig. 6.3)
- Gram-positive (thick peptidoglycan layer), Gram-negative (thin peptidoglycan) or unstainable

Microscopic morphology
- Cocci (round cells) or bacilli (elongated cells)
- Presence or absence of capsule

Cell association
- Associated in clusters, chains or pairs

Colonial characteristics
- Colony size, shape or colour
- Effect on culture media (e.g. β-haemolysis of blood agar in haemolytic streptococci; see Fig. 6.4)

Atmospheric requirements
- Strictly aerobic (requires O_2), strictly anaerobic (requires absence of O_2), facultatively aerobic (grows with or without O_2) or micro-aerophilic (requires reduced O_2)

Biochemical reactions
- Expression of enzymes (oxidase, catalase, coagulase)
- Ability to ferment or hydrolyse various biochemical substrates

Motility
- Motile or non-motile

Antibiotic susceptibility
- Identifies organisms with invariable susceptibility (e.g. to optochin in *Streptococcus pneumoniae* or metronidazole in obligate anaerobes)

Matrix-assisted laser desorption/ionisation – time of flight mass spectrometry (MALDI-TOF-MS)
- A rapid technique that identifies bacteria and some fungi from their specific molecular composition

DNA sequencing of bacterial 16s ribosomes
- A highly specific test for definitive identification of organisms in pure culture and in samples from normally sterile sites

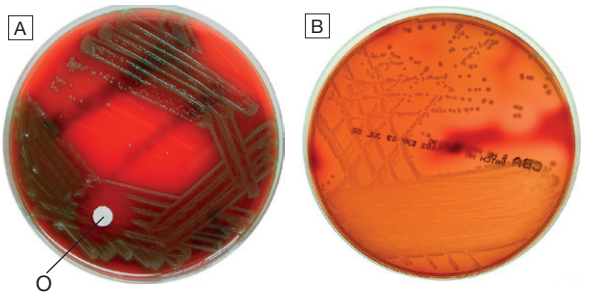


Fig. 6.4 Appearances of α- and β-haemolytic streptococci on blood agar. **A** Alpha-haemolytic streptococci. The colonies cause partial haemolysis, which imparts a green tinge to the agar. The organism shown is *Strep. pneumoniae* from the cerebrospinal fluid of a patient with meningitis (note also the susceptibility to optochin (O), which is another feature used to identify this organism). **B** Beta-haemolytic streptococci. The colonies cause complete haemolysis, which renders the agar transparent. The organism shown is *Strep. pyogenes* (group A β-haemolytic streptococci) from a superficial wound swab.

NORMAL FLORA

Every human is host to an estimated 10^{13}–10^{14} colonising microorganisms, which constitute the normal flora. Resident flora are able to survive and replicate at a body site, whereas transient flora are present only for short periods. Knowledge of non-sterile body sites and their normal flora is required to interpret culture results (Fig. 6.5).

The relationship between human host and normal flora is symbiotic, meaning that the organisms are in close proximity, and either mutualistic (both organisms benefit) or commensal (one organism benefits whilst the other derives neither benefit nor harm). The microbiome is the total burden of microorganisms, their genes and environmental interactions; the human microbiome is recognised increasingly as exerting a profound influence over human health and disease.

Maintenance of the normal flora is beneficial to health. For example, lower gastrointestinal tract bacteria synthesise and excrete vitamins (e.g. vitamins K and B_{12}); colonisation with normal flora confers 'colonisation resistance' to infection with pathogenic organisms by altering the local environment (e.g. lowering pH), producing antibacterial agents (e.g. bacteriocins, fatty acids and metabolic waste products), and inducing host antibodies which cross-react with pathogenic organisms.

Conversely, normally sterile body sites must be kept sterile. The mucociliary escalator transports environmental material deposited in the respiratory tract to the nasopharynx. The urethral sphincter prevents flow from the non-sterile urethra to the sterile bladder. Physical barriers, including the skin, lining of the gastrointestinal

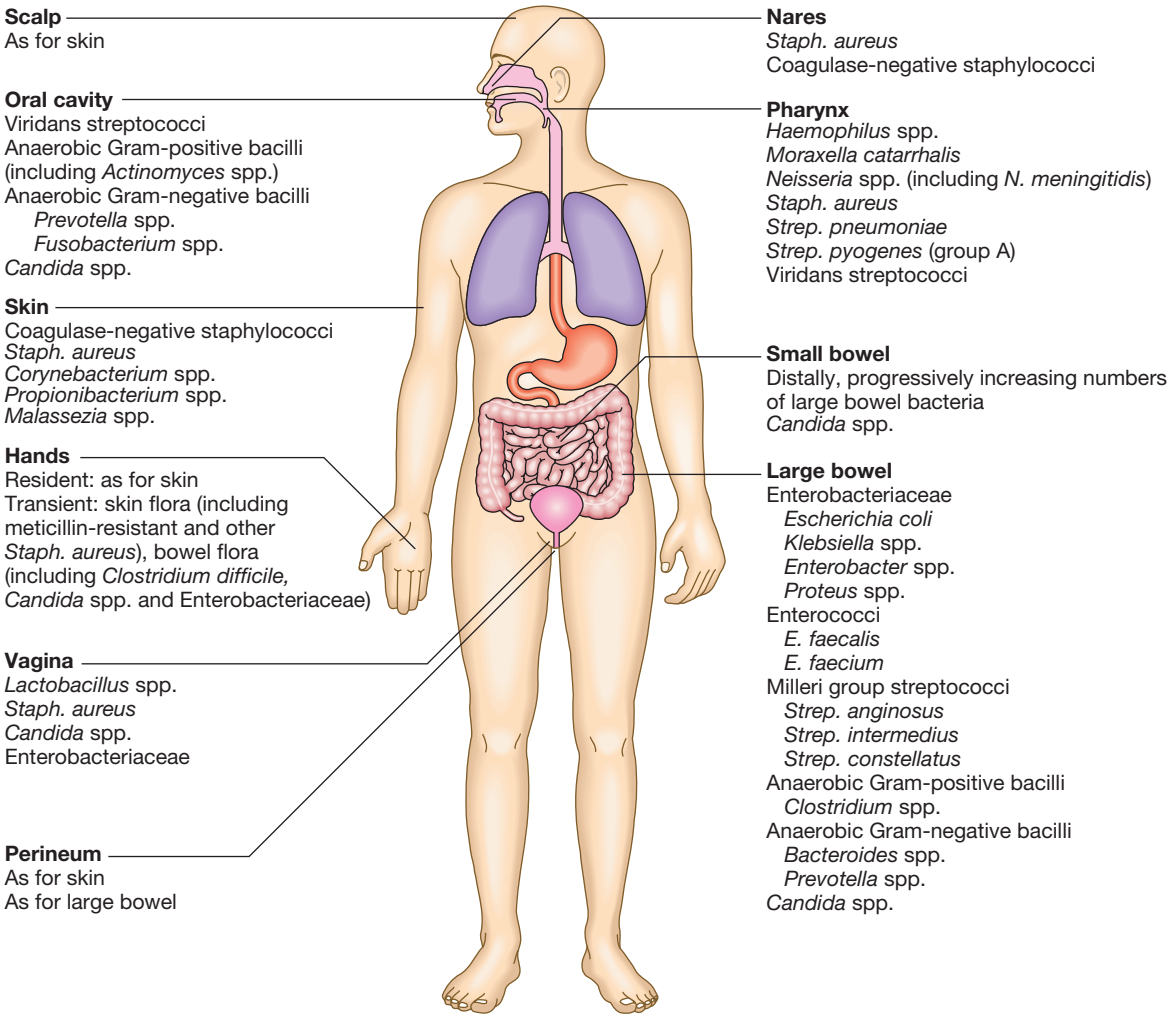

Fig. 6.5 Human non-sterile sites and normal flora in health.

tract and mucous membranes, maintain sterility of the blood stream, peritoneal and pleural cavities, chambers of the eye, subcutaneous tissue and so on.

The normal flora contribute to endogenous disease by either excessive growth at the 'normal' site (overgrowth) or translocation to a sterile site. Overgrowth is exemplified by 'blind loop' syndrome (p. 882), dental caries and vaginal thrush, in which external factors favour overgrowth of specific components of the normal flora. Translocation results from spread along a surface or penetration of a closed barrier: for example, in urinary tract infection caused by perineal/enteric flora, and in surgical site infections, particularly of prosthetic materials, caused by skin flora such as staphylococci. Normal flora also contribute to disease by cross-infection, in which organisms that are colonising one individual cause disease when transferred to another, more susceptible, individual.

HOST–PATHOGEN INTERACTIONS

Pathogenicity is the capability of an organism to cause disease and virulence is the extent to which a pathogen is able to cause disease. Pathogens produce proteins and other factors, termed virulence factors, which interact with host cells to contribute to disease.

- *Primary pathogens* cause disease in a proportion of individuals to whom they are exposed, regardless of their immunological status.
- *Opportunistic pathogens* cause disease only in individuals whose host defences are compromised; for example, by genetic susceptibility or immunosuppressive disease or therapy.

Characteristics of successful pathogens

Successful pathogens have a number of attributes. They compete with host cells and colonising flora by various methods, including sequestration of nutrients, use of metabolic pathways not used by competing bacteria, and production of bacteriocins (small antimicrobial peptides/proteins that kill closely related bacteria). Motility enables pathogens to reach their site of infection, often in sterile sites that colonising bacteria do not reach, such as the distal airway. Many microorganisms, including viruses, use 'adhesins' to attach to host cells at the site of infection. Other pathogens can invade through tissues.

6.3 Exotoxin-mediated bacterial diseases

Disease	Organism
Antibiotic-associated diarrhoea/pseudo-membranous colitis	*Clostridium difficile* (p. 308)
Botulism	*Clostridium botulinum* (p. 1210)
Cholera	*Vibrio cholerae* (p. 344)
Diphtheria	*Corynebacterium diphtheriae* (p. 345)
Haemolytic uraemic syndrome	*Escherichia coli* 0157 (and other strains) (p. 495)
Necrotising pneumonia	*Staphylococcus aureus* (p. 682)
Tetanus	*Clostridium tetani* (p. 1209)
Toxic shock syndrome	*Staphylococcus aureus* (p. 331)

Pathogens may produce toxins, microbial molecules that cause adverse effects on host cells, either at the site of infection, or remotely following carriage through the blood stream. Endotoxin is the lipid A domain of Gram-negative bacterial outer membrane lipopolysaccharide. It is released when bacterial cells are damaged and has generalised inflammatory effects. Exotoxins are proteins released by living bacteria, which often have specific effects on target organs (Box 6.3).

Intracellular pathogens, including viruses, bacteria (e.g. *Salmonella* spp., *Listeria monocytogenes* and *Mycobacterium tuberculosis*), parasites (e.g. *Leishmania* spp.) and fungi (e.g. *Histoplasma capsulatum*), are able to survive in intracellular environments, including after phagocytosis by macrophages.

Pathogenic bacteria express different arrays of genes, depending on environmental stress (pH, iron starvation, O_2 starvation and so on) and anatomical location. In quorum sensing, bacteria communicate with one another to adapt their replication or metabolism according to local population density. Bacteria and fungi may respond to the presence of an artificial surface (e.g. prosthetic device, venous catheter) by forming a biofilm, which is a population of organisms encased in a matrix of extracellular molecules. Biofilm-associated organisms are highly resistant to antimicrobial agents.

Genetic diversity enhances the pathogenic capacity of bacteria. Some virulence factor genes are found on plasmids or in phages and are exchanged between different strains or species. The ability to acquire genes from the gene pool of all strains of the species (the 'bacterial supragenome') increases diversity and the potential for pathogenicity. Viruses exploit their rapid reproduction and potential to exchange nucleic acid with host cells to enhance diversity. Once a strain acquires a particularly effective combination of virulence genes, it may become an epidemic strain, accounting for a large subset of infections in a particular region. This phenomenon accounts for influenza pandemics.

The host response

Innate and adaptive immune and inflammatory responses which humans use to control the normal flora and respond to pathogens are reviewed in Chapter 4.

Pathogenesis of infectious disease

The harmful manifestations of infection are determined by a combination of the virulence factors of the organism and the host response to infection. Despite the obvious benefits of an intact host response, an excessive response is undesirable. Cytokines and antimicrobial factors contribute to tissue injury at the site of infection, and an excessive inflammatory response may lead to hypotension and organ dysfunction (p. 82). The contribution of the immune response to disease manifestations is exemplified by the immune reconstitution inflammatory syndrome (IRIS). This is seen, for example, in human immunodeficiency virus (HIV) infection, post-transplantation neutropenia or tuberculosis (which causes suppression of T-cell function): there is a paradoxical worsening of the clinical condition as the immune dysfunction is corrected, caused by an exuberant but dysregulated inflammatory response.

The febrile response

Thermoregulation (p. 103) is altered in infectious disease. Microbial pyrogens or the endogenous pyrogens released during tissue necrosis stimulate specialised cells such as monocytes/macrophages to release cytokines, including interleukin (IL)-lβ, tumour necrosis factor-alpha (TNF)-α, IL-6 and interferon (IFN)-γ. Cytokine receptors in the pre-optic region of the anterior hypothalamus activate phospholipase A, releasing arachidonic acid as substrate for the cyclo-oxygenase pathway and producing prostaglandin E_2 (PGE_2), which in turn alters the responsiveness of thermosensitive neurons in the thermoregulatory centre. Rigors occur when the body inappropriately attempts to 'reset' core temperature to a higher level by stimulating skeletal muscle activity and shaking.

The role of the febrile response as a defence mechanism requires further study, but there are data to support the hypothesis that raised body temperature interferes with the replication and/or virulence of pathogens.

INVESTIGATION OF INFECTION

Patients in whom a diagnosis of infectious disease is being considered are investigated with non-specific tests that reflect innate immune and acute phase responses (p. 82), and specific tests, which detect either a microorganism or the host response to the organism (Box 6.4). Careful sampling increases the likelihood of diagnosis (Box 6.5). Culture results must be interpreted in the context of the normal flora at the sampled site (see Fig. 6.5). The extent to which a microbiological test result supports or excludes a particular diagnosis depends on its statistical performance (e.g. sensitivity, specificity, positive and negative predictive value, p. 5). Sensitivity and specificity vary according to the time between infection and testing, and positive and negative predictive values depend on the prevalence of the condition in the test population. The complexity of test interpretation is illustrated in Figure 6.7 (p. 141), which shows the 'windows of opportunity' afforded by various testing methods. Given this complexity, effective communication between the clinician and the microbiologist is vital to ensure accurate test interpretation.

6.4 Tests used to diagnose infection

Non-specific markers of inflammation/infection

- e.g. Full blood count (FBC), plasma C-reactive protein (CRP), procalcitonin, cell counts in urine or cerebrospinal fluid (CSF), CSF protein and glucose

Direct detection of organisms or organism components

- Microscopy
- Detection of organism components (e.g. antigen, toxin)
- Nucleic acid amplification (e.g. polymerase chain reaction)

Culture of organisms

- ± Antimicrobial sensitivity testing

Tests of the host's specific immune response

- Antibody detection
- Interferon-γ release assays (IGRA)

Direct detection

Direct detection methods provide rapid results and may be applied to organisms that cannot be grown easily on artificial culture media, such as *Chlamydia* spp. They do not usually provide information on antimicrobial susceptibility or the degree to which organisms are related to each other (which is important in the investigation of possible outbreaks), unless relevant specific nucleic acid sequences are detected by polymerase chain reaction (PCR).

Detection of whole organisms

Whole organisms are detected by examination of biological fluids or tissue using a microscope.

- *Bright field microscopy* (in which the test sample is interposed between the light source and the objective lens) uses stains to enhance visual contrast between the organism and its background. Examples include Gram staining of bacteria and Ziehl–Neelsen or auramine staining of acid- and alcohol-fast bacilli (AAFB) in tuberculosis. In histopathological examination of tissue samples, multiple stains are used to demonstrate not only the presence of microorganisms, but also features of disease pathology.
- *Dark field microscopy* (in which light is scattered to make organisms appear bright on a dark background) is used, for example, to examine genital chancre fluid in suspected syphilis.
- *Electron microscopy* may be used to examine stool and vesicle fluid to detect enteric and herpesviruses, respectively, but its use has largely been supplanted by nucleic acid detection (see below).

Detection of components of organisms

Components of microorganisms detected for diagnostic purposes include nucleic acids, cell wall molecules, toxins and other antigens. Commonly used examples include *Legionella pneumophila* serogroup 1 antigen in urine and cryptococcal polysaccharide antigen in cerebrospinal fluid (CSF). Most antigen detection methods are based on in vitro binding of specific antigen/antibody and are described below (p. 141). However, other methods may be used, such as mouse bioassay for detection of *Clostridium botulinum* toxin or tissue culture cytotoxicity assay for *C. difficile* toxin. In toxin-mediated disease, detection of toxin may be of greater relevance than identification of the organism itself (e.g. stool *C. difficile* toxin).

Nucleic acid amplification tests (NAAT)

Specific sequences of microbial DNA and RNA are identified using a nucleic acid primer which is amplified exponentially by enzymes to generate multiple copies of the specific sequence. The most commonly used amplification method is the polymerase chain reaction (PCR; see Fig. 3.12, p. 60). Reverse transcription (RT) PCR is used to detect RNA from RNA viruses

6.5 How to provide samples for microbiological sampling

Communication

- Discuss samples that may require forwarding to another laboratory or processing urgently or by an unusual method with laboratory staff *before* collection
- Communication is the most important requirement for good microbiological sampling. If there is doubt about any aspect of sampling, it is far better to discuss it with laboratory staff beforehand than to risk diagnostic delay by inappropriate sampling or sample handling

Indication

- Screening (e.g. collecting 'routine' urine, intravenous cannulae or sputum) in the absence of clinical evidence of infection is rarely appropriate

Container

- Certain tests (e.g. nucleic acid and antigen detection tests) require proprietary sample collection equipment

Collection

- Follow sample collection instructions precisely (e.g. proper collection of mid-stream, terminal and early morning urine samples, skin decontamination prior to blood culture etc.) to increase diagnostic yield

Labelling

- Label sample containers and request forms according to local policies, with demographic identifiers, specimen type and time/date collected
- Include clinical details on request forms
- Identify samples carrying a high risk of infection (e.g. blood liable to contain a blood-borne virus) with a hazard label

Packaging

- Close sample containers tightly and package securely (usually in sealed plastic bags)
- Attach request forms to samples but not in the same compartment (to avoid contamination, should leakage occur)

Storage and transport

- Transport samples to the microbiology laboratory quickly
- If pre-transport storage is required, conditions (e.g. refrigeration, incubation, storage at room temperature) vary with sample type
- Notify the receiving laboratory prior to arrival of samples, to ensure timely processing

(e.g. hepatitis C virus and HIV-1). The use of fluorescent-labelled primers and probes enables 'real-time' detection of amplified DNA; quantification is based on the principle that the time taken to reach the detection threshold is proportional to the initial number of copies of the target nucleic acid sequence. In multiplex PCR, multiple primer pairs are used to enable detection of several different organisms in a single assay.

Nucleic acid sequencing is also used to assign microorganisms to specific strains according to their genotype, which may be relevant to treatment and/or prognosis (e.g. in hepatitis C infection, p. 954). Genes that are relevant to pathogenicity (such as toxin genes) or antimicrobial resistance can also be detected. For example, detection of the *mecA* gene is used to screen for MRSA.

NAAT are the most sensitive direct detection methods and are particularly useful when a rapid diagnosis is required. They are used widely in virology, where the possibility of false-positive results from colonising or contaminating organisms is remote, and are applied to blood, respiratory samples, stool and urine. In bacteriology, PCR is used to examine CSF, blood, tissue and genital samples, and multiplex PCR is being developed for use in faeces. PCR is also being used increasingly in mycology and parasitology.

Culture

Microorganisms may be both detected and further characterised by culture from clinical samples (e.g. tissue, swabs and body fluids).

- *In vivo culture* (in a living organism) is not used in routine diagnostic microbiology.
- *Ex vivo culture* (tissue or cell culture) was widely used in the isolation of viruses, but has been largely supplanted by nucleic acid amplification techniques.

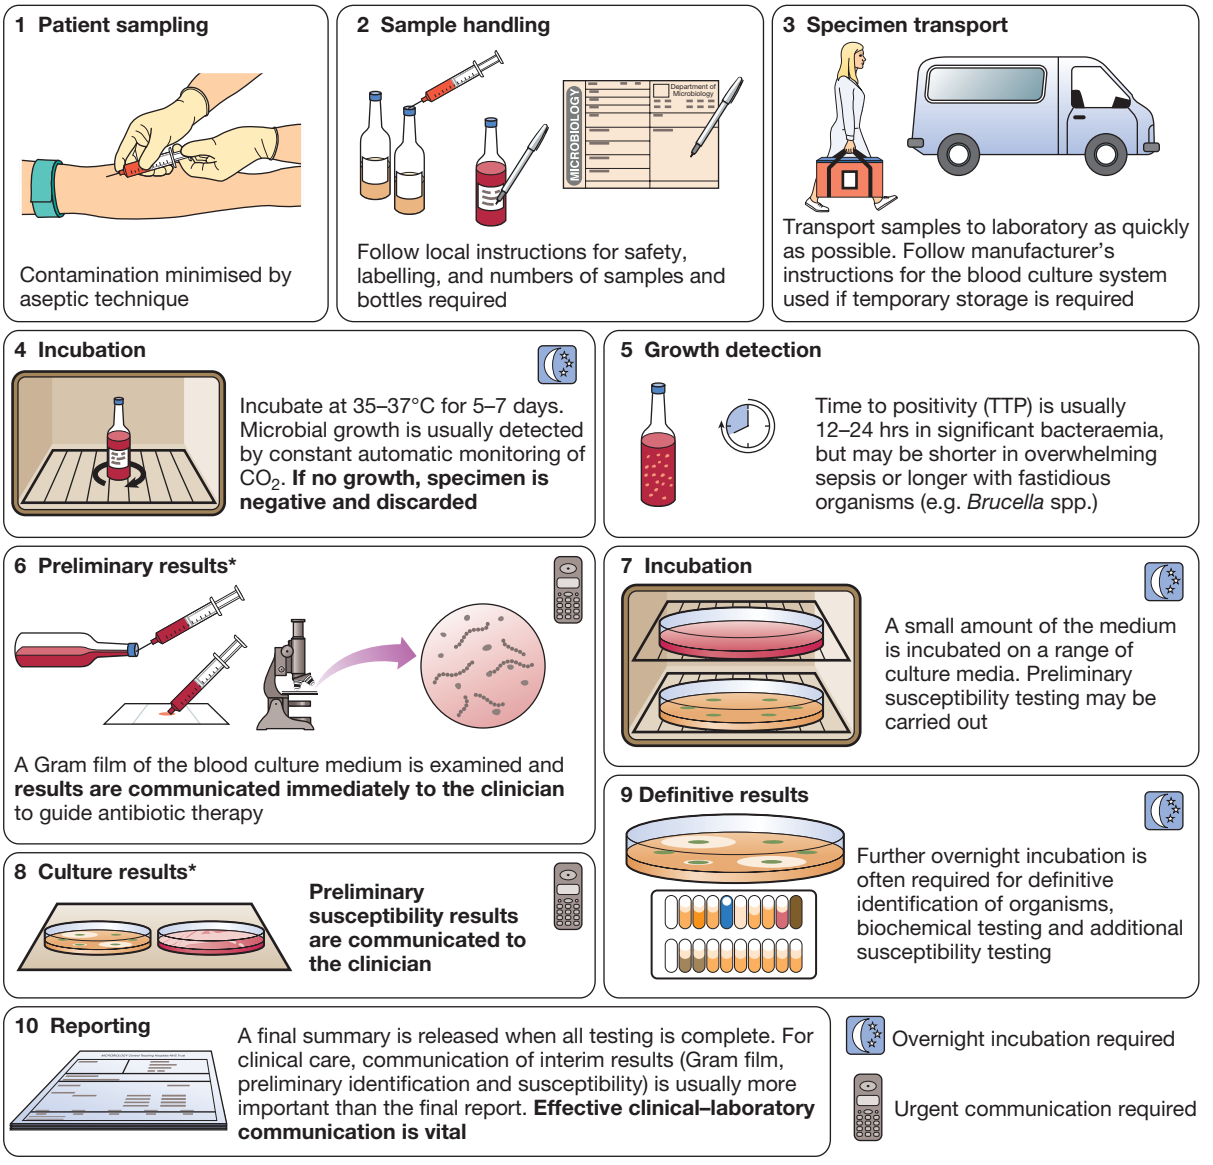

Fig. 6.6 An overview of the processing of blood cultures. *In laboratories equipped with MALDI-TOF (p. 136), rapid definitive organism identification may be achieved at stage 6 and/or stage 8.

- *In vitro culture* (in artificial culture media) of bacteria and fungi is used for definitive identification, to test for antimicrobial susceptibility and to subtype the organism for epidemiological purposes.

However, culture has its limitations. Results are not immediate, even for organisms which are easy to grow, and negative culture rarely excludes infection completely. Organisms such as *Mycobacterium tuberculosis* are inherently slow-growing, typically taking at least 2 weeks to be detectable, even in specialised systems. Certain organisms, such as *Mycobacterium leprae* and *Tropheryma whipplei*, cannot be cultivated on artificial media, and others (e.g. *Chlamydia* spp. and viruses) grow only in ex vivo systems, which are slow and labour-intensive to use.

Blood culture

Rapid microbiological diagnosis is required for bloodstream infection (BSI; Fig. 6.6). To diagnose BSI, a liquid culture medium is inoculated with freshly drawn blood, transported to the microbiology laboratory and incubated in a system that monitors it constantly for products of microbial respiration (mainly CO_2), generally using fluorescence. If growth is detected, organisms are identified and sensitivity testing is performed. Traditionally, identification has been achieved by Gram stain and culture. However, MALDI-TOF (see Box 6.2) is being used increasingly, as it is rapid and inexpensive, and enables identification of organisms directly from the blood-culture medium.

Specific immunological tests

Immunological tests may be used to detect the host response to a specific microorganism, and can enable the diagnosis of infection with organisms that are difficult to detect by other methods or are no longer present in the host. The term 'serology' describes tests carried out on serum, and is used to include both antigen and antibody detection.

Antibody detection

Organism-specific antibody detection is applied mainly to blood (Fig. 6.7). Results are typically expressed as titres: that is, the reciprocal of the highest dilution of the serum at which antibody is detectable (for example, detection at serum dilution of 1:64 gives a titre of 64). 'Seroconversion' is defined as either a change from negative to positive detection or a fourfold rise in titre between acute and convalescent serum samples. An acute sample is usually taken during the first week of disease and the convalescent sample 2–4 weeks later. Earlier diagnosis can be achieved by detection of IgM antibodies, which are produced early in infection (p. 77). A limitation of these tests is that antibody production requires a fully functional host immune system, so there may be false-negative results in immunocompromised patients. Also, other than in chronic infections and with IgM detection, antibody tests usually provide a retrospective diagnosis.

Antibody detection methods are described below (antigen detection methods are also described here as they share similar methodology).

Enzyme-linked immunosorbent assay

The principles of the enzyme-linked immunosorbent assay (ELISA, EIA) are illustrated in Figure 6.8. These assays rely on linking an antibody with an enzyme which generates a colour change on exposure to a chromogenic substrate. Various configurations allow detection of antigens or specific subclasses of immunoglobulin (e.g. IgG, IgM, IgA). ELISA may also be adapted to detect PCR products, using immobilised oligonucleotide hybridisation probe and various detection systems.

Immunoblot (Western blot)

Microbial proteins are separated according to molecular weight by polyacrylamide gel electrophoresis (PAGE) and transferred (blotted) on to a nitrocellulose membrane, which is incubated with patient serum. Binding of specific antibody is detected with an

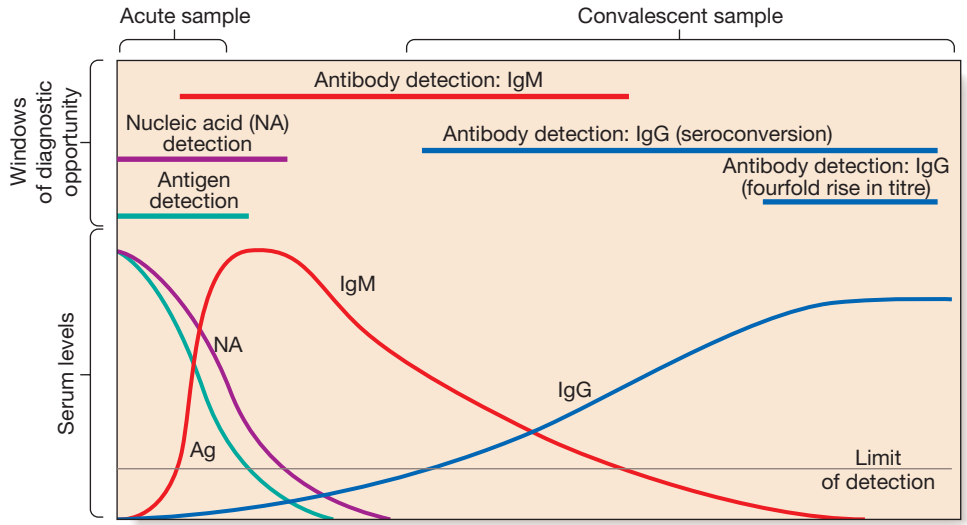

Fig. 6.7 Detection of antigen, nucleic acid and antibody in infectious disease. The acute sample is usually taken during the first week of illness, and the convalescent sample 2–4 weeks later. Detection limits and duration of detectability vary between tests and diseases, although in most diseases immunoglobulin (Ig) M is detectable within the first 1–2 weeks.

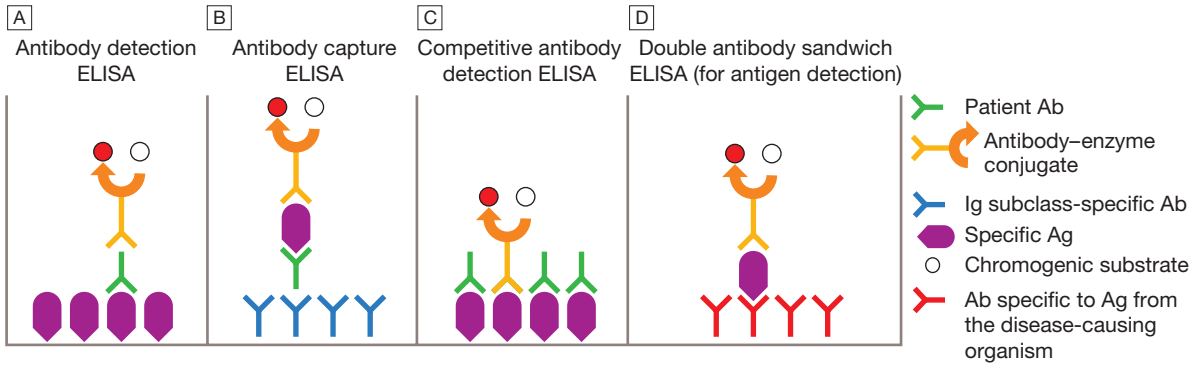

Fig. 6.8 Antibody (Ab) and antigen (Ag) detection by enzyme-linked immunosorbent assay (ELISA). This can be configured in various ways. A Patient Ab binds to immobilised specific Ag, and is detected by addition of anti-immunoglobulin–enzyme conjugate and chromogenic substrate. B Patient Ab binds to immobilised Ig subclass-specific Ab, and is detected by addition of specific Ag, followed by antibody–enzyme conjugate and chromogenic substrate. C Patient Ab and antibody–enzyme conjugate bind to immobilised specific Ag. Magnitude of colour change reaction is inversely proportional to concentration of patient Ab. D Patient Ag binds to immobilised Ab, and is detected by addition of antibody–enzyme conjugate and chromogenic substrate. In A, the conjugate Ab is specific for human immunoglobulin. In B–D, it is specific for Ag from the disease-causing organism.

enzyme–anti-immunoglobulin conjugate similar to that used in ELISA, and specificity is confirmed by its location on the membrane. Immunoblotting is a highly specific test, which may be used to confirm the results of less specific tests such as ELISA.

Immunofluorescence assays

Immunofluorescence assays (IFAs) are highly specific. In indirect immunofluorescence, a serum sample is incubated with immobilised antigen (e.g. cells known to be infected with virus on a glass slide) and antibody binding is detected using a fluorescent-labelled anti-human immunoglobulin (the 'secondary' antibody). This method can also detect organisms in clinical samples (usually tissue or centrifuged cells) using a specific antibody in place of patient serum. In direct immunofluorescence, clinical samples are incubated directly with fluorescent-labelled specific antibodies to detect antigen, eliminating the need for secondary antibody.

Complement fixation test

In a complement fixation test (CFT), patient serum is heat-treated to inactivate complement, and added to specific antigen. Any specific antibody present in the serum will complex with the antigen. Complement is then added to the reaction. If antigen–antibody complexes are present, the complement will be 'fixed' (consumed). Sheep erythrocytes, coated with an anti-erythrocyte antibody, are added. The degree of erythrocyte lysis reflects the remaining complement and is inversely proportional to the level of the specific antigen–antibody complexes.

Agglutination tests

When antigens are present on the surface of particles (e.g. cells, latex particles or microorganisms) and cross-linked with antibodies, visible clumping (or 'agglutination') occurs.

- In *direct agglutination*, patient serum is added to a suspension of organisms that express the test antigen. For example, in the Weil–Felix test, host antibodies to various rickettsial species cause agglutination of *Proteus* bacteria because they cross-react with bacterial cell surface antigens.
- In *indirect (passive) agglutination*, specific antigen is attached to the surface of carrier particles which agglutinate when incubated with patient samples that contain specific antibodies.
- In *reverse passive agglutination* (an antigen detection test), the carrier particle is coated with antibody rather than antigen.

Other tests

Immunodiffusion involves antibodies and antigen migrating through gels, with or without the assistance of electrophoresis, and forming insoluble complexes where they meet. The complexes are seen on staining as 'precipitin bands'. Immunodiffusion is used in the diagnosis of endemic mycoses (p. 381) and some forms of aspergillosis (p. 697).

Immunochromatography is used to detect antigen. The system consists of a porous test strip (e.g. a nitrocellulose membrane), at one end of which there is target-specific antibody, complexed with coloured microparticles. Further specific antibody is immobilised in a transverse narrow line some distance along the strip. Test material (e.g. blood or urine) is added to the antibody–particle complexes, which then migrate along the strip by capillary action. If these are complexed with antigen, they will be immobilised by the specific antibody and visualised as a transverse line across the strip. If the test is negative, the antibody–particle complexes will bind to a line of immobilised anti-immunoglobulin antibody placed further along the strip, which acts as a negative control. Immunochromatographic tests are rapid and relatively cheap to perform, and are appropriate for point-of-care testing, e.g. in HIV 1.

Antibody-independent specific immunological tests

Interferon-gamma release assays (IGRA) are being used increasingly to diagnose tuberculosis (p. 692). The principle of the assay is that T lymphocytes of patients infected with *Mycobacterium tuberculosis* (MTB) release IFN-γ when they are exposed to MTB-specific peptides. The absence of these peptides in bacille Calmette–Guérin (BCG; see Box 6.14) vaccine results in IGRA tests being more specific for the diagnosis of tuberculosis

infection than the tuberculin skin test (p. 692), because the latter may be positive as a result of previous BCG vaccination.

Antimicrobial susceptibility testing

If growth of microorganisms in culture is inhibited by the addition of an antimicrobial agent, the organism is considered to be susceptible. Bacteriostatic agents cause reversible inhibition of growth and bactericidal agents cause cell death; the terms fungistatic/fungicidal are equivalent for antifungal agents, and virustatic/virucidal for antiviral agents. The lowest concentration of antimicrobial agent at which growth is inhibited is the minimum inhibitory concentration (MIC), and the lowest concentration that causes cell death is the minimum bactericidal concentration (MBC). If the MIC is less than or equal to a predetermined *breakpoint* threshold, the organism is considered susceptible, and if the MIC is greater than the breakpoint, it is resistant.

Breakpoints are determined for each antimicrobial agent from a combination of pharmacokinetic and clinical data. The relationship between in vitro antimicrobial susceptibility and clinical response is complex, as response also depends on immune status, pharmacokinetic variability (p. 21), comorbidities that may influence pharmacokinetics or pharmacodynamics, and antibiotic dosing, as well as MIC/MBC. Thus, susceptibility testing does not guarantee therapeutic success.

Susceptibility testing is most often carried out by disc diffusion (Fig. 6.9). Antibiotic-impregnated filter paper discs are placed on an agar plate containing bacteria. The antibiotic diffuses through the agar, resulting in a concentration gradient centred on the disc. Bacteria are unable to grow where the antibiotic concentration exceeds the MIC, which may therefore be inferred from the size of the zone of inhibition. Susceptibility testing methods using antimicrobials diluted in liquid media are generally more accurate and reproducible, and are used for generating epidemiological data.

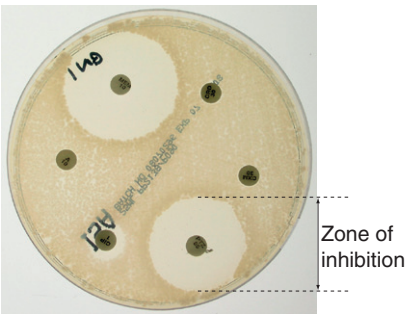

Fig. 6.9 Antimicrobial susceptibility testing by disc diffusion.
The test organism is grown as a 'lawn' on an agar plate in the presence of antimicrobial-impregnated discs. The organism is considered susceptible if the diameter of the zone of inhibition exceeds a predetermined threshold.

EPIDEMIOLOGY OF INFECTION

The communicability of infectious disease means that, once a clinician has diagnosed an infectious disease, potential exposure of other patients must be considered. The patient may require treatment in isolation, or an outbreak of disease may need to be investigated in the community (Ch. 5). The approach will be specific to the microorganism involved (Chs 13–15) but the principles are outlined below.

Geographic and temporal patterns of infection

Endemic disease

Endemic disease has a constant presence within a given geographic area or population. The infectious agent may have a reservoir, vector or intermediate host that is geographically restricted, or may itself have restrictive environmental requirements (e.g. temperature range, humidity). The population affected may be geographically isolated, or the disease may be limited to unvaccinated populations. Factors that alter geographical restriction include:

- expansion of an animal reservoir (e.g. Lyme disease from reforestation)
- vector escape (e.g. airport malaria)
- extension of host range (e.g. schistosomiasis from dam construction)
- human migration (e.g. severe acute respiratory syndrome (SARS) coronavirus)
- public health service breakdown (e.g. diphtheria in unvaccinated areas)
- climate change.

Emerging and re-emerging disease

An emerging infectious disease is one that has newly appeared in a population, or has been known for some time but is increasing in incidence or geographic range. If the disease was previously known and thought to have been controlled or eradicated, it is considered to be re-emerging. Many emerging diseases are caused by organisms which infect animals and have undergone adaptations that enable them to infect humans. This is exemplified by HIV, which is believed to have originated in higher primates in Africa. The geographical pattern of some recent emerging and re-emerging infections is shown in Figure 6.10.

Reservoirs of infection

The US Centers for Disease Control (CDC) define a reservoir of infection as 'one or more epidemiologically connected populations or environments in which a pathogen can be permanently maintained, and from which infection is transmitted to a defined target population'. Reservoirs of infection may be human, animal or environmental.

Human reservoirs

Colonised individuals or those with clinical infectious disease may act as reservoirs, e.g. for *Staph. aureus* (including MRSA), which is carried in the nares of 30–40% of humans, and *C. difficile*. For infected humans to act as reservoirs, the infections caused must be long-lasting and/or non-fatal, at least in a proportion of those affected, to enable onward transmission (e.g. tuberculosis, sexually transmitted infections). Humans are the only reservoir for some organisms (e.g. smallpox and measles).

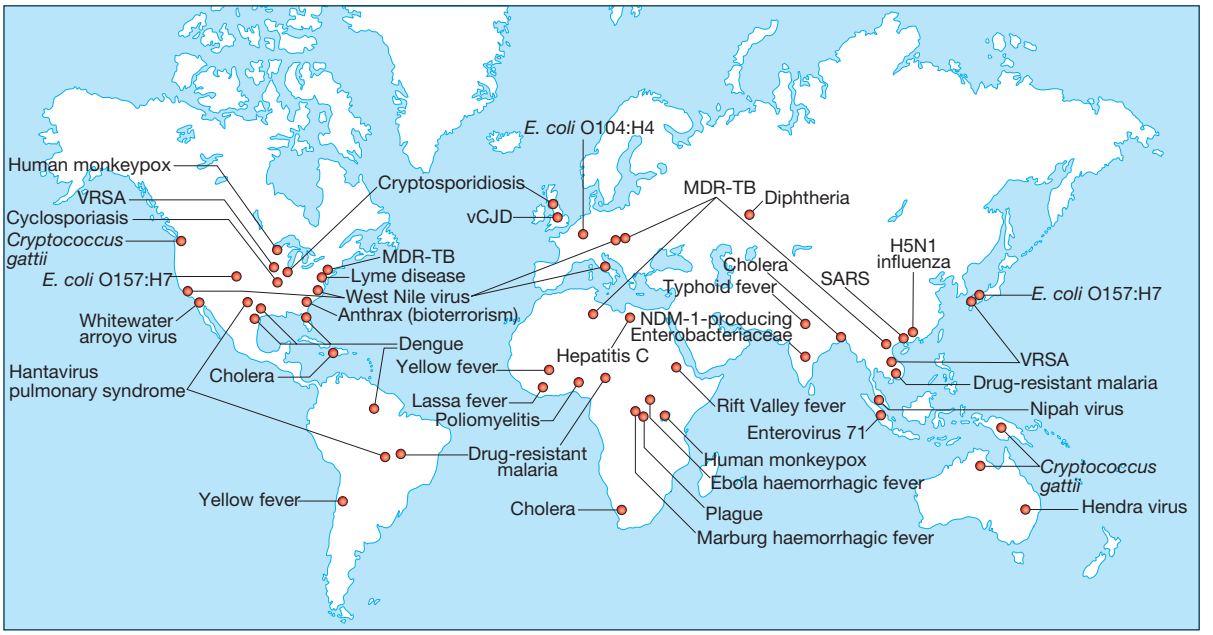

Fig. 6.10 Geographic locations of some infectious disease outbreaks, with examples of emerging and re-emerging diseases. (MDR-TB = multidrug-resistant tuberculosis; SARS = severe acute respiratory syndrome; vCJD = variant Creutzfeldt–Jakob disease; VRSA = vancomycin-resistant *Staph. aureus*) Adapted from Samaranayake 2006 – see p. 164.

Animal reservoirs

The World Health Organization (WHO) defines a zoonosis as 'a disease or infection that is naturally transmissible from vertebrate animals to humans'. The infected animal may be asymptomatic. Zoonotic agents may be transmitted via any of the routes described below. Primary infection with zoonoses may be transmitted onward between humans, causing secondary disease (e.g. Q fever, brucellosis, Ebola).

Environmental reservoirs

Many infective pathogens are acquired from an environmental source. However, some of these are maintained in human or animal reservoirs, with the environment acting only as a conduit for infection.

Transmission of infection

Infectious agents may be transmitted by one or more of the following routes:

- *Respiratory route*: inhalation.
- *Faecal–oral route*: ingestion of infectious material originating from faecal matter.
- *Sexually transmitted infections*: direct contact between mucous membranes.
- *Blood-borne infections*: direct inoculation of infected blood or body fluids.
- *Direct contact*: very few organisms are capable of causing infection by direct contact with intact skin. Most infection by this route requires inoculation or contact with damaged skin.
- *Via a vector or fomite*: the vector/fomite bridges the gap between the infected host or reservoir and the uninfected host. Vectors are animate, and include mosquitoes in malaria and dengue, fleas in plague and humans in MRSA. Fomites are inanimate, and include items such as door handles, water taps, ultrasound probes and so on, which are particularly associated with health care-associated infection.

6.6 Periods of infectivity in childhood infectious diseases[1]

Disease	Infectious period
Chickenpox	From 4 days before[2] until 5 days after appearance of the rash[3]
Measles	From 1–2 days before onset of rash; duration unknown[3]
Mumps	Unknown[4]
Rubella	Unknown, but most infectious during prodromal illness[3]
Scarlet fever	Unknown[5]
Whooping cough	Unknown[5,6]

[1]From Richardson M, Elliman D, Maguire H, et al. Pediatr Infect Dis J 2001; 20:380–388. These recommendations may differ from local or national guidance. [2]Transmission before 48 hrs prior to the onset of rash is rare. [3,4,5]Exclude from contact with non-immune and immunocompromised people for 5 days from [3]onset of rash, [4]onset of parotitis or [5]start of antibiotic treatment. [6]Exclude for 3 weeks if untreated.

The likelihood of infection following transmission of an infectious agent depends on organism factors and host susceptibility. The number of organisms required to cause infection or death in 50% of the exposed population is referred to as the ID_{50} (infectious dose) and LD_{50} (lethal dose), respectively. The incubation period is the time between exposure and development of disease, and the period of infectivity is the period after exposure during which the patient is infectious to others. Knowledge of incubation periods and periods of infectivity is important in controlling the spread of disease, although for many diseases these estimates are imprecise (Boxes 6.6 and 6.7).

6.7 Incubation periods of important infections[1]

Infection	Incubation period
Short incubation periods	
Anthrax, cutaneous[3]	9 hrs to 2 wks
Anthrax, inhalational[3]	2 days[2]
Bacillary dysentery[5]	1–6 days
Cholera[3]	2 hrs to 5 days
Dengue haemorrhagic fever[6]	3–14 days
Diphtheria[6]	1–10 days
Gonorrhoea[4]	2–10 days
Influenza[5]	1–3 days
Meningococcaemia[3]	2–10 days
Norovirus[1]	1–3 days
SARS coronavirus[3]	2–7 days[2]
Scarlet fever[5]	2–4 days
Intermediate incubation periods	
Amoebiasis[6]	1–4 wks
Brucellosis[4]	5–30 days
Chickenpox[5]	11–20 days
Lassa fever[3]	3–21 days
Malaria[3]	10–15 days
Measles[5]	6–19 days
Mumps[5]	15–24 days
Poliomyelitis[6]	3–35 days
Psittacosis[4]	1–4 wks
Rubella[5]	15–20 days
Typhoid[5]	5–31 days
Whooping cough[5]	5–21 days
Long incubation periods	
Hepatitis A[5]	3–7 wks
Hepatitis B[4]	6 wks to 6 mths
Leishmaniasis, cutaneous[6]	Weeks to months
Leishmaniasis, visceral[6]	Months to years
Leprosy[3]	5–20 yrs
Rabies[4]	2–8 wks[2]
Trypanosoma brucei gambiense infection[6]	Months to years
Tuberculosis[5]	1–12 mths

[1]Incubation periods are approximate and may differ from local or national guidance. [2]Longer incubation periods have been reported.

Reference sources:
[3]WHO. [4]Health Protection Agency (now Health Protection England). [5]Richardson M, Elliman D, Maguire H, et al. Pediatr Infect Dis J 2001; 20:380–388. [6]Centers for Disease Control, USA.

Deliberate release

The deliberate release of infectious agents with the intention of causing disease is known as biological warfare or bioterrorism, depending on the scale and context. Deliberate release incidents have included a 750-person outbreak of *Salmonella typhimurium* by contamination of salads in 1984 (Oregon, USA) and 22 cases of anthrax (five fatal) from the mailing of finely powdered (weaponised) anthrax spores in 2001 (New Jersey, USA). Diseases with high potential for deliberate release include anthrax, plague, tularaemia, smallpox and botulism (through toxin release).

INFECTION PREVENTION AND CONTROL

Infection prevention and control (IPC) describes the measures applied to populations with the aim of breaking the chain of infection (see Fig. 6.1, p. 134).

6.8 Measures used in infection prevention and control (IPC)

Institutional

- Handling, storage and disposal of clinical waste
- Containment and safe removal of spilled blood and body fluids
- Cleanliness of environment and medical equipment
- Specialised ventilation (e.g. laminar flow, air filtration, controlled pressure gradients)
- Sterilisation and disinfection of instruments and equipment
- Food hygiene
- Laundry management

Health-care staff

- Education
- Hand hygiene, including hand-washing (see Fig. 6.12)
- Sharps management and disposal
- Use of personal protective equipment (masks, sterile and non-sterile gloves, gowns and aprons)
- Screening health workers for disease (e.g. tuberculosis, hepatitis B virus, MRSA)
- Immunisation and post-exposure prophylaxis

Clinical practice

- Antibiotic stewardship (use only when necessary; avoid drugs known to select multi-resistant organisms or predispose to other infections)
- Aseptic technique (see Box 6.10)
- Perioperative antimicrobial prophylaxis
- Screening patients for colonisation or infection (e.g. MRSA, GRE, CPE)

Response to infections

- Surveillance to detect alert organism (see text) outbreaks and antimicrobial resistance
- Antibiotic chemoprophylaxis to infectious disease contacts, if indicated (see Box 6.19)
- Isolation (see Box 6.9)
- Reservoir control
- Vector control

(CPE = carbapenemase-producing Enterobacteriaceae; GRE = glycopeptide-resistant enterococci; MRSA = meticillin-resistant *Staphyloccus aureus*)

Health care-acquired infection

Admission to a health-care facility in the developed world carries a considerable risk of acquiring infection, estimated by the UK Department of Health as 6–10%. Factors that contribute to health care-acquired infection (HCAI, or nosocomial infection) are shown in Figure 6.11. Many nosocomial bacterial infections are caused by organisms that are resistant to numerous antibiotics (multi-resistant bacteria), including meticillin-resistant *Staph. aureus* (MRSA) (p. 330), extended-spectrum β-lactamase (ESBL)-producing Enterobacteriaceae, glycopeptide-resistant enterococci (GRE) and carbapenemase-producing Enterobacteriaceae (CPE). Other infections of particular concern in hospitals include *C. difficile* (p. 342) and norovirus (p. 327).

IPC measures are described in Box 6.8. The most important infection prevention practice is maintenance of good hand hygiene (Fig. 6.12). Hand decontamination or washing is *mandatory* before and after every patient contact. In most cases, decontamination with alcohol gel

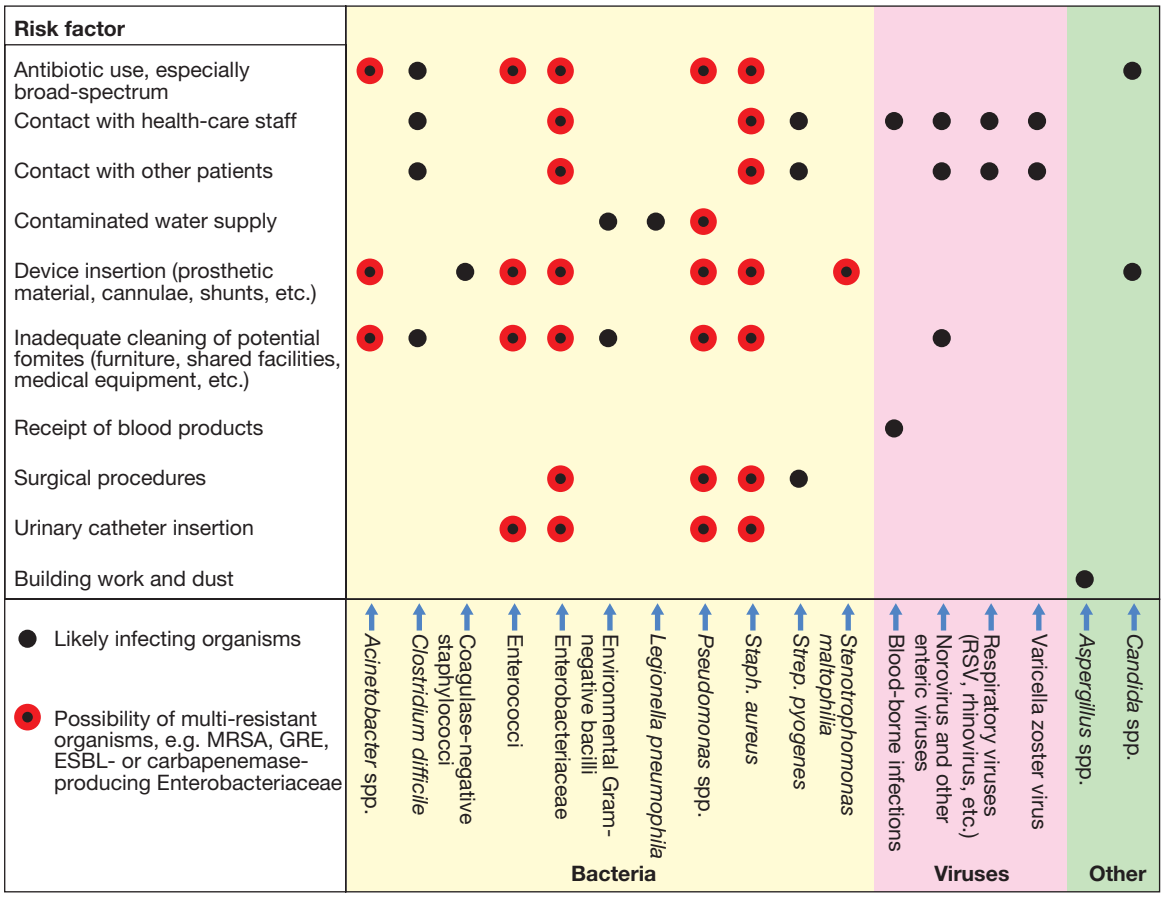

Fig. 6.11 Commonly encountered health care-associated infections (HCAI) and the factors that predispose to them. (ESBL = extended spectrum β-lactamases; GRE = glycopeptide-resistant enterococci; MRSA = multidrug-resistant *Staph. aureus*; RSV = respiratory syncytial virus)

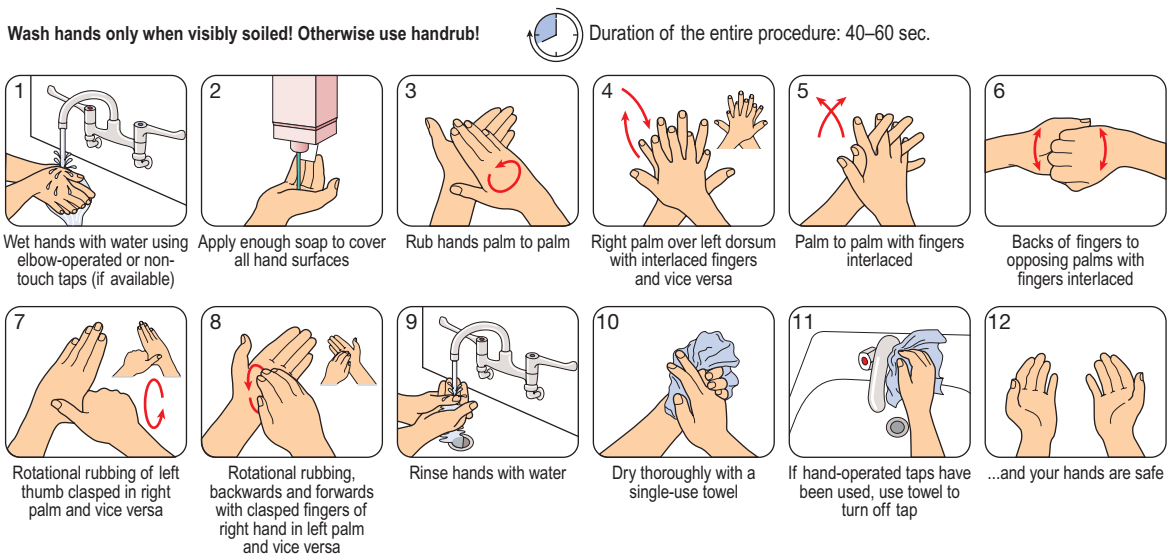

Fig. 6.12 Hand-washing. Good hand hygiene, whether with soap/water or alcohol handrub, includes areas that are often missed, such as fingertips, web spaces, palmar creases and the backs of hands. Adapted from WHO guidance at www.who.int – see p. 164.

is adequate. However, hand-washing (with hot water, liquid soap and complete drying) is required after any procedure that involves more than casual physical contact, or if hands are visibly soiled. In situations where the prevalence of *C. difficile* is high (e.g. a local outbreak), alcohol gel decontamination between patient contacts is inadequate, as it does not kill *C. difficile* spores, and hands must be washed with soap and water.

Some infections necessitate additional measures to prevent cross-infection (Box 6.9). To avoid infection, all

6.9 Types of isolation precaution[1]

Airborne transmission	Contact transmission	Droplet transmission
Precautions		
Negative pressure room with air exhausted externally or filtered N95 masks or personal respirators for staff; avoid using non-immune staff	Private room preferred (otherwise, inter-patient spacing ≥ 1 m) Gloves and gown for staff in contact with patient or contaminated areas	Private room preferred (otherwise, inter-patient spacing ≥ 1 m) Surgical masks for staff in close contact with patient
Infections managed with these precautions		
Measles Tuberculosis, pulmonary or laryngeal, confirmed or suspected	Enteroviral infections in young children (diapered or incontinent) Norovirus[2] *C. difficile* infection Multidrug-resistant organisms (e.g. MRSA, ESBL, GRE, VRSA, penicillin-resistant *Strep. pneumoniae*)[3] Parainfluenza in infants and young children Rotavirus RSV in infants, children and immunocompromised Viral conjunctivitis, acute	Diphtheria, pharyngeal *Haemophilus influenzae* type B infection Herpes simplex virus, disseminated or severe Influenza Meningococcal infection Mumps *Mycoplasma pneumoniae* Parvovirus (erythrovirus) B19 (erythema infectiosum, fifth disease) Pertussis Plague, pneumonic/bubonic Rubella *Strep. pyogenes* (group A), pharyngeal
Infections managed with multiple precautions		
← Smallpox, monkeypox, VZV, (chickenpox or disseminated disease)[4] →		
← Adenovirus pneumonia →		
← SARS, viral haemorrhagic fever[2] →		

[1]Recommendations based on 2007 CDC guideline for isolation precautions. May differ from local or national recommendations. [2]Not a CDC recommendation. [3]Subject to local risk assessment. [4]Or in any immunocompromised patient until possibility of disseminated infection excluded.
(ESBL = extended-spectrum β-lactamase; GRE = glycopeptide-resistant enterococci; MRSA = meticillin-resistant *Staph. aureus*; RSV = respiratory syncytial virus; SARS = severe acute respiratory syndrome; VRSA = vancomycin-resistant *Staph. aureus*; VZV = varicella zoster virus)

EBM 6.10 Skin antisepsis prior to insertion of central venous catheters

'Skin preparation with chlorhexidine in 70% isopropyl alcohol is more effective than povidone-iodine or aqueous antiseptic solutions in preventing catheter infections.'

- Pratt RJ, et al. J Hosp Infect 2007; 65S:S1–S64.

invasive procedures must be performed with strict aseptic technique (Box 6.10).

Outbreaks of infection

Descriptive terms are defined in Box 6.11. Confirmation of an infectious disease outbreak usually requires evidence from typing (p. 138) that the causal organisms have identical genotypic characteristics. If this is found not to be the case, the term pseudo-outbreak is used. When an outbreak of infection is suspected, a case definition is agreed. The number of cases that meet the case definition is then assessed by case-finding, using methods ranging from administration of questionnaires to national reporting systems. Case-finding usually includes microbiological testing, at least in the early stages of an outbreak. Temporal changes in cases are noted in order to plot an outbreak curve, and demographic details are collected to identify possible sources of infection. A case control study, in which recent activities (potential exposures) of affected 'cases' are compared to those of unaffected 'controls', may be undertaken to establish the outbreak source, and measures are taken to manage the outbreak and control its spread. Good communication between relevant personnel during and after the outbreak is important to inform practice in future outbreaks.

Surveillance ensures that disease outbreaks are either pre-empted or identified early. In hospitals, staff are made aware of the isolation of alert organisms, which have the propensity to cause outbreaks, and alert conditions, which are likely to be caused by such organisms. Analogous systems are used nationally; many countries publish lists of organisms and diseases, which, if detected (or suspected), must be reported to public health authorities (reportable or notifiable diseases). Reasons for a disease to be classified as reportable are shown in Box 6.12.

Principles of food hygiene

'Food poisoning' (p. 306) is largely preventable by food hygiene measures. The main principles are:

- segregation of uncooked food (which may be contaminated with pathogenic microorganisms) from cooked food
- avoidance of conditions which allow growth of pathogenic bacteria before or after cooking
- adequate bacterial killing during cooking.

Safe storage depends on the temperatures at which food bacteria are inhibited and destroyed (Fig. 6.13).

6.11 Terminology in outbreaks of infection

Term	Definition
Classification of related cases of infectious disease*	
Cluster	An aggregation of cases of a disease which are closely grouped in time and place, and may or may not exceed the expected number
Epidemic	The occurrence of more cases of disease than expected in a given area or among a specific group of people over a particular period of time
Outbreak	Synonymous with epidemic. Alternatively, a localised, as opposed to generalised, epidemic
Pandemic	An epidemic occurring over a very wide area (several countries or continents) and usually affecting a large proportion of the population
Classification of affected patients (cases)	
Index case	The first case identified in an outbreak
Primary cases	Cases acquired from a specific source of infection
Secondary cases	Cases acquired from primary cases
Types of outbreak	
Common source outbreak	Exposure to a common source of infection (e.g. water-cooling tower, medical staff member shedding MRSA). New primary cases will arise until the source is no longer present
Point source outbreak	Exposure to a single source of infection at a specific point in time (e.g. contaminated food at a party). Primary cases will develop disease synchronously
Person-to-person spread	Outbreak with both primary and secondary cases. May complicate point source or common source outbreak

*Adapted from www.cdc.gov.

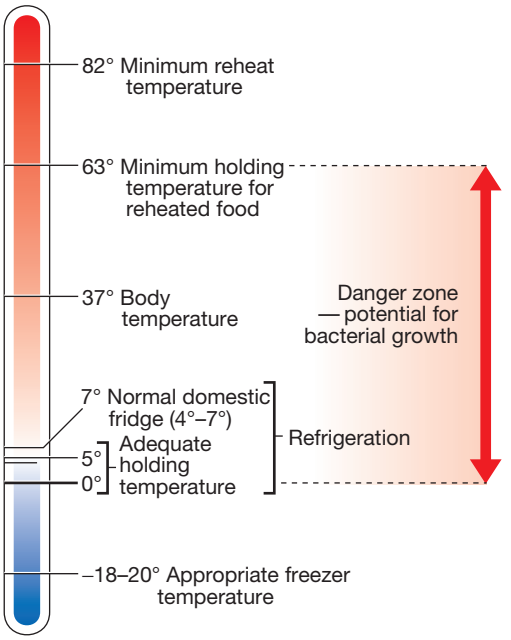

Fig. 6.13 Important temperatures (°C) in food hygiene.

6.12 Reasons for including an infectious disease on a regional/national list of reportable diseases*

Reason for inclusion	Common examples
Endemic/local disease with the potential to spread and/or cause outbreaks	Influenza, *Salmonella*, tuberculosis
Imported disease with the propensity to spread and/or cause outbreaks	Typhoid, cholera (depending on local epidemiology)
Evidence of a possible breakdown in health protection/public health functions	*Legionella*, *Cryptosporidium*
Evidence of a possible breakdown in food safety practices	Botulism, verotoxigenic *E. coli*
Evidence of a possible failure of a vaccination programme	Measles, poliomyelitis, pertussis
Disease with the potential to be a novel or increasing threat to human health	SARS, multi-resistant bacteria
Evidence of expansion of the range of a reservoir/vector	Lyme disease, rabies, West Nile encephalitis
Evidence of possible deliberate release	Anthrax, tularaemia, plague, smallpox, botulism

*Given the different geographic ranges of individual diseases, and wide national variations in public health services, vaccination programmes and availability of resources, reporting regulations vary between regions, states and countries. Many diseases are reportable for more than one reason.

Immunisation

Immunisation may be passive or active. Passive immunisation is achieved by administering antibodies targeted against a specific pathogen. Antibodies are obtained from blood, so confer some of the risks associated with blood products (p. 1012). The protection afforded by passive immunisation is immediate but of short duration (a few weeks or months); it is used to prevent or attenuate infection before or after exposure (Box 6.13).

Vaccination

Active immunisation is achieved by vaccination with whole organisms or organism components (Box 6.14).

Types of vaccine

Whole cell vaccines consist of live or inactivated (killed) microorganisms; component vaccines contain only extracted or synthesised components of microorganisms (e.g. polysaccharides or proteins). Live vaccines contain organisms with attenuated (reduced) virulence, which induce T-lymphocyte and humoral responses (p. 77) and are therefore more immunogenic than inactivated whole cell vaccines. The use of live vaccines in immunocompromised individuals requires careful consideration.

Component vaccines consisting only of polysaccharides, such as the pneumococcal polysaccharide vaccine (PPV), are poor activators of T-lymphocytes, and produce a short-lived antibody response without long-lasting memory. Conjugation of polysaccharide to

6.13 Indications for post-exposure prophylaxis with immunoglobulins

Human normal immunoglobulin (pooled immunoglobulin)

- Hepatitis A (unvaccinated contacts*)
- Measles (if exposed child has heart or lung disease)

Human specific immunoglobulin

- Hepatitis B (sexual partners, inoculation injuries, infants born to infected mothers)
- Tetanus (high-risk wounds or when immunisation status is incomplete or unknown)
- Rabies
- Chickenpox (immunosuppressed children and adults, pregnant women)

*Active immunisation is preferred if contact is with a patient who is within 1 wk of onset of jaundice.

6.14 Vaccines in current clinical use

Live attenuated vaccines

- Measles, mumps, rubella (MMR)
- Oral poliomyelitis (OPV, not used in UK)
- Tuberculosis (bacille Calmette–Guérin, BCG)
- Typhoid (oral typhoid vaccine)
- Varicella zoster virus
- Rotavirus

Inactivated (killed) whole-cell vaccines

- Cholera
- Hepatitis A
- Influenza
- Poliomyelitis (inactivated polio virus, IPV)
- Rabies

Component vaccines

- Anthrax (adsorbed extracted antigens)
- Diphtheria (adsorbed toxoid)
- Hepatitis B (adsorbed recombinant HBsAg)
- *Haemophilus influenzae* type B (conjugated capsular polysaccharide)
- Human papillomavirus (recombinant capsid proteins)
- Meningococcal, quadrivalent A, C, Y, W135 (conjugated capsular polysaccharide)
- Meningococcal, serogroup C (conjugated capsular polysaccharide)
- Pertussis (adsorbed extracted antigens)
- Pneumococcal conjugate (PCV; conjugated capsular polysaccharide, 13 serotypes)
- Pneumococcal polysaccharide (PPV; purified capsular polysaccharide, 23 serotypes)
- Tetanus (adsorbed toxoid)
- Typhoid (purified Vi capsular polysaccharide)

a protein, as in the *Haemophilus influenzae* type B (Hib) vaccine, activates T lymphocytes, which results in a sustained response and immunological memory. Toxoids are bacterial toxins that have been modified to reduce toxicity but maintain antigenicity. Vaccine response can be improved by co-administration with mildly pro-inflammatory adjuvants, such as aluminium hydroxide.

Use of vaccines

Vaccination may be applied to entire populations or to subpopulations at specific risk through travel, occupation or other activities. In ring vaccination, the population immediately surrounding a case or outbreak of infectious disease is vaccinated to curtail further spread. Vaccination is aimed mainly at preventing infectious disease. However, vaccination against human papillomavirus (HPV) was introduced to prevent cervical and other cancers which complicate HPV infection. Vaccination guidelines for individuals are shown in Box 6.15.

6.15 Guidelines for vaccination against infectious disease

- The principal contraindication to inactivated vaccines is an anaphylactic reaction to a previous dose or a component of the vaccine
- Live vaccines should not be given in the presence of an acute infection, to pregnant women or to the immunosuppressed, unless the immunosuppression is mild and the benefits outweigh the risks
- If two live vaccines are required, they should be given either simultaneously in opposite arms or 4 wks apart
- Live vaccines should not be given for 3 mths after an injection of human normal immunoglobulin (HNI)
- HNI should not be given for 2 wks after a live vaccine
- Hay fever, asthma, eczema, sickle-cell disease, topical corticosteroid therapy, antibiotic therapy, prematurity and chronic heart and lung diseases, including tuberculosis, are not contraindications to vaccination

Vaccination becomes successful once the number of susceptible hosts in a population falls below the level required to sustain continued transmission of the target organism (herd immunity). Naturally acquired smallpox was declared to have been eradicated worldwide in 1980 through mass vaccination. In 1988, the WHO resolved to eradicate poliomyelitis by vaccination; the number of cases worldwide has since fallen from approximately 350 000 per annum to 223 in 2012. Recommended vaccination schedules vary between countries. In addition to standard vaccination schedules, catch-up schedules are specified for individuals who join vaccination programmes later than the recommended age.

TREATMENT OF INFECTIOUS DISEASES

The key components of treating infectious disease are:

- addressing predisposing factors, e.g. diabetes mellitus or known immune deficit (HIV, neutropenia)
- antimicrobial therapy
- adjuvant therapy, e.g. removal of an indwelling catheter (urinary or vascular), abscess drainage or débridement of an area of necrotising fasciitis
- treatment of the consequences of infection, e.g. the systemic inflammatory response syndrome (SIRS; p. 184), inflammation and pain.

For communicable disease, treatment must also take into account contacts of the infected patient, and may include infection prevention and control activities such as isolation, antimicrobial prophylaxis, vaccination and contact tracing.

Principles of antimicrobial therapy

When infection is diagnosed, it is important to start appropriate antimicrobial therapy promptly. The principles underlying the choice of antimicrobial agent(s) are

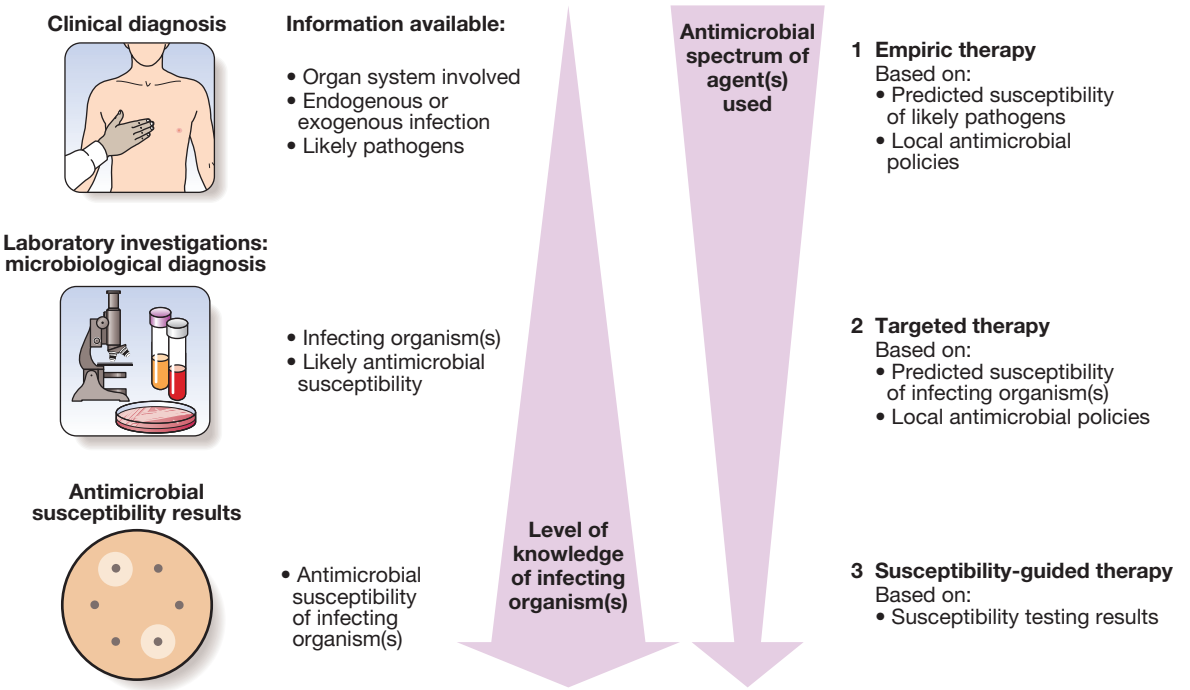

Fig. 6.14 Stages in the selection and refinement of antimicrobial therapy: 'Start Smart – Then Focus'.

discussed below. The process of selecting appropriate antimicrobial therapy has been summarised in UK guidance as 'Start Smart – Then Focus' (Fig. 6.14).

Antimicrobial action and spectrum

Antimicrobial agents kill microorganisms by inhibiting, damaging or destroying a target that is a required component of the organism. The range, or spectrum, of microorganisms that is killed by a particular antimicrobial agent must be considered in selecting therapy. The mechanisms of action of the major classes of antibacterial agent are listed in Box 6.16 and appropriate antibiotic choices for a range of common infecting organisms are shown in Box 6.17. In severe infections and/or immunocompromised patients, it is customary to use bactericidal agents in preference to bacteriostatic agents.

Empiric versus targeted therapy

Empiric antimicrobial therapy is selected to treat a clinical syndrome (e.g. meningitis) before a microbiological diagnosis has been made. Targeted therapy is aimed at the causal pathogen(s) of known antimicrobial sensitivity. 'Start Smart – Then Focus' describes the principle of using appropriate broad-spectrum agents in empiric therapy, followed by narrow-spectrum agents in targeted therapy. Optimum empiric therapy depends on the site of infection, patient characteristics and local antimicrobial resistance patterns. Hospital antibiotic policies are used to guide rational antimicrobial prescribing, maximising efficacy while minimising antimicrobial resistance and cost.

Combination therapy

It is sometimes appropriate to use antimicrobial agents in combination:

- to increase efficacy (e.g. enterococcal endocarditis, where a β-lactam/aminoglycoside combination

6.16 Target and mechanism of action of common antibacterial agents

Aminoglycosides, chloramphenicol, macrolides, lincosamides and streptogramins, oxazolidinones (linezolid)
• Inhibition of bacterial protein synthesis by binding to subunits of bacterial ribosomes
Tetracyclines
• Inhibition of protein synthesis by preventing transfer RNA binding to ribosomes
Beta-lactams
• Inhibition of cell wall peptidoglycan synthesis by competitive inhibition of transpeptidases ('penicillin-binding proteins')
Cyclic lipopeptide (daptomycin)
• Insertion of lipophilic tail into plasma membrane causes depolarisation and cell death
Glycopeptides
• Inhibition of cell wall peptidoglycan synthesis by forming complexes with D-alanine residues on peptidoglycan precursors
Nitroimidazoles
• The reduced form of the drug causes strand breaks in DNA
Quinolones
• Inhibition of DNA replication by binding to DNA topoisomerases (DNA gyrase and topoisomerase IV), preventing supercoiling and uncoiling of DNA
Rifamycins
• Inhibition of DNA synthesis by inhibiting DNA-dependent RNA polymerase
Sulphonamides and trimethoprim
• Inhibition of folate synthesis by dihydropteroate synthase (sulphonamides) and dihydrofolate reductase (trimethoprim) inhibition

6.17 Antimicrobial options for common infecting bacteria

Organism	Antimicrobial options*
Gram-positive organisms	
Enterococcus faecalis	Ampicillin, vancomycin/teicoplanin
Enterococcus faecium	Vancomycin/teicoplanin, linezolid
Glycopeptide-resistant enterococci (GRE)	Linezolid, tigecycline, quinupristin–dalfopristin, daptomycin
MRSA	Clindamycin, vancomycin, rifampicin (never used as monotherapy), linezolid, daptomycin, tetracyclines, tigecycline, co-trimoxazole
Staph. aureus	Flucloxacillin, clindamycin
Strep. pyogenes	Penicillin, clindamycin, erythromycin
Strep. pneumoniae	Penicillin, macrolides, cephalosporins, levofloxacin, vancomycin
Gram-negative organisms	
E. coli, 'coliforms' (enteric Gram-negative bacilli)	Trimethoprim, cefuroxime, ciprofloxacin, co-amoxiclav
Enterobacter spp., *Citrobacter* spp.	Ciprofloxacin, meropenem, ertapenem, aminoglycosides
ESBL-producing Enterobacteriaceae	Ciprofloxacin, meropenem, ertapenem (if sensitive), piperacillin–tazobactam, aminoglycosides, tigecycline
Carbapenemase-producing Enterobacteriaceae	Ciprofloxacin, aminoglycosides, tigecycline, colistin
Haemophilus influenzae	Amoxicillin, co-amoxiclav, macrolides, cefuroxime, cefotaxime, ciprofloxacin
Legionella pneumophila	Azithromycin, levofloxacin, doxycycline
Neisseria gonorrhoeae	Ceftriaxone/cefixime, spectinomycin
Neisseria meningitidis	Penicillin, cefotaxime/ceftriaxone, chloramphenicol
Pseudomonas aeruginosa	Ciprofloxacin, piperacillin–tazobactam, aztreonam, meropenem, aminoglycosides, ceftazidime/cefepime
Salmonella typhi	Ceftriaxone, azithromycin (uncomplicated typhoid), chloramphenicol (resistance common)
Strict anaerobes	
Bacteroides spp.	Metronidazole, clindamycin, co-amoxiclav, piperacillin–tazobactam, meropenem
Clostridium difficile	Metronidazole, vancomycin (oral), fidaxomicin
Clostridium spp.	Penicillin, metronidazole, clindamycin
Fusobacterium spp.	Penicillin, metronidazole, clindamycin
Other organisms	
Chlamydia trachomatis	Azithromycin, doxycycline
Treponema pallidum	Penicillin, doxycycline

*Antibiotic selection depends on multiple factors, including local susceptibility patterns, which vary enormously between geographic areas. There are many appropriate alternatives to those listed.

results in better outcomes than a β-lactam alone)
- when no single agent's spectrum covers all potential pathogens (e.g. in polymicrobial infection or empiric treatment of sepsis)
- to reduce antimicrobial resistance, as the organism would need to develop resistance to multiple agents simultaneously (e.g. antituberculous chemotherapy (p. 693), antiretroviral therapy (ART, p. 407)).

Antimicrobial resistance

Microorganisms have evolved in the presence of naturally occurring antibiotics, and have therefore developed resistance mechanisms (categorised in Fig. 6.15) to all classes of antimicrobial agent (antibiotics and their derivatives). Intrinsic resistance is an innate property of a microorganism, whereas acquired resistance arises by spontaneous mutation or horizontal transfer of genetic material from another organism in a phage or plasmid. Plasmids often encode resistance to multiple antibiotics. For some agents, e.g. penicillins, a degree of resistance occurs in vivo when the bacterial load is high and the molecular target for the antimicrobial is down-regulated (an 'inoculum effect').

The *mecA* gene encodes a low-affinity penicillin-binding protein, which confers resistance to β-lactam antibiotics in staphylococci. Extended spectrum β-lactamases (ESBL) are encoded on plasmids which are transferred relatively easily between bacteria, including Enterobacteriaceae. Plasmid-encoded carbapenemases have been detected in strains of *Klebsiella pneumoniae* (e.g. New Delhi metallo-β-lactamase 1, NDM-1). Strains of MRSA have been described that exhibit intermediate resistance to glycopeptides (GISA) through the development of a relatively impermeable cell wall.

Factors promoting antimicrobial resistance include the inappropriate use of antibiotics (e.g. in viral infections), inadequate dosage or treatment duration, and use

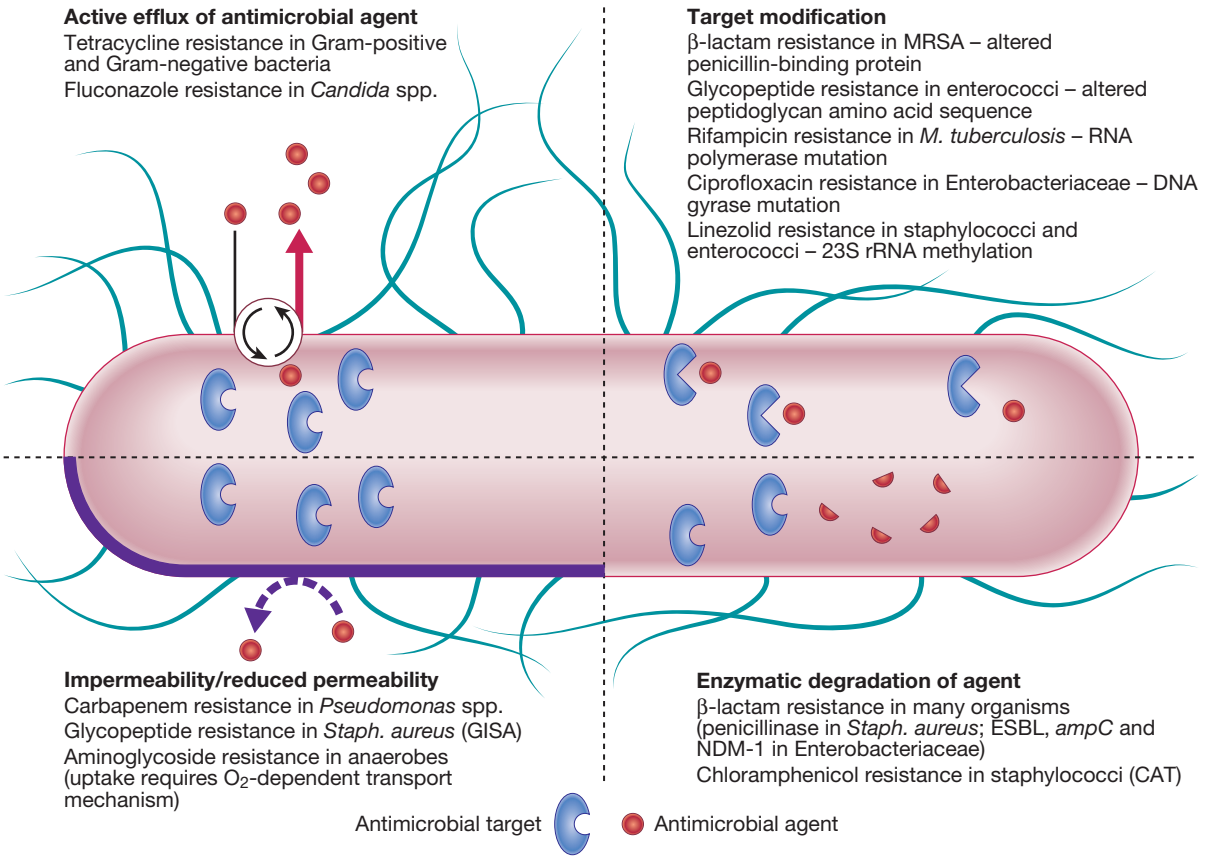

Fig. 6.15 Examples of mechanisms of antimicrobial resistance. (CAT = chloramphenicol acetyltransferase; ESBL = extended spectrum β-lactamases; GISA = glycopeptide-intermediate *Staph. aureus*; MRSA = meticillin-resistant *Staph. aureus*; NDM-1 = New Delhi metallo-β-lactamase 1).

of antimicrobials as growth-promoters in agriculture. However, *any* antimicrobial use exerts a selection pressure that favours the development of resistance. Combination antimicrobial therapy may reduce the emergence of resistance. This is recommended in treatment of patients infected with HIV, which is highly prone to spontaneous mutation (p. 407). Despite use of combination therapy for *M. tuberculosis*, multidrug-resistant tuberculosis (MDR-TB, resistant to isoniazid and rifampicin) and extremely drug-resistant tuberculosis (XDR-TB, resistant to isoniazid and rifampicin, any fluoroquinolone and at least one injectable antimicrobial antituberculous agent) have been reported worldwide and are increasing in incidence (p. 693).

The term post-antibiotic era has been coined to describe a future in which the acquisition of resistance by bacteria will have been so extensive that antibiotic therapy is rendered useless. A more realistic scenario, which is currently being experienced, is a gradual but inexorable progression of resistance, necessitating the use of ever more toxic and expensive antimicrobials.

Duration of therapy

Treatment duration reflects the severity of infection and accessibility of the infected site to antimicrobial agents. For most infections, there is limited evidence available to support a specific duration of treatment (Box 6.18). Depending on the indication, initial intravenous therapy may be switched to oral after fever has settled for approximately 48 hours. In the absence of specific guidance, antimicrobial therapy should be stopped when there is no longer any clinical evidence of infection.

Antimicrobial prophylaxis

Primary prophylaxis is used when there is a risk of infection from a procedure or exposure (Box 6.19). It should be of short duration with minimal adverse effects, and may be combined with passive immunisation (see Box 6.13). Secondary prophylaxis is used in patients who have been treated successfully for an infection but remain predisposed to it. It is used in haemato-oncology patients in the context of fungal infection and in HIV-positive individuals with an opportunistic infection who do not respond to antiretroviral therapy.

Pharmacokinetics and pharmacodynamics

Pharmacokinetics of antimicrobial agents determine whether adequate concentrations are obtained at the sites of infection. Septic patients often have poor gastrointestinal absorption, so the preferred initial route of therapy is intravenous. Knowledge of anticipated antimicrobial drug concentrations at sites of infection is critical. For example, achieving a 'therapeutic' blood level of gentamicin is of little practical use in treating meningitis, as CSF penetration of the drug is poor. Knowledge of routes of antimicrobial elimination is also critical; for instance, urinary tract infection is ideally treated with a drug that is excreted unchanged in the urine.

Pharmacodynamics describes the relationship between antimicrobial concentration and microbial

6.18 Duration of antimicrobial therapy for some common infections*

Infection	Duration of therapy
Viral infections	
Herpes simplex encephalitis	2–3 wks
Bacterial infections	
Gonorrhoea	Single dose
Infective endocarditis (streptococcal, native valve)	4 wks ± gentamicin for first 2 wks
Infective endocarditis (prosthetic valve)	≥ 6 wks
Osteomyelitis	4–6 wks
Pneumonia (community-acquired, severe)	10 days (no organism identified), 14–21 days (*Staph. aureus* or *Legionella* spp.)
Septic arthritis	2–4 wks
Urinary tract infection (male)	2 wks
Urinary tract infection, upper (female)	7 days
Urinary tract infection, lower (female)	3 days
Mycobacterial infections	
Tuberculosis (meningeal)	12 mths
Tuberculosis (pulmonary)	6 mths
Fungal infections	
Invasive pulmonary aspergillosis	Until clinical/radiological resolution and reversal of predisposition
Candidaemia (acute disseminated)	2 wks after last positive blood culture and resolution of signs and symptoms

*All recommendations are indicative. Actual duration takes into account predisposing factors, specific organisms and antimicrobial susceptibility, adjuvant therapies, current guidelines and clinical response.

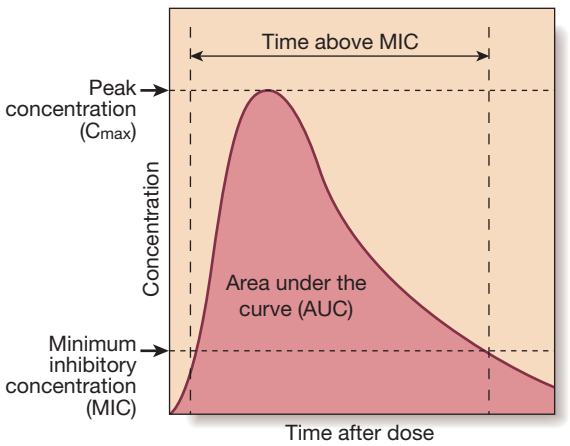

Fig. 6.16 Antimicrobial pharmacodynamics. The curve represents drug concentrations after a single dose of an antimicrobial agent. Factors that determine microbial killing are C_{max}:MIC ratio (concentration-dependent killing), time above MIC (time-dependent killing) and AUC:MIC ratio.

6.19 Recommendations for antimicrobial prophylaxis in adults*

Infection risk	Recommended antimicrobial
Bacterial	
Diphtheria (prevention of secondary cases)	Erythromycin
Gas gangrene (after high amputation or major trauma)	Penicillin or metronidazole
Lower gastrointestinal tract surgery	Cefuroxime + metronidazole, gentamicin + metronidazole, or co-amoxiclav (single dose only)
Meningococcal disease (prevention of secondary cases)	Rifampicin or ciprofloxacin
Rheumatic fever (prevention of recurrence)	Phenoxymethylpenicillin or sulfadiazine
Tuberculosis (prevention of secondary cases)	Isoniazid ± rifampicin
Whooping cough (prevention of secondary cases)	Erythromycin
Viral	
HIV, occupational exposure (sharps injury)	Combination tenofovir/emtricitabine and lopinavir/ritonavir. Modified if index case's virus known to be resistant
Influenza A (prevention of secondary cases in adults with chronic respiratory, cardiovascular or renal disease, immunosuppression or diabetes mellitus)	Oseltamivir
Fungal	
Aspergillosis (in high-risk haematology patients)	Itraconazole, voriconazole or posaconazole
Pneumocystis pneumonia (prevention in HIV and other immunosuppressed states)	Co-trimoxazole, pentamidine or dapsone
Protozoal	
Malaria (prevention of travel-associated disease)	Specific antimalarials depend on travel itinerary (p. 357)

*These are based on current UK practice. Recommendations may vary locally or nationally. Antimicrobial prophylaxis for infective endocarditis during dental procedures is not currently recommended in the UK.

killing. For many agents, antimicrobial effect can be categorised as concentration-dependent or time-dependent. The concentration of antimicrobial achieved after a single dose is illustrated in Figure 6.16. The maximum concentration achieved is C_{max} and the measure of overall exposure is the area under the curve (AUC). The efficacy of antimicrobial agents whose killing is concentration-dependent (e.g. aminoglycosides) increases with the amount by which C_{max} exceeds the minimum inhibitory concentration (C_{max}:MIC ratio). For this reason, it has become customary to administer aminoglycosides (e.g. gentamicin) infrequently at high doses (e.g. 7 mg/kg) rather than frequently at low doses. This has the added advantage of minimising toxicity by reducing the likelihood of drug accumulation. Conversely, the β-lactam antibiotics, macrolides and clindamycin exhibit time-dependent killing, and their efficacy depends on C_{max}

6.20 Antimicrobial agents in pregnancy[1]

Contraindicated

- Chloramphenicol: neonatal 'grey baby' syndrome – collapse, hypotension and cyanosis
- Fluconazole: teratogenic in high doses
- Quinolones: arthropathy in animal studies
- Sulphonamides: neonatal haemolysis and methaemoglobinaemia
- Tetracyclines, glycylcyclines: skeletal abnormalities in animals in 1st trimester; fetal dental discoloration and maternal hepatotoxicity with large parenteral doses in 2nd or 3rd trimesters
- Trimethoprim: teratogenic in 1st trimester

Relatively contraindicated

- Aminoglycosides: potential damage to fetal auditory and vestibular nerves in 2nd and 3rd trimesters
- Metronidazole: avoidance of high dosages is recommended[2]

Not known to be harmful; use only when necessary

- Aciclovir
- Cephalosporins
- Clarithromycin
- Clindamycin
- Erythromycin
- Glycopeptides
- Linezolid
- Meropenem
- Penicillins

[1]Data extracted from Joint Formulary Committee. British National Formulary (online). London: BMJ Group and Pharmaceutical Press; (www.medicinescomplete.com) [accessed on 16 March 2013].
[2]Theoretical risk of teratogenicity, not supported by available clinical evidence.

6.21 Problems with antimicrobial therapy in old age

- ***Clostridium difficile* infection**: all antibiotics predispose to some extent, but second- and third-generation cephalosporins and co-amoxiclav especially so.
- **Hypersensitivity reactions**: rise in incidence due to increased previous exposure.
- **Renal impairment**: may be significant in old age, despite 'normal' creatinine levels (p. 467).
- **Nephrotoxicity**: more likely, e.g. first-generation cephalosporins, aminoglycosides.
- **Accumulation of β-lactam antibiotics**: may result in myoclonus, seizures or coma.
- **Reduced gastric acid production**: gastric pH is higher, which causes increased penicillin absorption.
- **Reduced hepatic metabolism**: results in a higher risk of isoniazid-related hepatotoxicity.
- **Quinolones**: associated with confusion and may increase the risk of seizures.

exceeding the MIC for a certain time (which is different for each class of agent). This is reflected in the dosing interval of benzylpenicillin, which is usually given every 4 hours in severe infection (e.g. meningococcal meningitis), and may be administered by continuous infusion. For other antimicrobial agents, the pharmacodynamic relationships are more complex and often less well understood. With some agents, bacterial inhibition persists after antimicrobial exposure (post-antibiotic and post-antibiotic sub-MIC effects).

Therapeutic drug monitoring

Therapeutic drug monitoring is used to confirm that levels of antimicrobial agents with a low therapeutic index (e.g. aminoglycosides) are not excessive, and that levels of agents with marked pharmacokinetic variability (e.g. vancomycin) are adequate. Specific recommendations for monitoring depend on individual clinical circumstances; for instance, different pre- and post-dose levels of gentamicin are recommended, depending on whether it is being used in traditional divided doses, once daily or for synergy in endocarditis (p. 625).

Beta-lactam antibiotics

These antibiotics have a β-lactam ring structure (Fig. 6.17) and exert a bactericidal action by inhibiting enzymes involved in cell wall synthesis (penicillin-binding proteins, PBP). They are classified in Box 6.22.

Pharmacokinetics

- Good drug levels are achieved in lung, kidney, bone, muscle and liver, and in pleural, synovial, pericardial and peritoneal fluids.
- CSF levels are low, except in the presence of inflammation.
- Activity is not inhibited in abscess (e.g. by low pH and PO_2, high protein or neutrophils).
- Beta-lactams are subject to an 'inoculum effect' – activity is reduced in the presence of a high organism burden (PBP expression is down-regulated by high organism density).
- Generally safe in pregnancy (except imipenem/cilastatin).

Adverse effects

Generalised allergy to penicillin occurs in 0.7–10% of cases and anaphylaxis in 0.004–0.015%. A large proportion of patients with infectious mononucleosis develop a rash if given aminopenicillins; this does not imply lasting allergy. The relationship between allergy to penicillin and allergy to cephalosporins depends on the specific cephalosporin used. Although there is significant cross-reactivity with first-generation cephalosporins, cross-reactivity to second- and third-generation cephalosporins is less common. However, avoidance of cephalosporins is recommended in patients who have a type 1 penicillin allergy (p. 89). Cross-reactivity between penicillin and carbapenems is rare (approximately 1%

6.22 Beta-lactam antibiotics

Penicillins

- Natural penicillins: benzylpenicillin, phenoxymethylpenicillin
- Penicillinase-resistant penicillins: meticillin, flucloxacillin, nafcillin, oxacillin
- Aminopenicillins: ampicillin, amoxicillin
- Carboxy- and ureido-penicillins: ticarcillin, piperacillin

Cephalosporins

- See Box 6.23

Monobactams

- Aztreonam

Carbapenems

- Imipenem, meropenem, ertapenem, doripenem

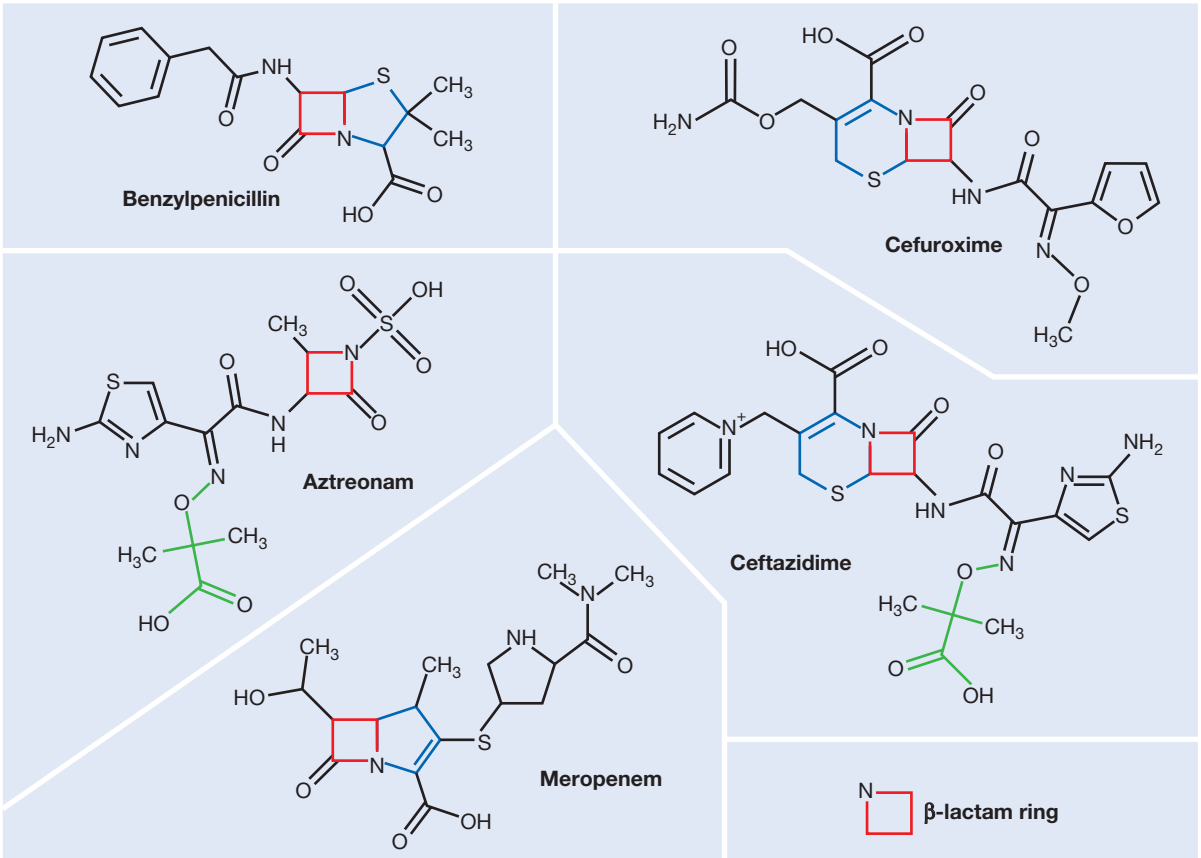

Fig. 6.17 Beta-lactam antibiotics. With the exception of aztreonam (monobactam), the β-lactam antibiotics have bicyclic nuclei. This may explain the absence of cross-reaction to aztreonam in penicillin-allergic patients. However, aztreonam and ceftazidime have identical side-chains, so patients with a specific ceftazidime allergy should not be given aztreonam.

by skin-prick testing). Although avoidance of carbapenems is recommended in penicillin-allergic patients, these drugs may be administered if there are no suitable alternatives and appropriate resuscitation facilities are available.

Gastrointestinal upset and diarrhoea are common, and a mild reversible hepatitis is recognised with many β-lactams. Leucopenia, thrombocytopenia and coagulation deficiencies, and interstitial nephritis and potentiation of aminoglycoside-mediated renal damage are also recognised (p. 502). Seizures and encephalopathy have been reported, particularly with high doses in the presence of renal insufficiency. Thrombophlebitis occurs in up to 5% of patients receiving parenteral β-lactams.

Drug interactions

Synergism occurs in combination with aminoglycosides. Ampicillin decreases the biological effect of oral contraceptives and the whole class is significantly affected by concurrent administration of probenecid, producing a 2–4-fold increase in the peak serum concentration.

Penicillins

Natural penicillins are primarily effective against Gram-positive organisms (except staphylococci, most of which produce a penicillinase) and anaerobic organisms. *Strep. pyogenes* has remained sensitive to natural penicillins worldwide. According to the European Antimicrobial Resistance Surveillance Network (EARS-Net), the prevalence of high-level penicillin resistance in *Strep. pneumoniae* in Europe in 2010 was 2.7%. However, the prevalence in individual countries was as high as 33% (Cyprus).

Penicillinase-resistant penicillins are the mainstay of treatment for infections with *Staph. aureus*, other than meticillin-resistant strains (MRSA). However, EARS-Net data from 2010 indicate that almost 1:5 (18.5%) *Staph. aureus* isolates in Europe were MRSA.

Aminopenicillins have the same spectrum of activity as the natural penicillins, with additional Gram-negative cover against Enterobacteriaceae. Amoxicillin has better oral absorption than ampicillin. Unfortunately, resistance to these agents is widespread (54% of *E. coli* Europe-wide in 2010, range 34–83%), so they are no longer appropriate for first-line use in Gram-negative infections. In many organisms, resistance is due to β-lactamase production, which can be overcome by the addition of β-lactamase inhibitors (clavulanic acid or sulbactam).

Carboxypenicillins (e.g. ticarcillin) and ureidopenicillins (e.g. piperacillin) are particularly active against Gram-negative organisms, especially *Pseudomonas* spp. which are resistant to the aminopenicillins. Beta-lactamase inhibitors may be added to extend their spectrum of activity (e.g. piperacillin–tazobactam).

Cephalosporins and cephamycins

Cephalosporins are reliable broad-spectrum agents. Unfortunately, their use is associated with *C. difficile*

6.23 Cephalosporins

First generation	
• Cefalexin, cefradine (oral)	• Cefazolin (IV)
Second generation	
• Cefuroxime (oral/IV) • Cefaclor (oral)	• Cefoxitin (IV)
Third generation	
• Cefixime (oral) • Cefotaxime (IV)	• Ceftriaxone (IV) • Ceftazidime (IV)
Fourth generation	
• Cefepime (IV)	
'Next generation'	
• Ceftobiprole (IV)	• Ceftaroline (IV)

infection (p. 343). With the exception of ceftobiprole, the group has no activity against *Enterococcus* spp. Only the cephamycins have significant anti-anaerobic activity. All cephalosporins are inactivated by ESBL. Cephalosporins are arranged in 'generations' (Box 6.23).

- *First-generation compounds* have excellent activity against Gram-positive organisms and some activity against Gram-negatives.
- *Second-generation drugs* retain Gram-positive activity but have extended Gram-negative activity. Cephamycins (e.g. cefoxitin), included in this group, are active against anaerobic Gram-negative bacilli.
- *Third-generation agents* further improve anti-Gram-negative cover. For some (e.g. ceftazidime), this is extended to include *Pseudomonas* spp. Cefotaxime and ceftriaxone have excellent Gram-negative activity and retain good activity against *Strep. pneumoniae* and β-haemolytic streptococci. Ceftriaxone is administered once daily, and is therefore a suitable agent for outpatient antimicrobial therapy.
- *Fourth-generation agents* have an extremely broad spectrum of activity, including *Pseudomonas* spp., *Staph. aureus* and streptococci.
- *'Next generation' agents* have a third- or fourth-generation spectrum enhanced to include MRSA.

Monobactams

Aztreonam is the only available monobactam. It is excellent against Gram-negative, except ESBL-producing, organisms, but no useful activity against Gram-positive organisms or anaerobes. It is a parenteral-only agent and may be used safely in penicillin-allergic patients.

Carbapenems

These intravenous agents have the broadest antibiotic activity of the β-lactam antibiotics, covering most clinically significant bacteria, including anaerobes.

Macrolide and lincosamide antibiotics

Macrolides (erythromycin, clarithromycin and azithromycin) and lincosamides (lincomycin and clindamycin) are bacteriostatic agents which have related properties. Both classes bind to the same component of the ribosome, so they are potentially competitive and should not be administered together. Macrolides are used for Gram-positive infections in penicillin-allergic patients and in *Mycoplasma* and *Chlamydia* infections. Erythromycin is administered 4 times daily and clarithromycin twice daily. The long intracellular half-life of azithromycin allows single-dose/short-course therapy for genitourinary *Chlamydia/Mycoplasma* spp. infections. Clarithromycin and azithromycin are also used to treat legionellosis.

Pharmacokinetics

Macrolides

- Variable bioavailability.
- Short half-life (except azithromycin).
- High protein binding.
- Excellent intracellular accumulation.

Lincosamides (e.g. clindamycin)

- Good bioavailability.
- Food has no effect on absorption.
- Limited CSF penetration.

Adverse effects

- Gastrointestinal upset, especially in young adults (erythromycin 30%).
- Cholestatic jaundice with erythromycin estolate.
- Prolongation of QT interval on ECG, potential for torsades de pointes.
- Clindamycin predisposes to *C. difficile* infection.

Ketolides

The ketolides were developed in response to the emergence of penicillin and macrolide resistance in respiratory pathogens. Cross-resistance with macrolides is uncommon. Telithromycin is administered orally and has useful activity against common bacterial causes of respiratory infection, as well as *Mycoplasma*, *Chlamydia* and *Legionella* spp.

Aminoglycosides

Aminoglycosides are effective mainly in Gram-negative infections. They act synergistically with β-lactam antibiotics and are particularly useful where β-lactam or quinolone resistance occurs in health care-acquired infections. They cause very little local irritation at injection sites and negligible allergic responses. Oto- and nephrotoxicity must be avoided by monitoring of renal function and drug levels and by use of short treatment regimens. Aminoglycosides are not subject to an inoculum effect (p. 151) and they all exhibit a post-antibiotic effect (p. 153).

Pharmacokinetics

- Negligible oral absorption.
- Hydrophilic, so excellent penetration to extracellular fluid in body cavities and serosal fluids.
- Very poor intracellular penetration (except hair cells in cochlea and renal cortical cells).
- Negligible CSF and corneal penetration.
- Peak plasma levels 30 minutes after infusion.
- Monitoring of therapeutic levels required.

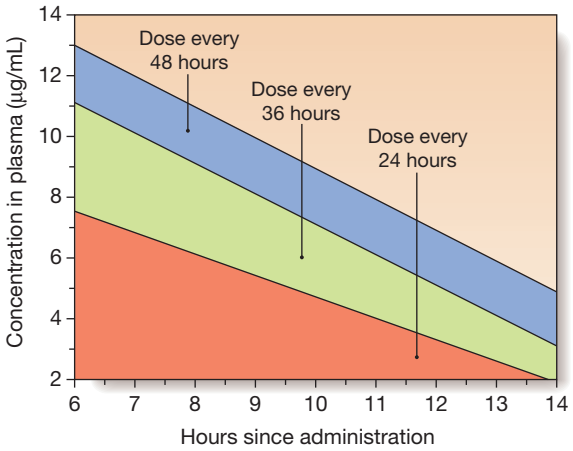

Fig. 6.18 Dosing of aminoglycosides using the Hartford nomogram. The nomogram is used to determine the dose interval for 7 mg doses of gentamicin or tobramycin, using measurements of drug levels in plasma 6–14 hours after a single dose.

Gentamicin dosing

- Except in certain forms of endocarditis, pregnancy, severe burns, end-stage renal disease and paediatric patients, gentamicin is administered at 7 mg/kg body weight. The appropriate dose interval depends on drug clearance, and is determined by reference to the Hartford nomogram (Fig. 6.18).
- In streptococcal and enterococcal endocarditis, gentamicin is used with a cell wall active agent (usually a β-lactam), to provide synergy. The usual dose is 1 mg/kg/day 3 times daily for enterococcal endocarditis and 3 mg/kg once a day for most strains of viridans streptococci. Target pre- and post-dose levels are < 1 mg/L and 3–5 mg/L respectively when gentamicin is dosed 3 times daily.
- When not used once daily or for endocarditis, gentamicin is administered twice or 3 times daily at 3–5 mg/kg/day. Target pre- and post-dose levels are < 1 mg/L and 5–10 mg/L (7–10 mg/L with less sensitive organisms, e.g. *Pseudomonas* spp.) respectively.
- For other aminoglycosides, consult local guidance.

Adverse effects

- Renal toxicity (usually reversible) accentuated by other nephrotoxic agents.
- Cochlear toxicity (permanent) more likely in older people and those with a predisposing mitochondrial gene mutation.
- Neuromuscular blockade after rapid intravenous infusion (potentiated by calcium channel blockers, myasthenia gravis and hypomagnesaemia).

Quinolones and fluoroquinolones

These are effective and generally well-tolerated bactericidal agents. The quinolones have purely anti-Gram-negative activity, whereas the fluoroquinolones are broad-spectrum agents (Box 6.24). Ciprofloxacin has anti-pseudomonal activity but resistance emerges rapidly. In 2010, 21% of *E. coli* isolates were resistant to fluoroquinolones in Europe.

6.24 Quinolones and fluoroquinolones

Agent	Route of administration	Typical antimicrobial spectrum
Quinolones		
Nalidixic acid	Oral	Enteric Gram-negative bacilli (not *Pseudomonas aeruginosa*)
Fluoroquinolones		
Ciprofloxacin	IV/oral	Enteric Gram-negative bacilli, *P. aeruginosa*, *Haemophilus* spp., 'atypical' respiratory pathogens*
Norfloxacin	Oral	
Ofloxacin	IV/oral/topical	
Levofloxacin (L-isomer of ofloxacin)	IV/oral	*Haemophilus* spp., *Strep. pneumoniae*, 'atypical' respiratory pathogens*
Moxifloxacin	Oral	*Strep. pneumoniae*, *Staph. aureus*, 'atypical' respiratory pathogens*, Mycobacteria and anaerobes

*'Atypical' pathogens include *Mycoplasma pneumoniae* and *Legionella* spp. Fluoroquinolones have variable activity against *M. tuberculosis and* other mycobacteria.

Pharmacokinetics

- Well absorbed after oral administration but delayed by food, antacids, ferrous sulphate and multivitamins.
- Wide volume of distribution; tissue concentrations twice those in serum.
- Good intracellular penetration, concentrating in phagocytes.

Adverse effects

- Gastrointestinal side-effects in 1–5%.
- Rare skin reactions (phototoxicity).
- Achilles tendon rupture is reported, especially in older people.
- CNS effects (confusion, tremor, dizziness and occasional seizures in 5–12%), especially in older people.
- Reduces clearance of xanthines and theophyllines, potentially inducing insomnia and increased seizure potential.
- Reports of prolongation of QT interval on ECG with newer fluoroquinolones.
- Cases of hypo- or hyperglycaemia in association with gatifloxacin, so glucose monitoring is needed in patients with diabetes or those with severe hepatic dysfunction.
- Ciprofloxacin use is associated with the acquisition of MRSA and emergence of *C. difficile* ribotype 027 (p. 343).

Glycopeptides

Glycopeptides (vancomycin and teicoplanin) are effective against Gram-positive organisms only, and are used against MRSA and ampicillin-resistant enterococci. Some staphylococci and enterococci demonstrate intermediate sensitivity or resistance. Vancomycin use

should be restricted to limit emergence of resistant strains. Teicoplanin is not available in all countries. Neither drug is absorbed after oral administration, but vancomycin is used orally to treat *C. difficile* infection.

Pharmacokinetics

Vancomycin

- Administered by slow intravenous infusion, good tissue distribution and short half-life.
- Enters the CSF only in the presence of inflammation.
- Therapeutic monitoring of intravenous vancomycin is recommended, to maintain pre-dose levels of > 10 mg/L (15–20 mg/L in serious staphylococcal infections).

Teicoplanin

- Long half-life allows once-daily dosing.

Adverse effects

- Histamine release due to rapid vancomycin infusion produces a 'red man' reaction (rare with modern preparations).
- Nephrotoxicity is rare, but may occur with concomitant aminoglycoside use, as may ototoxicity.
- Teicoplanin can cause rash, bronchospasm, eosinophilia and anaphylaxis.

Folate antagonists

These bacteriostatic antibiotics interfere with the bacterial synthesis of folic acid from para-aminobenzoic acid. A combination of a sulphonamide and either trimethoprim or pyrimethamine is most commonly used, which interferes with two consecutive steps in the metabolic pathway. Available combinations include trimethoprim/sulfamethoxazole (co-trimoxazole) and pyrimethamine with either sulfadoxine (used to treat malaria) or sulfadiazine (used in toxoplasmosis). Co-trimoxazole in high dosage (120 mg/kg daily in 2–4 divided doses) is the first-line drug for *Pneumocystis jirovecii (carinii)* infection. The clinical use of these agents is limited by adverse effects. Folinic acid should be given if they are used long-term or unavoidably in early pregnancy.

Pharmacokinetics

- Well absorbed orally.
- Sulphonamides are hydrophilic, distributing well to the extracellular fluid.
- Trimethoprim is lipophilic with high tissue concentrations.

Adverse effects

- Trimethoprim is generally well tolerated, with few adverse effects.
- Sulphonamides and dapsone may cause haemolysis in glucose-6-phosphate dehydrogenase deficiency (p. 1029).
- Sulphonamides and dapsone cause skin and mucocutaneous reactions, including Stevens–Johnson syndrome and 'dapsone syndrome' (rash, fever and lymphadenopathy).
- Dapsone causes methaemoglobinaemia and peripheral neuropathy.

Tetracyclines and glycylcyclines

Tetracyclines

Of this mainly bacteriostatic class, the newer drugs doxycycline and minocycline show better absorption and distribution than older ones. Most streptococci and Gram-negative bacteria are now resistant, in part due to use in animals (which is banned in Europe). Tetracyclines are indicated for *Mycoplasma* spp., *Chlamydia* spp., *Rickettsia* spp., *Coxiella* spp., *Bartonella* spp., *Borrelia* spp., *Helicobacter pylori*, *Treponema pallidum* and atypical mycobacterial infections. Minocycline is occasionally used in chronic staphylococcal infections.

Pharmacokinetics

- Best oral absorption is in the fasting state (doxycycline is 100% absorbed unless gastric pH rises).

Adverse effects

- All tetracyclines except doxycycline are contraindicated in renal failure.
- Dizziness with minocycline.
- Binding to metallic ions in bones and teeth causes discoloration (avoid in children and pregnancy) and enamel hypoplasia.
- Phototoxic skin reactions.

Glycylcyclines (tigecycline)

Chemical modification of tetracycline has produced tigecycline, a broad-spectrum, parenteral-only antibiotic with activity against resistant Gram-positive and Gram-negative pathogens, such as MRSA and ESBL (but excluding *Pseudomonas* spp.). Re-analysis of trial data has shown that there was excess mortality following tigecycline treatment compared with comparator antibiotics, so tigecycline should be used only when there are no available alternative agents.

Nitroimidazoles

Nitroimidazoles are highly active against strictly anaerobic bacteria, especially *Bacteroides fragilis*, *C. difficile* and other *Clostridium* spp. They also have significant antiprotozoal activity against amoebae and *Giardia lamblia*.

Pharmacokinetics

- Almost completely absorbed after oral administration (60% after rectal administration).
- Well distributed, especially to brain and CSF.
- Safe in pregnancy.

Adverse effects

- Metallic taste (dose-dependent).
- Severe vomiting if taken with alcohol – 'Antabuse effect'.
- Peripheral neuropathy with prolonged use.

Other antibacterial agents

Anti-tuberculous agents are discussed in detail on page 693.

Chloramphenicol

This is a potent and cheap antibiotic, still widely prescribed throughout the world despite its potential toxicity. Its use is increasingly reserved for severe and life-threatening infections where other antibiotics are either unavailable or impractical. It is bacteriostatic to most organisms but apparently bactericidal to *H. influenzae*, *Strep. pneumoniae* and *Neisseria meningitidis*. It has a very broad spectrum of activity against aerobic and anaerobic organisms, spirochaetes, *Rickettsia*, *Chlamydia* and *Mycoplasma* spp. It also has quite useful activity against anaerobes, such as *B. fragilis*. It competes with macrolides and lincosamides for ribosomal binding sites, so should not be used in combination with these agents. Significant adverse effects are 'grey baby' syndrome in infants (cyanosis and circulatory collapse due to inability to conjugate drug and excrete the active form in urine); reversible dose-dependent bone marrow depression in adults receiving high cumulative doses; and severe aplastic anaemia in 1 in 25 000–40 000 exposures (unrelated to dose, duration of therapy or route of administration).

Daptomycin

Daptomycin is a cyclic lipopeptide with bactericidal activity against Gram-positive organisms (including MRSA and GRE) but not Gram-negatives. It is not absorbed orally, and is used intravenously to treat resistant Gram-positive infections, e.g. soft tissue infections and infective endocarditis, if other options are not available. Treatment can be associated with increased levels of creatine kinase and patients receiving lipid-lowering statins (p. 453) should discontinue these to avoid myopathy.

Fusidic acid

This antibiotic, active against Gram-positive bacteria, is available in intravenous, oral or topical formulations. It is lipid-soluble and distributes well to tissues. However, its antibacterial activity is unpredictable. Fusidic acid is used in combination, typically with antistaphylococcal penicillins, or for MRSA with clindamycin or rifampicin. It interacts with coumarin derivatives and oral contraceptives.

Nitrofurantoin

This drug has very rapid renal elimination and is active against aerobic Gram-negative and Gram-positive bacteria, including enterococci. It is used only for treatment of urinary tract infection, being generally safe in pregnancy and childhood. However, with prolonged use, it can cause eosinophilic lung infiltrates, fever, pulmonary fibrosis, peripheral neuropathy, hepatitis and haemolytic anaemia.

Linezolid

Linezolid is the only currently licensed oxazolidinone antibiotic. It shows excellent oral absorption with good activity against Gram-positive organisms, including MRSA and GRE. It is competitively inhibited by co-administration of chloramphenicol, vancomycin or clindamycin. Common adverse effects include mild gastrointestinal upset and tongue discoloration. Myelodysplasia and peripheral neuropathy can occur with prolonged use. Linezolid has monoamine oxidase inhibitor (MAOI) activity (p. 244), and co-administration with other MAOIs or serotonin re-uptake inhibitors should be avoided, as this may precipitate a serotonin syndrome (neuromuscular effects, autonomic hyperactivity and altered mental status).

Fidaxomicin

Fidaxomicin is an inhibitor of RNA synthesis, which was introduced for the treatment of *C. difficile* infection (CDI) in 2012. In non-severe CDI, it appears to be non-inferior to oral vancomycin and is associated with a lower recurrence rate. Its effectiveness has not been assessed in severe CDI.

Spectinomycin

Chemically similar to the aminoglycosides and given intramuscularly, spectinomycin was developed to treat strains of *N. gonorrhoeae* resistant to β-lactam antibiotics. Unfortunately, resistance to spectinomycin is very common. Its only indication is the treatment of gonococcal urethritis in pregnancy or in patients allergic to β-lactam antibiotics.

Streptogramins

Quinupristin/dalfopristin (supplied as a 30:70% combination) is active against MRSA and GRE (*Enterococcus faecium* but not *E. faecalis*), and its use should be reserved for these organisms. It is available in intravenous formulation only and shows good tissue penetration, but does not cross the blood–brain barrier or the placenta. Significant phlebitis occurs at injection sites and a raised serum creatinine and eosinophilia may occur.

Antifungal agents

See Box 6.25.

Azole antifungals

The azoles (imidazoles and triazoles) inhibit synthesis of ergosterol, a constituent of the fungal cell membrane. Side-effects vary but include gastrointestinal upset, hepatitis and rash. Azoles are inhibitors of cytochrome p450 enzymes, so tend to increase exposure to cytochrome p450-metabolised drugs (p. 28).

Imidazoles

Miconazole, econazole, clotrimazole and ketoconazole are relatively toxic and therefore mainly administered topically. Clotrimazole is used extensively to treat superficial fungal infections. Ketoconazole may be given orally, but causes severe hepatitis in 1:15 000 cases and inhibits enzymes involved in steroid hormone biosynthesis. Triazoles are preferred for systemic administration because of their reduced toxicity.

Triazoles

Fluconazole is effective against yeasts (*Candida* and *Cryptococcus* spp.). It is well absorbed after oral administration, and has a long half-life (approximately 30 hours) and an excellent safety profile. The drug is highly water-soluble and distributes widely to all body sites and tissues, including CSF.

Itraconazole is lipophilic and distributes extensively, including to toenails and fingernails. CSF penetration

6.25 Antifungal agents

Agent	Usual route(s) of administration	Clinically relevant antifungal spectrum
Imidazoles		
Miconazole Econazole Clotrimazole	Topical	*Candida* spp., dermatophytes
Ketoconazole	Topical, oral	*Malassezia* spp., dermatophytes, agents of eumycetoma
Triazoles		
Fluconazole	Oral, IV	Yeasts (*Candida* and *Cryptococcus* spp.)
Itraconazole	Oral, IV	Yeasts, dermatophytes, dimorphic fungi (p. 376), *Aspergillus* spp.
Voriconazole	Oral, IV	Yeasts and most filamentous fungi (excluding mucoraceous moulds)
Posaconazole	Oral	Yeasts and many filamentous fungi (including most mucoraceous moulds)
Echinocandins		
Anidulafungin Caspofungin Micafungin	IV only	*Candida* spp., *Aspergillus* spp. (no activity against *Cryptococcus* spp. or mucoraceous moulds)
Polyenes		
Amphotericin B Nystatin	IV Topical	Yeasts and most dimorphic and filamentous fungi (including mucoraceous moulds)
Others		
Flucytosine	Oral, IV	Yeasts
Griseofulvin	Oral	Dermatophytes
Terbinafine	Topical, oral	Dermatophytes

is poor. Oral absorption is erratic and formulation-dependent, necessitating therapeutic drug monitoring.

Voriconazole is well absorbed (96% oral bioavailability) and used mainly in aspergillosis (p. 697).

Posaconazole is the broadest-spectrum antifungal azole, and the only one with consistent activity against mucoraceous moulds. It is currently available as an oral agent only.

Echinocandins

The echinocandins inhibit β-1,3-glucan synthesis in the fungal cell wall. They have few significant adverse effects. Caspofungin, anidulafungin and micafungin are used to treat systemic candidosis, and caspofungin is also used in aspergillosis.

Polyenes

Amphotericin B (AmB) deoxycholate causes cell death by binding to ergosterol and damaging the fungal cytoplasmic membrane. Its use in resource-rich countries has been largely supplanted by less toxic agents. It is lipophilic, insoluble in water and not absorbed orally. Its long half-life enables once-daily administration. CSF penetration is poor.

Adverse effects include immediate anaphylaxis, other infusion-related reactions and nephrotoxicity. Nephrotoxicity may be sufficient to require dialysis, and occurs in most patients who are adequately dosed. It may be ameliorated by concomitant infusion of normal saline. Irreversible nephrotoxicity occurs with large cumulative doses of AmB.

Nystatin has a similar spectrum of antifungal activity to AmB. Its toxicity limits it to topical use, e.g. in oral and vaginal candidiasis.

Lipid formulations of amphotericin B

Lipid formulations of AmB have been developed to reduce AmB toxicity. They consist of AmB encapsulated in liposomes (liposomal AmB, L-AmB) or complexed with phospholipids (AmB lipid complex, ABLC). The drug becomes active on dissociating from its lipid component. Adverse effects are similar to, but considerably less frequent than, those with AmB deoxycholate, and efficacy is similar. Lipid formulations of AmB are used in invasive fungal disease, as empirical therapy in patients with neutropenic fever (p. 1004), and also in visceral leishmaniasis (p. 362).

Other antifungal agents

Flucytosine

This drug has particular activity against yeasts. When used as monotherapy, resistance develops rapidly, so it should be administered in combination with another antifungal agent. Oral dosing is effective. Adverse effects include myelosuppression, gastrointestinal upset and hepatitis.

Griseofulvin

Griseofulvin has been largely superseded by terbinafine and itraconazole for treatment of dermatophyte infections, except in children, for whom these agents remain largely unlicensed. It demonstrates excellent oral bioavailability and is deposited in keratin precursor cells, which become resistant to fungal invasion. The duration of treatment is 2–4 weeks for tinea corporis/capitis, 4–8 weeks for tinea pedis, and 4–6 months for onychomycosis (fungal nail infections).

Terbinafine

Terbinafine is well absorbed orally, can be given once daily and distributes with high concentration to sebum and skin, with a half-life of more than 1 week. It is used topically for dermatophyte skin infections and orally for onychomycosis. The major adverse reaction is hepatic toxicity (approximately 1:50000 cases). Terbinafine is not recommended for breastfeeding mothers.

Antiviral agents

Most viral infections in immunocompetent individuals resolve without intervention. Antiviral therapy is

6.26 Antiviral agents

Drug	Route(s) of administration	Indications	Significant side-effects
Antiretroviral therapy (ART, p. 403)	Oral	HIV infection (including AIDS)	CNS symptoms, anaemia, lipodystrophy
Anti-herpesvirus agents			
Aciclovir	Topical/oral/IV	Herpes zoster Chickenpox (esp. in immunosuppressed) Herpes simplex infections: encephalitis (IV only), genital tract, oral, ophthalmic	Significant side-effects rare. Hepatitis, renal impairment and neurotoxicity reported rarely
Valaciclovir	Oral	Herpes zoster, herpes simplex	As for aciclovir
Famciclovir	Oral	Herpes zoster, herpes simplex (genital)	As for aciclovir
Penciclovir	Topical	Labial herpes simplex	Local irritation
Ganciclovir	IV	Treatment and prevention of CMV infection in immunosuppressed	Gastrointestinal symptoms, liver dysfunction, neurotoxicity, myelosuppression, renal impairment, fever, rash, phlebitis at infusion sites. Potential teratogenicity
Valganciclovir	Oral	Treatment and prevention of CMV infection in immunosuppressed	As for ganciclovir but neutropenia is predominant
Cidofovir	IV Topical	HIV-associated CMV infections and occasionally other viruses (see text)	Renal impairment, neutropenia
Foscarnet	IV	CMV and aciclovir-resistant HSV and VZV infections in immunosuppressed	Gastrointestinal symptoms, renal impairment, electrolyte disturbances, genital ulceration, neurotoxicity
Anti-influenza agents			
Zanamivir	Inhalation	Influenza A and B	Allergic reactions (very rare)
Oseltamivir	Oral	Influenza A and B	Gastrointestinal side-effects, rash, hepatitis (very rare)
Amantadine, rimantadine	Oral	Influenza A (but see text)	CNS symptoms, nausea
Agents used in viral hepatitis			
Ribavirin	Oral/IV/ inhalation	Hepatitis C infection (with interferons) (oral) Lassa fever (IV) RSV infection in infants (inhalation)	Haemolytic anaemia, cough, dyspnoea, bronchospasm and ocular irritation (when given by inhalation)
Interferon-α, pegylated interferon-α	SC	Chronic hepatitis B and (with ribavirin) hepatitis C	Influenza-like syndrome following dose, gastrointestinal symptoms, hepatitis, myelosuppression
Adefovir dipivoxil, entecavir, lamivudine, telbivudine	Oral	Chronic hepatitis B infection	Generally well tolerated with minimal side-effects Creatine kinase elevation (telbivudine only)
Tenofovir	Oral	Hepatitis B in co-infection with HIV (with other antiretroviral agents)	Minimal side-effects Rarely, nephrotoxicity
Telaprevir	Oral	Hepatitis C genotype 1 with interferon–ribavirin combination treatment	Anaemia, rash, fatigue, nausea and vomiting
Boceprevir	Oral	Hepatitis C genotype 1 with interferon–ribavirin combination treatment	Anaemia, taste disturbance

(CMV = cytomegalovirus; HSV = herpes simplex virus; RSV = respiratory syncytial virus; VZV = varicella zoster virus)

available for a limited number of infections only (Box 6.26 and p. 407).

Antiretroviral agents

These agents, used predominantly against HIV, are discussed in Chapter 14.

Anti-herpesvirus agents

Aciclovir, valaciclovir, penciclovir and famciclovir

Aciclovir, valaciclovir, penciclovir and famciclovir are acyclic analogues of guanosine, which inhibit viral DNA polymerase after being phosphorylated by

virus-derived thymidine kinase (TK). Aciclovir is poorly absorbed after oral dosing; better levels are achieved intravenously or by use of the prodrug valaciclovir. Famciclovir is the prodrug of penciclovir. Resistance is mediated by viral kinase or polymerase mutations.

Ganciclovir

Chemical modification of the aciclovir molecule allows preferential phosphorylation by protein kinases of cytomegalovirus (CMV) and other β-herpesviruses (e.g. human herpesvirus (HHV) 6/7) and hence greater inhibition of the DNA polymerase, but at the expense of increased toxicity. Ganciclovir is administered intravenously or as a prodrug (valganciclovir) orally.

Cidofovir

Cidofovir inhibits viral DNA polymerases with potent activity against CMV, including most ganciclovir-resistant CMV. It also has activity against aciclovir-resistant herpes simplex virus (HSV) and varicella zoster virus (VZV), HHV6 and occasionally adenovirus, poxvirus, papillomavirus or polyoma virus, and may be used to treat these infections in immunocompromised hosts.

Foscarnet

This analogue of inorganic pyrophosphate acts as a non-competitive inhibitor of HSV, VZV, HHV6/7 or CMV DNA polymerase. It does not require significant intracellular phosphorylation and so may be effective when HSV or CMV resistance is due to altered drug phosphorylation. It has variable CSF penetration.

Anti-influenza agents

Zanamivir and oseltamivir

These agents inhibit influenza A and B neuraminidase, which is required for release of virus from infected cells (see Fig. 6.2, p. 135). They are used in treatment and prophylaxis of influenza. Administration within 48 hours of disease onset reduces the duration of symptoms by approximately 1–1½ days. In the UK, their use is limited mainly to adults with chronic respiratory or renal disease, significant cardiovascular disease, immunosuppression or diabetes mellitus, during known outbreaks. Peramivir has a distinct chemical structure, which means that it retains activity against some oseltamivir and zanamivir-resistant strains. It has poor oral bioavailability and is being developed as an intravenous or intramuscular formulation. An intravenous formulation of zanamivir is in development for critically ill patients.

Amantadine and rimantadine

These drugs reduce replication of influenza A by inhibition of viral M2 protein ion channel function, which is required for uncoating (see Fig. 6.2, p. 135). Resistance develops rapidly and is widespread, and amantadine and rimantadine should be used only if the prevalence of resistance locally is known to be low. They are no longer recommended for treatment or prophylaxis in the UK or USA, having been superseded by zanamivir and oseltamivir. However, they may still be indicated to treat oseltamivir-resistant influenza A in patients unable to take zanamivir (e.g. ventilated patients).

Agents used against hepatitis viruses

Ribavirin

Ribavirin is a guanosine analogue that inhibits nucleic acid synthesis in a variety of viruses and is used in particular in the treatment of hepatitis C virus.

Lamivudine, adefovir dipivoxil, tenofovir, entecavir and telbivudine

These agents have excellent activity against hepatitis B virus DNA polymerase–reverse transcriptase. They are well tolerated after oral administration but resistance develops with monotherapy. Resistance seems to emerge most rapidly for lamivudine (via the tyrosine–methionine–aspartate–aspartate, or YMDD, mutation) and most slowly for entecavir (multiple mutations required). Organisms resistant to lamivudine are usually also resistant to telbivudine, but not to adefovir/tenofovir. The role of monotherapy for hepatitis B virus is currently a matter for debate, and combination therapy, as used in HIV treatment, is likely to be increasingly employed. Lamivudine and tenofovir are also used against HIV (p. 407).

Telaprevir and boceprevir

A number of antiviral inhibitors of the hepatitis C virus NS3 serine protease or NS5B polymerase are in development. Telaprevir and boceprevir have been licensed for use in chronic hepatitis C virus genotype 1 disease. Addition of these agents to standard interferon–ribavirin combination therapy improves sustained virological response rates. They are prone to drug–drug interactions, including those involving antiretrovirals. Resistance develops to these agents, so they are administered as part of combination treatment.

Interferon-α

The interferons are naturally occurring cytokines that are produced as an early response to viral infection (p. 74). The addition of a polyethylene glycol (PEG) moiety to the molecule significantly enhances pharmacokinetics and efficacy.

Antiparasitic agents

Drugs used against helminths

Benzimidazoles (albendazole, mebendazole)

These agents act by inhibiting both helminth glucose uptake, causing depletion of glycogen stores, and fumarate reductase. Albendazole is used for hookworm, ascariasis, threadworm, *Strongyloides* infection, trichinellosis, *Taenia solium* (cysticercosis) and hydatid disease. Mebendazole is used for hookworm, ascariasis, threadworm and whipworm. The drugs are administered orally. Absorption is relatively poor, but increased by a fatty meal. Significant adverse effects are uncommon.

Bithionol

Bithionol is used to treat fluke infections with *Fasciola hepatica*. It is well absorbed orally. Adverse effects are mild (e.g. nausea, vomiting, diarrhoea, rashes) but relatively common (approximately 30%).

Diethylcarbamazine

Diethylcarbamazine (DEC) is an oral agent used to treat filariasis and loiasis. Treatment of filariasis is often followed by fever, headache, nausea, vomiting, arthralgia and prostration. This is caused by the host response to dying microfilariae, rather than the drug, and may be reduced by pre-treatment with corticosteroids.

Ivermectin

Ivermectin binds to helminth nerve and muscle cell ion channels, causing increased membrane permeability. It is an oral agent, used in *Strongyloides* infection, filariasis and onchocerciasis. Significant side-effects are uncommon.

Niclosamide

Niclosamide inhibits oxidative phosphorylation, causing paralysis of helminths. It is an oral agent, used in *Taenia saginata* and intestinal *T. solium* infection. Systemic absorption is minimal and it has few significant side-effects.

Piperazine

Piperazine inhibits neurotransmitter function, causing helminth muscle paralysis. It is an oral agent, used in ascariasis and threadworm (*Enterobius vermicularis*) infection. Significant adverse effects are uncommon, but include neuropsychological reactions such as vertigo, confusion and convulsions.

Praziquantel

Praziquantel increases membrane permeability to Ca^{++}, causing violent contraction of worm muscle. It is the drug of choice for schistosomiasis, and is also used in *T. saginata*, *T. solium* (cysticercosis) and fluke infections (*Clonorchis*, *Paragonimus*) and in echinococcosis. It is administered orally and is well absorbed. Adverse effects are usually mild and transient, and include nausea and abdominal pain.

Pyrantel pamoate

This agent causes spastic paralysis of helminth muscle through a suxamethonium-like action. It is used orally in ascariasis and threadworm infection. Systemic absorption is poor and adverse effects are uncommon.

Thiabendazole

Thiabendazole inhibits fumarate reductase, which is required for energy production in helminths. It is used orally in *Strongyloides* infection and topically to treat cutaneous larva migrans. Significant adverse effects are uncommon.

Antimalarial agents

Artemisinin (quinghaosu) derivatives

Artemisinin originates from a herb (sweet wormwood, *Artemisia annua*), which was used in Chinese medicine to treat fever. Its derivatives, artemether and artesunate, were developed for use in malaria in the 1970s. Their mechanism of action is unknown. They are used in the treatment, but not prophylaxis, of malaria, usually in combination with other antimalarials, and are effective against strains of *Plasmodium* spp. that are resistant to other antimalarials. Artemether is lipid-soluble and may be administered via intramuscular and oral routes. Artesunate is water-soluble and is administered intravenously or orally. Serious adverse effects are uncommon. Current advice for malaria in pregnancy is that the artemisinin derivatives should be used to treat uncomplicated *falciparum* malaria in the second and third trimesters, but should not be prescribed in the first trimester until more information becomes available.

Atovaquone

Atovaquone inhibits mitochondrial function. It is an oral agent, used for treatment and prophylaxis of malaria, in combination with proguanil (see below), without which it is ineffective. It is also employed in the treatment of mild cases of *Pneumocystis jirovecii (carinii)* pneumonia, where there is intolerance to co-trimoxazole. Significant adverse effects are uncommon.

Folate synthesis inhibitors (proguanil, pyrimethamine–sulfadoxine)

Proguanil inhibits dihydrofolate reductase and is used for malaria prophylaxis. Pyrimethamine–sulfadoxine is used in the treatment of malaria (p. 356).

Quinoline-containing compounds

Chloroquine and quinine are believed to act by intraparasitic inhibition of haem polymerisation, resulting in toxic build-up of intracellular haem. The mechanisms of action of other agents in this group (quinidine, amodiaquine, mefloquine, primaquine, etc.) may differ. They are employed in the treatment and prophylaxis of malaria. Primaquine is used for radical cure of malaria due to *Plasmodium vivax* and *P. ovale* (destruction of liver hypnozoites). Chloroquine is also given for extraintestinal amoebiasis.

Chloroquine can cause a pruritus sufficient to compromise compliance with therapy. If used in long-term, high-dose regimens, it causes an irreversible retinopathy. Overdosage leads to life-threatening cardiotoxicity. The side-effect profile of mefloquine includes neuropsychiatric effects ranging from mood change, nightmares and agitation to hallucinations and psychosis. Quinine may cause hypoglycaemia and cardiotoxicity, especially when administered parenterally. Primaquine causes haemolysis in people with glucose-6-phosphate dehydrogenase deficiency (p. 1029), which should be excluded before therapy. Chloroquine is considered safe in pregnancy, but mefloquine should be avoided in the first trimester.

Lumefantrine

Lumefantrine is used in combination with artemether to treat uncomplicated *falciparum* malaria, including chloroquine-resistant strains. Its mechanism of action is unknown. Significant adverse effects are uncommon.

Drugs used in trypanosomiasis

Benznidazole

Benznidazole is an oral agent used to treat South American trypanosomiasis (Chagas' disease, p. 360). Significant and common adverse effects include dose-related peripheral neuropathy, purpuric rash and granulocytopenia.

Eflornithine

Eflornithine inhibits biosynthesis of polyamines by ornithine decarboxylase inhibition, and is used in West African trypanosomiasis (*T. brucei gambiense* infection) of the CNS. It is administered as an intravenous infusion 4 times daily, which may be logistically difficult in the geographic areas affected by this disease. Significant adverse effects are common, and include convulsions, gastrointestinal upset and bone marrow depression. Eflornithine is also used (topically) to treat hirsutism (p. 763).

Melarsoprol

This is an arsenical agent, used to treat CNS infections in East and West African trypanosomiasis (*T. brucei rhodesiense* and *gambiense*). It is administered intravenously. Melarsoprol treatment is associated with peripheral neuropathy and reactive arsenical encephalopathy (RAE), which carries a significant mortality.

Nifurtimox

Nifurtimox is administered orally to treat South American trypanosomiasis (Chagas' disease). Gastrointestinal and neurological adverse effects are common.

Pentamidine isetionate

Pentamidine is an inhibitor of DNA replication used in West African trypanosomiasis (*T. brucei gambiense*) and, to a lesser extent, in visceral and cutaneous leishmaniasis. It is also prescribed in *Pneumocystis jirovecii (carinii)* pneumonia. It is administered via intravenous or intramuscular routes. It is a relatively toxic drug, commonly causing rash, renal impairment, profound hypotension (especially on rapid infusion), electrolyte disturbances, blood dyscrasias and hypoglycaemia.

Suramin

Suramin is a naphthaline dye derivative, used to treat East African trypanosomiasis (*T. brucei rhodesiense*). It is administered intravenously. Adverse effects are common, and include rash, gastrointestinal disturbance, blood dyscrasias, peripheral neuropathies and renal impairment.

Other antiprotozoal agents

Pentavalent antimonials

Sodium stibogluconate and meglumine antimoniate inhibit protozoal glycolysis by phosphofructokinase inhibition. They are used parenterally (intravenous or intramuscular) to treat leishmaniasis. Adverse effects include arthralgia, myalgias, raised hepatic transaminases, pancreatitis and ECG changes. Severe cardiotoxicity leading to death is not uncommon.

Diloxanide furoate

This oral agent is used to eliminate luminal cysts following treatment of intestinal amoebiasis, or in asymptomatic cyst excreters. The drug is absorbed slowly (enabling luminal persistence) and has no effect in hepatic amoebiasis. It is a relatively non-toxic drug, the most significant adverse effect being flatulence.

Iodoquinol (di-iodohydroxyquinoline)

Iodoquinol is a quinoline derivative (p. 163) with activity against *Entamoeba histolytica* cysts and trophozoites. It is used orally to treat asymptomatic cyst excreters or, in association with another amoebicide (e.g. metronidazole), to treat extra-intestinal amoebiasis. Long-term use of this drug is not recommended, as neurological adverse effects include optic neuritis and peripheral neuropathy.

Nitazoxanide

Nitazoxanide is an inhibitor of pyruvate–ferredoxin oxidoreductase-dependent anaerobic energy metabolism in protozoa. It is a broad-spectrum agent, active against various nematodes, tapeworms, flukes and intestinal protozoa. Nitazoxanide also has activity against some anaerobic bacteria and viruses. It is administered orally in giardiasis and cryptosporidiosis. Adverse effects are usually mild and involve the gastrointestinal tract (e.g. nausea, diarrhoea and abdominal pain).

Paromomycin

Paromomycin is an aminoglycoside (p. 156) that is used to treat visceral leishmaniasis and intestinal amoebiasis. It is not significantly absorbed when administered orally, and is therefore given orally for intestinal amoebiasis and by intramuscular injection for leishmaniasis. It showed early promise in the treatment of HIV-associated cryptosporidiosis, but subsequent trials have demonstrated that this effect is marginal at best.

COMPREHENSIVE GERIATRIC ASSESSMENT

Insets (*Wasted hand, kyphosis*) From Afzal Mir 2003; (*Senile purpura*) Forbes and Jackson 2004; (*Venous ulceration*) Mosti 2012 – see p. 177.

History

- **Slow down** the pace.
- **Ensure the patient can hear**.
- Establish the **speed of onset** of the illness.
- If the presentation is vague, carry out a **systematic enquiry**.
- Obtain full details of:

  all drugs, especially any recent prescription changes

  past medical history, even from many years previously

  usual function

  1. Can the patient walk normally?
  2. Has the patient noticed memory problems?
  3. Can the patient perform all household tasks?
- **Obtain a collateral history**: confirm information with a relative or carer and the general practitioner, particularly if the patient is confused or communication is limited by deafness or speech disturbance.

Examination

- **Thorough** to identify all comorbidities.
- **Tailored to the patient's stamina** and ability to cooperate.
- Include **functional status**:

  cognitive function
  gait and balance
  nutrition
  hearing and vision.

Domains of Comprehensive Geriatric Assessment.

Social assessment

Home circumstances

- Living alone, with another or in a care home.

Activities of daily living (ADL)

- Tasks for which help is needed:

  domestic ADL: shopping, cooking, housework

  personal ADL: bathing, dressing, walking.
- **Informal help**: relatives, friends, neighbours.
- **Formal social services**: home help, meals on wheels.
- Carer stress.

Multidisciplinary team (MDT) roles

Team member	Activity assessed and promoted
Physiotherapist	Mobility, balance and upper limb function
Occupational therapist	ADL, e.g. dressing, cooking Home environment and care needs
Dietitian	Nutrition
Speech and language therapist	Communication and swallowing
Social worker	Care needs and discharge planning, including organisation of institutional care
Nurse	Motivation and initiation of activities; promotion of self-care Education Feeding, continence, skin care Communication with relatives and other professionals Assessment of care needs for discharge
Doctor	Diagnosis and management of medical problems Coordinator of assessment, management and rehabilitation programme

12 Get up and go test

To assess gait and balance, ask the patient to stand up from a sitting position, walk 10 m, turn and go back to the chair. A normal performance takes less than 12 seconds.

Difficulty rising? | Unsteady on standing? | Unsteady gait? | Unsteady on turning? | Unsteady on sitting down?

Sweeping demographic change has meant that older people now represent the core practice of medicine in many countries. A good knowledge of the effects of ageing and the clinical problems associated with old age is thus essential in most medical specialties. The older population is extremely diverse; a substantial proportion of 90-year-olds enjoy an active healthy life, while some 70-year-olds are severely disabled by chronic disease. The terms 'chronological' and 'biological' ageing have been coined to describe this phenomenon. Biological rather than chronological age is taken into consideration when making clinical decisions about, for example, the extent of investigation and intervention that is appropriate.

Geriatric medicine is concerned particularly with frail older people, in whom physiological capacity is so reduced that they are incapacitated by even minor illness. They frequently have multiple comorbidities, and acute illness may present in non-specific ways, such as confusion, falls or loss of mobility and day-to-day functioning. These patients are prone to adverse drug reactions, partly because of polypharmacy and partly because of age-related changes in responses to drugs and their elimination (p. 36). Disability is common, but patients' function can often be improved by the interventions of the multidisciplinary team (p. 167).

Older people have been neglected in research terms and, until recently, were rarely included in randomised controlled clinical trials. There is thus little evidence on which to base practice.

DEMOGRAPHY

The demography of developed countries has changed rapidly in recent decades. In the UK, for example, the total population grew by 11% over the last 30 years, but the number of people aged over 65 years rose by 24%. The steepest rise occurred in those aged over 85 – from 600 000 in 1981 to 1.5 million in 2011 – and this number is projected to increase to 2.4 million by 2026, whilst the working-age population (20–64 years) is expected to grow by only 4% between 2011 and 2026. This will have a significant impact on the old-age dependency ratio, i.e. the number of people of working age for each person over retirement age. Young people support older members of the population directly (e.g. through living arrangements) and financially (e.g. through taxation and pension contributions), so the consequences of a reduced ratio are far-reaching. However, many older people support the younger population, through care of children and other older people.

Life expectancy in the developed world is now prolonged, even in old age (Box 7.1); women aged 80 years can expect to live for a further 10 years. However, rates of disability and chronic illness rise sharply with ageing and have a major impact on health and social services. In the UK, the reported prevalence of a chronic illness or disability sufficient to restrict daily activities is around 25% in those aged 50–64, but is 66% in men and 75% in women aged over 85.

Although the proportion of the population aged over 65 years is greater in developed countries, two-thirds of the world population of people aged over 65 live in developing countries at present, and this is projected to rise to 75% in 2025. The rate of population ageing is much faster in developing countries (Fig. 7.1) and so they have less time to adjust to its impact.

7.1 Mean life expectancy in years, UK and India

	Males		Females	
	UK	India	UK	India
At birth	79.1	65.1	83.0	67.2
At 60 years	22.8	16.7	25.5	18.9
At 70 years	15.0	10.9	17.1	12.4
At 80 years	8.7	7.5	9.9	8.0

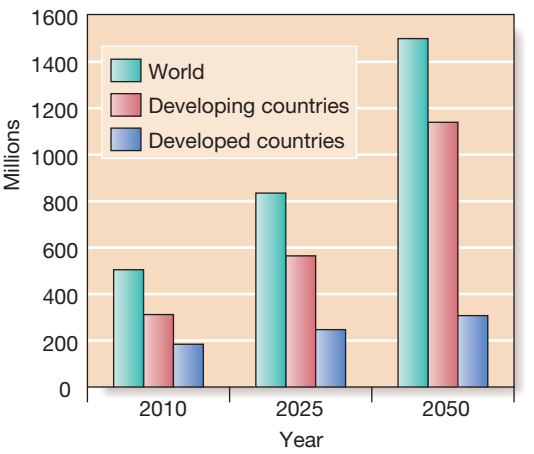

Fig. 7.1 Number of people aged 65 years and over projected in the world population.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Biology of ageing

Ageing can be defined as a progressive accumulation through life of random molecular defects that build up within tissues and cells. Eventually, despite multiple repair and maintenance mechanisms, these result in age-related functional impairment of tissues and organs.

Many genes probably contribute to ageing, with those that determine durability and maintenance of somatic cell lines particularly important. However, genetic factors only account for around 25% of variance in human lifespan; nutritional and environmental factors determine the rest.

A major contribution to random molecular damage is made by reactive oxygen species produced during the metabolism of oxygen to produce cellular energy. These cause oxidative damage at a number of sites:

- *Nuclear chromosomal DNA*, causing mutations and deletions which ultimately lead to aberrant gene function and potential for malignancy.
- *Telomeres*, which are the protective end regions of chromosomes which shorten with each cell division

because telomerase (which copies the end of the 3′ strand of linear DNA in germ cells) is absent in somatic cells. When telomeres are sufficiently eroded, cells stop dividing. It has been suggested that telomeres represent a 'biological clock' which prevents uncontrolled cell division and cancer. Telomeres are particularly shortened in patients with premature ageing due to Werner's syndrome, in which DNA is damaged due to lack of a helicase.

- *Mitochondrial DNA and lipid peroxidation*, resulting in reduced cellular energy production and ultimately cell death.
- *Proteins* – e.g. those increasing formation of advanced glycosylation end-products from spontaneous reactions between proteins and sugars. These damage structure and function of the affected protein, which becomes resistant to breakdown.

The rate at which damage occurs is malleable and this is where the interplay with environment, particularly nutrition, takes place. There is evidence in some organisms that this interplay is mediated by insulin signalling pathways. Chronic inflammation also plays an important role, again in part by driving the production of reactive oxygen species.

Physiological changes of ageing

The physiological features of normal ageing have been identified by examining disease-free populations of older people, to separate the effects of pathology from those due to time alone. However, the fraction of older people who age without disease ultimately declines to very low levels, so that use of the term 'normal' becomes debatable. There is a marked increase in inter-individual variation in function with ageing; many physiological processes deteriorate substantially when measured across populations, but some individuals show little or no change. This heterogeneity is a hallmark of ageing, meaning that each person must be assessed individually and that one cannot unthinkingly apply the same management to all people of a certain age.

Although some genetic influences contribute to heterogeneity, environmental factors, such as poverty, nutrition, exercise, cigarette smoking and alcohol misuse, play a large part, and a healthy lifestyle should be encouraged even when old age has been reached.

The effects of ageing are usually not enough to interfere with organ function under normal conditions, but reserve capacity is significantly reduced. Some changes

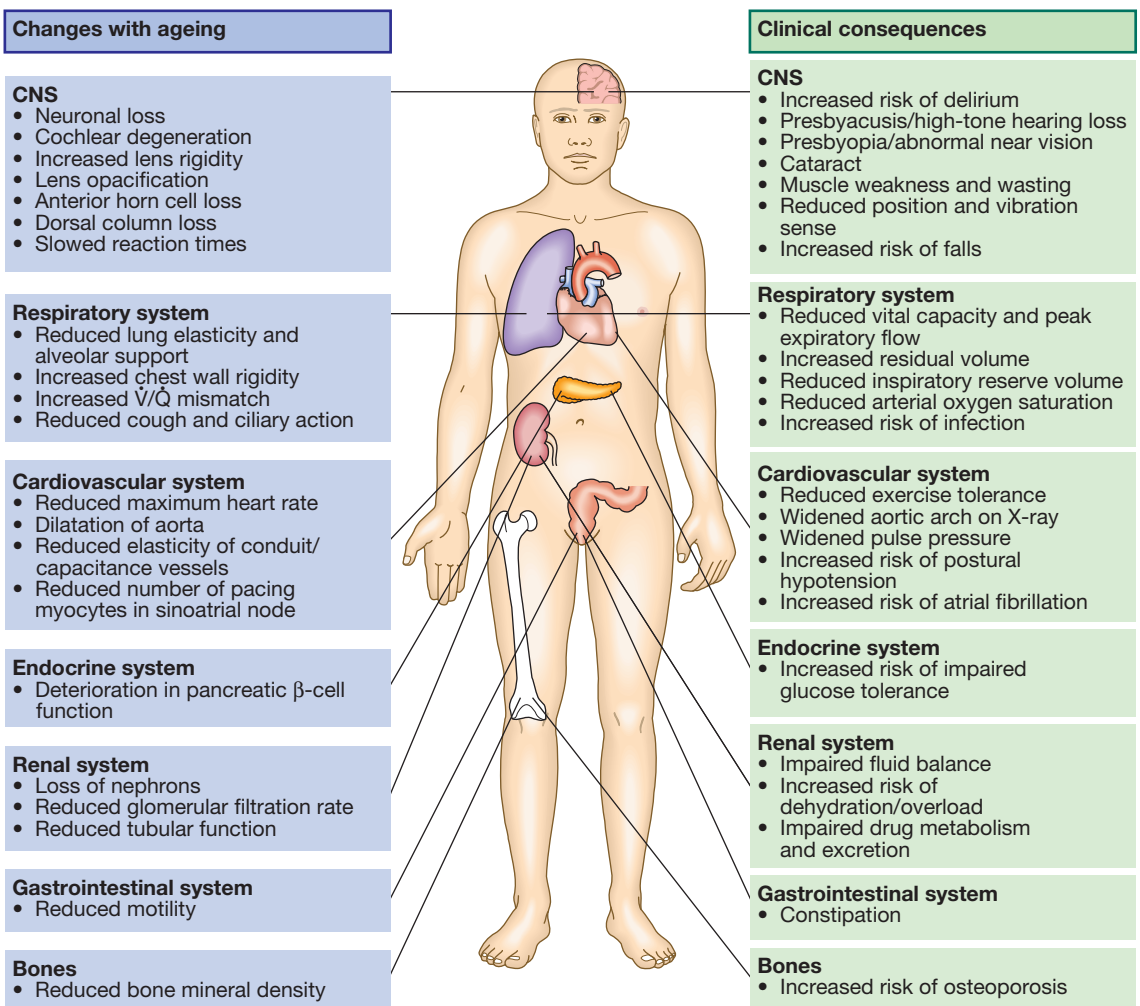

Fig. 7.2 Features and consequences of normal ageing.

of ageing, such as depigmentation of the hair, are of no clinical significance. Figure 7.2 shows many factors that are clinically important.

Frailty

Frailty is defined as the loss of an individual's ability to withstand minor stresses because the reserves in function of several organ systems are so severely reduced that even a trivial illness or adverse drug reaction may result in organ failure and death. The same stresses would cause little upset in a fit person of the same age.

It is important to understand the difference between 'disability', 'comorbidity' and 'frailty'. Disability indicates established loss of function (e.g. mobility; see Box 7.13, p. 176), while frailty indicates increased vulnerability to loss of function. Disability may arise from a single pathological event (such as a stroke) in an otherwise healthy individual. After recovery, function is largely stable and the patient may otherwise be in good health. When frailty and disability coexist, function deteriorates markedly even with minor illness, to the extent that the patient can no longer manage independently. Similarly, comorbidity (the number of diagnoses present) is not equivalent to frailty; it is quite possible to have several diagnoses without major impact on homeostatic reserve.

Unfortunately, the term 'frail' is often used rather vaguely, sometimes to justify a lack of adequate investigation and intervention in older people. However, it can be specifically identified by assessing function in a number of domains. Two main approaches to evaluating frailty exist: measurement of physiological function across a number of domains (e.g. the Fried Frailty score, Box 7.2), or a score based on the number of deficits or problems – for example, the Rockwood score.

Frail older people particularly benefit from a clinical approach that addresses both the precipitating acute illness and their underlying loss of reserves. It may be possible to prevent further loss of function through early intervention; for example, a frail woman with myocardial infarction will benefit from specific cardiac investigation and drug treatment, but may benefit even further from an exercise programme to improve musculoskeletal function, balance and aerobic capacity, with nutritional support to restore lost weight. Establishing a patient's level of frailty also helps inform decisions regarding further investigation and management, and the need for rehabilitation.

7.2 How to assess a Fried Frailty score

- Handgrip strength in bottom 20% of healthy elderly distribution*
- Walking speed in bottom 20% of healthy elderly distribution*
- Self-reported exhaustion
- Physically inactive
- At least 6 kg weight loss within 1 year

Patient is defined as frail if 3 or more factors are present.

*Varies between populations. Grip cutoff is 30 kg for men, 18 kg for women in US adults; 5 m walk time cutoff is 7 seconds in US adults for both sexes.

INVESTIGATIONS

Comprehensive geriatric assessment

Although not strictly an investigation, one of the most powerful tools in the management of older people is the Comprehensive Geriatric Assessment, which identifies all the relevant factors contributing to their presentation (p. 166). In frail patients with multiple pathology, it may be necessary to perform the assessment in stages to allow for their reduced stamina. The outcome should be a management plan that not only addresses the acute presenting problems, but also improves the patient's overall health and function (Box 7.3).

Comprehensive Geriatric Assessment is performed by a multidisciplinary team (p. 167). Such an approach was pioneered by Dr Marjory Warren at the West Middlesex Hospital in London in the 1930s; her comprehensive assessment and rehabilitation of supposedly incurable, long-term bedridden older people revolutionised the approach of the medical profession to older, frail people and laid the foundations for the modern specialty of geriatric medicine.

EBM 7.3 Comprehensive geriatric assessment

'Inpatient comprehensive geriatric assessment reduces short-term mortality and increases the chance of patients living at home in the long term.'

- Ellis G, Langhorne P. Br Med Bull 2005; 71: 45–59.

Decisions about investigation

Accurate diagnosis is important at all ages but frail older people may not be able to tolerate lengthy or invasive procedures, and diagnoses may be revealed for which patients could not withstand intensive or aggressive treatment. On the other hand, disability should never be dismissed as due to age alone. For example, it would be a mistake to supply a patient no longer able to climb stairs with a stair lift, when simple tests would have revealed osteoarthritis of a hip and vitamin D deficiency, for which appropriate treatment would have restored his or her strength. So how do doctors decide when and how far to investigate?

The patient's general health

Does this patient have the physical and mental capacity to tolerate the proposed investigation? Does he have the aerobic capacity to undergo bronchoscopy? Will confusion prevent her from remaining still in the magnetic resonance imaging (MRI) scanner? The more comorbidities a patient has, the less likely he or she will be able to withstand an invasive intervention.

Will the investigation alter management?

Would the patient be fit for, or benefit from, the treatment that would be indicated if investigation proved positive? The presence of comorbidity is more important than age itself in determining this. When a patient with

severe heart failure and a previous disabling stroke presents with a suspicious mass lesion on chest X-ray, detailed investigation and staging may not be appropriate if he is not fit for surgery, radical radiotherapy or chemotherapy. On the other hand, if the same patient presented with dysphagia, investigation of the cause would be important, as he would be able to tolerate endoscopic treatment (for example, to palliate an obstructing oesophageal carcinoma).

The views of the patient and family

Older people may have strong views about the extent of investigation and the treatment they wish to receive, and these should be sought from the outset. If the patient wishes, the views of relatives can be taken into account. If the patient is not able to express a view or lacks the capacity to make decisions because of cognitive impairment or communication difficulties, then relatives' input becomes particularly helpful. They may be able to give information on views previously expressed by the patient or on what the patient would have wanted under the current circumstances. However, families should never be made to feel responsible for difficult decisions.

Advance directives

Advance directives or 'living wills' are statements made by adults at a time when they have the capacity to decide about the interventions they would refuse or accept in the future, should they no longer be able to make decisions or communicate them. An advance directive cannot authorise a doctor to do anything that is illegal and doctors are not bound to provide a specific treatment requested if, in their professional opinion, it is not clinically appropriate. However, any advance refusal of treatment, made when the patient was able to make decisions based on adequate information about their implications, is legally binding in the UK. It must be respected when it clearly applies to the patient's present circumstances and when there is no reason to believe that the patient has changed his or her mind.

PRESENTING PROBLEMS IN GERIATRIC MEDICINE

Characteristics of presenting problems in old age

Problem-based practice is central to geriatric medicine. Most problems are multifactorial and there is rarely a single unifying diagnosis. All contributing factors have to be taken into account and attention to detail is paramount. Two patients who share the same presenting problem may have completely disparate diagnoses. A wide knowledge of adult medicine is required, as disease in any, and often many, of the organ systems has to be managed at the same time. There are a number of features that are particular to older patients.

Late presentation

Many people (of all ages) accept ill health as a consequence of ageing and may tolerate symptoms for lengthy periods before seeking medical advice. Comorbidities may also contribute to late presentation; in a patient whose mobility is limited by stroke, angina may only present when coronary artery disease is advanced, as the patient has been unable to exercise sufficiently to cause symptoms at an earlier stage.

Atypical presentation

Infection may present with delirium and without clinical pointers to the organ system affected. Stroke may present with falls rather than symptoms of focal weakness. Myocardial infarction may present as weakness and fatigue, without the chest pain or dyspnoea. The reasons for these atypical presentations are not always easy to establish. Perception of pain is altered in old age, which may explain why myocardial infarction presents in other ways. The pyretic response is blunted in old age so that infection may not be obvious at first. Cognitive impairment may limit the patient's ability to give a history of classical symptoms.

Acute illness and changes in function

Atypical presentations in frail elderly patients include 'failure to cope', 'found on floor', 'confusion' and 'off feet', but these are *not* diagnoses. The possibility that an acute illness has been the precipitant must always be considered. To establish whether the patient's current status is a change from his or her usual level of function, it helps to ask a relative or carer (by phone if necessary). Investigations aimed at uncovering an acute illness will not be fruitful in a patient whose function has been deteriorating over several months, but are important if function has suddenly changed.

Multiple pathology

Presentations in older patients have a more diverse differential diagnosis because multiple pathology is so common. There are frequently a number of causes for any single problem, and adverse effects from medication often contribute. A patient may fall because of osteoarthritis of the knees, postural hypotension due to diuretic therapy for hypertension, and poor vision due to cataracts. All these factors have to be addressed to prevent further falls, and this principle holds true for most of the common presenting problems in old age.

Approach to presenting problems in old age

For the sake of clarity, the common presenting problems are described individually, but in real life, older patients often present with several at the same time, particularly confusion, incontinence and falls. These share some underlying causes and may precipitate each other.

The approach to most presenting problems in old age can be summarised as follows:

- *Obtain a collateral history.* Find out the patient's usual status (e.g. mobility, cognitive state) from a relative or carer. Call these people by phone if they are not present.
- *Check all medication.* Have there been any recent changes?
- *Search for and treat any acute illness.* See Box 7.4.
- *Identify and reverse predisposing risk factors.* These depend on the presenting problem.

7.4 Screening investigations for acute illness

- Full blood count
- Urea and electrolytes, liver function tests, calcium and glucose
- Chest X-ray
- Electrocardiogram
- C-reactive protein: useful marker for occult infection or inflammatory disease
- Blood cultures if pyrexial

Falls

Around 30% of those over 65 years of age fall each year, this figure rising to more than 40% in those aged over 80. Although only 10–15% of falls result in serious injury, they are the cause of more than 90% of hip fractures in this age group, compounded by the rising prevalence of osteoporosis. Falls also lead to loss of confidence and fear, and are frequently the 'final straw' that makes an older person decide to move to institutional care. Management will vary according to the underlying cause.

Acute illness

Falls are one of the classical atypical presentations of acute illness in frail people. The reduced reserves in older people's neurological function mean that they are less able to maintain their balance when challenged by an acute illness. Suspicion should be high when falls have suddenly occurred over a period of a few days. Common underlying illnesses include infection, stroke, metabolic disturbance and heart failure. Thorough examination and investigation are required (see Box 7.4). It is also important to establish whether any drug which precipitates falls, such as a psychotropic or hypotensive agent, has been started recently. Once the underlying acute illness has been treated, falls may stop.

Blackouts

A proportion of older people who 'fall' have, in fact, had a syncopal episode. A collateral history from a witness is of utmost importance in anyone falling over; people who lose consciousness do not always remember having done so. If loss of consciousness is suggested by the patient or witness, it is important to perform appropriate investigations (pp. 554 and 1157).

Mechanical and recurrent falls

Amongst patients who have tripped or are uncertain how they fell, those who have fallen more than once in the past year and those who are unsteady during a 'get up and go' test (p. 167) require further assessment. Patients with recurrent falls are commonly frail, with multiple medical problems and chronic disabilities. Obviously, such patients may present with a fall resulting from an acute illness or syncope, but they will remain at risk of further falls even when the acute illness has resolved. The risk factors for falls (Box 7.5) should be considered. If problems are identified with muscle strength, balance, vision or cognitive function, the causes of these must be identified by specific investigation, and treatment commenced if appropriate. Careful assessment of the patient's gait may provide important clues to an underlying diagnosis (Box 7.6). Common pathologies identified include cerebrovascular disease (Ch. 27), Parkinson's disease (p. 1195) and osteoarthritis of weight-bearing joints (p. 1081). Osteoporosis risk factors should also be sought and dual energy X-ray absorptiometry (DEXA) bone density scanning considered in all older patients who have recurrent falls, particularly if they have already sustained a fracture (p. 1065).

7.5 Risk factors for falls

- Muscle weakness
- History of falls
- Gait or balance abnormality
- Use of a walking aid
- Visual impairment
- Arthritis
- Impaired activities of daily living
- Depression
- Cognitive impairment
- Age over 80 years
- Psychotropic medication

7.6 Abnormal gaits and probable causes

Gait abnormality	Probable cause
Antalgic	Arthropathy
Waddling	Proximal myopathy
Stamping	Sensory neuropathy
Foot drop	Peripheral neuropathy or radiculopathy
Ataxic	Sensory neuropathy or cerebellar disease
Shuffling/festination	Parkinson's disease
Marche à petits pas	Small-vessel cerebrovascular disease
Hemiplegic	Cerebral hemisphere lesion
Apraxic	Bilateral hemisphere lesions

Prevention of falls and fractures

Falls can be prevented by multiple risk factor intervention (Box 7.7). The most effective intervention is balance and strength training by physiotherapists; an alternative with good evidence is tai chi training. An assessment of the patient's home environment for hazards should be undertaken by an occupational therapist, who may also provide personal alarms so that patients can summon help, should they fall again. Rationalising psychotropic medication may help to reduce sedation, although many older patients are reluctant to stop hypnotics. If postural hypotension is present (defined as a drop in blood pressure of > 20 mmHg systolic or > 10 mmHg diastolic pressure on standing from supine), reducing or stopping hypotensive drugs may be helpful. Evidence supporting the efficacy of other interventions for postural hypotension is lacking, but drugs, including fludrocortisone and midodrine, are sometimes used to try to improve dizziness on standing. Simple interventions, such as new glasses to correct visual acuity, and podiatry, can also have a significant impact on function in those who fall.

If osteoporosis is diagnosed, specific drug therapy should be commenced (p. 1122). In patients in institutional care, calcium and vitamin D_3 administration has

EBM 7.7 Evidence-based interventions to prevent falls in older people

- Individualised or group strength and balance training, or tai chi
- Rationalisation of medication, especially psychotropic drugs
- Correction of visual impairment, particularly cataract extraction
- Home environmental hazard assessment and safety education
- Calcium and vitamin D supplementation for those in institutional care

- Gillespie LD, et al. Interventions for preventing falls in older people living in the community. Cochrane Database of Systematic Reviews, 2012, Art. no. CD007146.
- Cameron ID, et al. Interventions for preventing falls in older people in care facilities and hospitals. Cochrane Database of Systematic Reviews, 2010, Art. no. CD005465.

been shown to reduce both falls and fracture rates, through effects on both bone mineral density and neuromuscular function. They are not effective in those with osteoporosis living in the community, in whom bisphosphonates are first-line therapy.

In the UK, government policy and National Institute for Health and Clinical Excellence guidelines (www.nice.org.uk) for falls prevention have led to the development of specific Falls and Fracture Prevention Services in many parts of the country.

Dizziness

Dizziness is very common, affecting at least 30% of those aged over 65 years in community surveys. Dizziness can be disabling in its own right and is also a risk factor for falls. Acute dizziness is relatively straightforward and common causes include:

- hypotension due to arrhythmia, myocardial infarction, gastrointestinal bleed or pulmonary embolism
- onset of posterior fossa stroke
- vestibular neuronitis.

Although older people more commonly present with recurrent dizzy spells and often find it difficult to describe the sensation they experience, the most effective way of establishing the cause(s) of the problem is nevertheless to determine which of the following is predominant (even if more than one is present):

- *lightheadedness*, suggestive of reduced cerebral perfusion
- *vertigo*, suggestive of labyrinthine or brainstem disease (p. 1167)
- *unsteadiness/poor balance*, suggestive of joint or neurological disease.

In lightheaded patients, structural cardiac disease (such as aortic stenosis) and arrhythmia must be considered, but disorders of autonomic cardiovascular control, such as vasovagal syndrome and postural hypotension, are the most common causes in old age. Hypotensive medication may exacerbate these. Further investigation and treatment are described on page 1157.

Vertigo in older patients is most commonly due to benign positional vertigo (p. 1158), but if other brainstem symptoms or signs are present, MRI of the brain is required to exclude a cerebello-pontine angle lesion.

Delirium

Delirium is a syndrome of transient, reversible cognitive dysfunction. It is very common, affecting up to 30% of older hospital inpatients, either at admission or during their hospital stay. It is associated with high rates of mortality, complication and institutionalisation, and with longer lengths of stay. Risk factors are shown in Box 7.8. Its pathophysiology is unclear; it may in part be due to the effect of increased cortisol release in acute illness, or it may reflect a sensitivity of cholinergic neurotransmission to toxic insults. Older terms for delirium, e.g. acute confusion or toxic confusional state, lack diagnostic precision and should be avoided.

Clinical assessment

Assessment has two main goals: firstly, to establish the diagnosis of delirium; and secondly, to identify all of the reversible precipitating factors to allow optimal treatment.

Delirium may be missed unless routine cognitive testing with an Abbreviated Mental Test, CLOX test or mini-mental state examination (MMSE; p. 234) is performed. Delirium often occurs in patients with dementia, and a history from a relative or carer about the onset and course of confusion is needed to distinguish acute from chronic features. The Confusion Assessment Method (Box 7.9) is a useful tool to diagnose delirium accurately and to differentiate the condition from dementia.

More than one of the precipitating causes of delirium (Fig. 7.3) is often present. Symptoms suggestive of a physical illness, such as an infection or stroke, should be elicited. An accurate drug and alcohol history is required, especially to ascertain whether any drugs have been recently stopped or started.

A full physical examination should be performed, noting in particular:

7.8 Risk factors for delirium

Predisposing factors

- Old age
- Dementia
- Frailty
- Sensory impairment
- Polypharmacy
- Renal impairment

Precipitating factors

- Intercurrent illness
- Surgery
- Change of environment or ward
- Sensory deprivation (e.g. darkness) or overload (e.g. noise)
- Medications (e.g. opioids, psychotropics)
- Dehydration
- Pain
- Constipation
- Urinary catheterisation
- Acute urinary retention
- Hypoxia
- Fever
- Alcohol withdrawal

7.9 How to make a diagnosis of delirium: the Confusion Assessment Method (CAM)

Talk to the patient and assess:

- *Cognition* (e.g. MMSE, p. 234). A normal score makes delirium unlikely.
- *Inattention.* Can the patient converse with you? If in doubt, give 6–7 digits (between 1 and 9) to remember and repeat back to you; failure suggests inattention.
- *Conscious level.* Alert, hyper-alert or drowsy?
- *Thinking.* Is speech rambling? Does it make sense? Is the patient hallucinating?

Obtain a collateral history (e.g. from carer, nurse or general practitioner):

- What is the patient normally like?
- Has there been a sudden deterioration, e.g. over a few days?
- Does confusion fluctuate through the day?

Consider the diagnosis. Delirium is present if there is:

Acute deterioration in cognition, which fluctuates over time
AND Evidence of inattention
WITH EITHER Evidence of disorganised thinking
OR Altered level of consciousness (either drowsy/stupor/coma *or* hyper-alert/agitated/irritable)

- pyrexia and any signs of infection in the chest, skin, urine or abdomen
- oxygen saturation
- signs of alcohol withdrawal, such as tremor or sweating
- any neurological signs.

A range of investigations are needed to identify the common causes (see Fig. 7.3).

Management

Specific treatment of all of the underlying causes must be commenced as quickly as possible. However, the symptoms of delirium also require specific management. To minimise ongoing confusion and disorientation, the environment should be kept well lit and not unduly noisy, with the patient's spectacles and hearing aids in place. Good nursing is needed to preserve orientation, prevent pressure sores and falls, and maintain hydration, nutrition and continence.

The use of sedatives should be kept to a minimum, as they can precipitate delirium. In any case, many confused patients are lethargic and apathetic rather than agitated. Sedation is very much a last resort, and is appropriate only if patients' behaviour is endangering

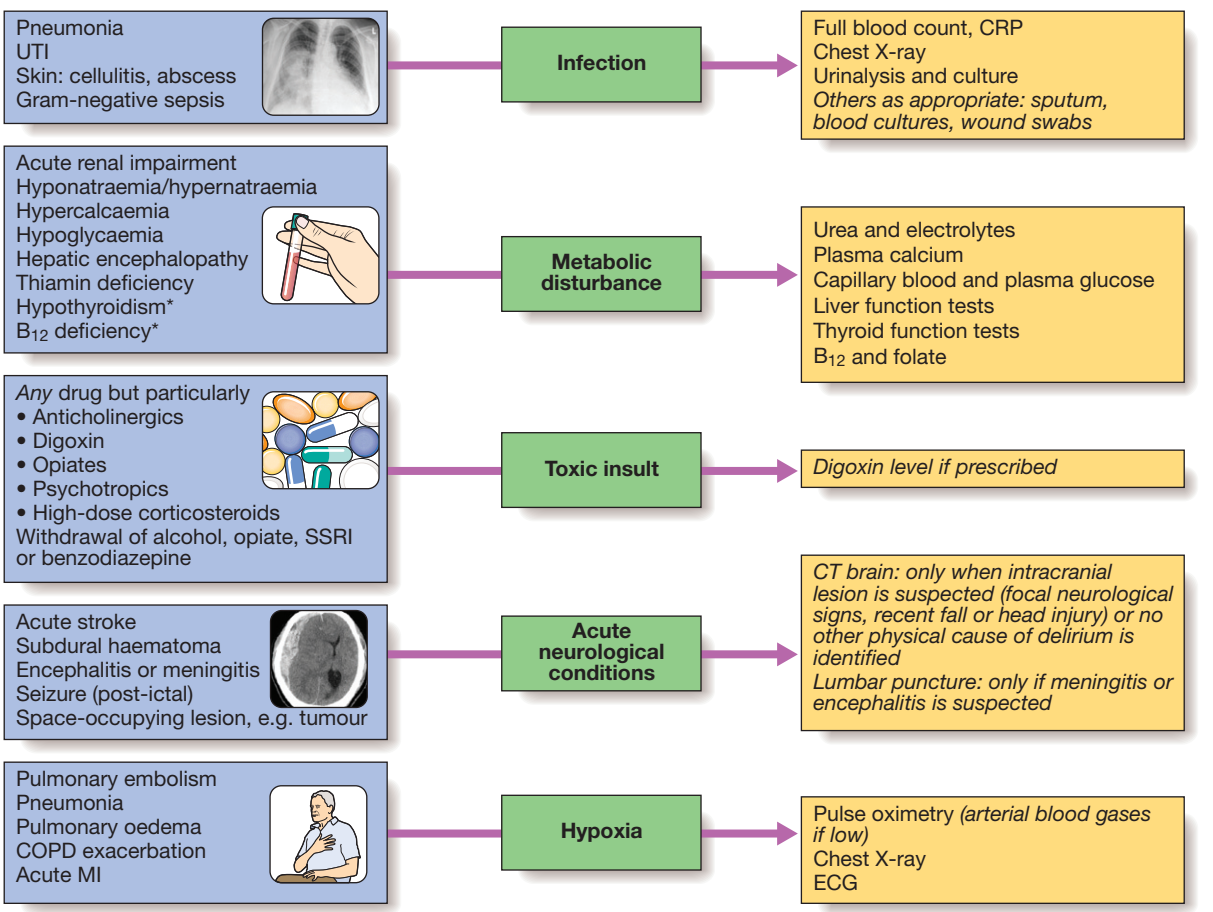

Fig. 7.3 Common causes and investigation of delirium. All investigations are performed routinely, except those in italics. *Tend to present over weeks to months rather than hours to days. The chest X-ray shows consolidation in pneumonia. The CT scan shows a cerebral haemorrhage. (COPD = chronic obstructive pulmonary disease; CRP = C-reactive protein; MI = myocardial infarction; SSRI = selective serotonin re-uptake inhibitor; UTI = urinary tract infection)

themselves or others. Small doses of haloperidol (0.5 mg twice daily) are tried orally first, and the dose increased if the patient fails to respond. Sedation can be given intramuscularly only if absolutely necessary. In those with alcohol withdrawal or Lewy body dementia (p. 252), a reducing course of a benzodiazepine should be prescribed. In other cases, benzodiazepines should be avoided, as they may prolong delirium.

The resolution of delirium in old age may be slow and incomplete. Many patients fail to recover to their pre-morbid level of cognition. Delirium may be the first presentation of an underlying dementia and is also a risk factor for subsequent dementia.

Urinary incontinence

Urinary incontinence is defined as the involuntary loss of urine and comes to medical attention when sufficiently severe to cause a social or hygiene problem. It occurs in all age groups but becomes more prevalent in old age, affecting about 15% of women and 10% of men aged over 65. It may lead to skin damage if severe and can be socially restricting. While age-dependent changes in the lower urinary tract predispose older people to incontinence, it is not an inevitable consequence of ageing and requires investigation and appropriate treatment. Urinary incontinence is frequently precipitated by acute illness in old age and is commonly multifactorial (Fig. 7.4).

Initial management is to identify and address contributory factors. If incontinence fails to resolve, further diagnosis and management should be pursued, as described on page 472.

- *Urge incontinence* is usually due to detrusor over-activity and results in urgency and frequency.
- *Stress incontinence* is almost exclusive to women and is due to weakness of the pelvic floor muscles, which allows leakage of urine when intra-abdominal pressure rises, e.g. on coughing. It may be compounded by atrophic vaginitis, associated with oestrogen deficiency in old age, which can be treated with oestrogen pessaries.
- *Overflow incontinence* is most commonly seen in elderly men with prostatic enlargement, which obstructs bladder outflow.

In patients with severe stroke disease or dementia, treatment may be ineffective, as frontal cortical inhibitory signals to bladder emptying are lost. A timed/prompted toileting programme may help. Other than in overflow incontinence, urinary catheterisation should never be viewed as first-line management, but may be required as a final resort if the perineal skin is at risk of breakdown or quality of life is affected.

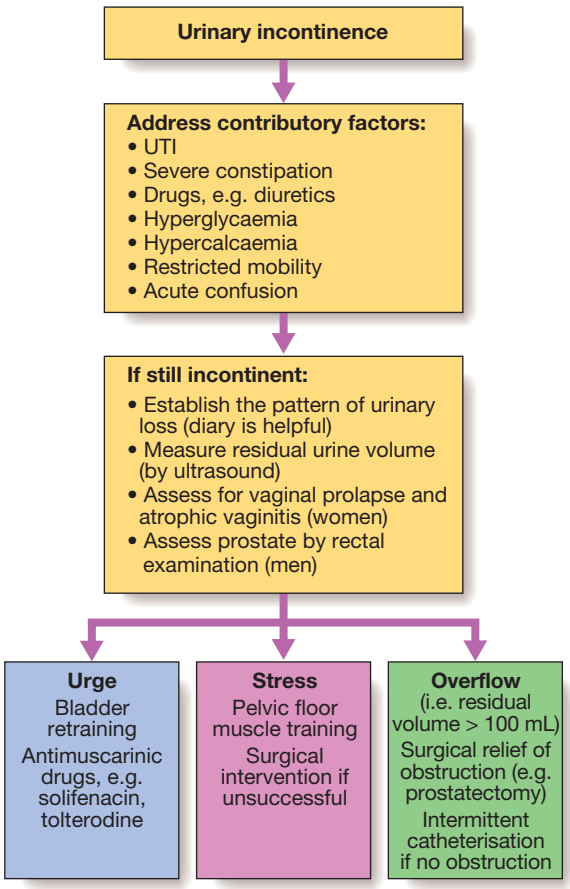

Fig. 7.4 Assessment and management of urinary incontinence in old age. See also page 472 and NICE guideline on the Management of Incontinence in Women: www.nice.org.uk. (UTI = urinary tract infection)

Adverse drug reactions

Adverse drug reactions (ADRs) and the effects of drug interactions are discussed on pages 24–28. They may result in symptoms, abnormal physical signs and altered laboratory test results (Box 7.10). ADRs are the cause of around 5% of all hospital admissions but account for up to 20% of admissions in those aged over 65. This is partly because older people receive many more prescribed drugs than younger people. Polypharmacy has been defined as the use of four or more drugs; this should be avoided if possible, but is not always inappropriate because many conditions, such as hypertension and heart failure, necessitate the use of several drugs, and older people may have several coexisting medical problems (Box 7.11). However, the more drugs that are taken, the greater the risk of an ADR. This risk is compounded by age-related changes in pharmacodynamic and pharmacokinetic factors (pp. 18–21), and by impaired homeostatic mechanisms, such as baroreceptor responses, plasma volume and electrolyte control. Older people are thus especially sensitive to drugs that can cause postural hypotension or volume depletion (see Box 7.10). Non-adherence to drug therapy also rises with the number of drugs prescribed.

The clinical presentations of ADRs are diverse, so for *any* presenting problem in old age the possibility that the patient's medication is a contributory factor should *always* be considered. Failure to recognise this may lead to the use of a further drug to treat the problem, making matters worse, when the better course would be to stop or reduce the dose of the offending drug or to find an alternative.

7.10 Common adverse drug reactions in old age

Drug class	Adverse reaction
NSAIDs	Gastrointestinal bleeding and peptic ulceration Renal impairment
Diuretics	Renal impairment, electrolyte disturbance Gout Hypotension, postural hypotension
Warfarin	Bleeding
ACE inhibitors	Renal impairment, electrolyte disturbance Hypotension, postural hypotension
β-blockers	Bradycardia, heart block Hypotension, postural hypotension
Opiates	Constipation, vomiting Delirium Urinary retention
Antidepressants	Delirium Hyponatraemia (SSRIs) Hypotension, postural hypotension Falls
Benzodiazepines	Delirium Falls
Anticholinergics	Delirium Urinary retention Constipation

(ACE = angiotensin-converting enzyme; NSAID = non-steroidal anti-inflammatory drug; SSRI = selective serotonin re-uptake inhibitor)

7.11 Factors leading to polypharmacy in old age

- Multiple pathology
- Poor patient education (see Box 2.20, p. 35)
- Lack of routine review of all medications
- Patient expectations of prescribing
- Over-use of drug interventions by doctors
- Attendance at multiple specialist clinics
- Poor communication between specialists

Regular review of medications is important in preventing ADRs. The patient or carer should be asked to bring all medication for review rather than the doctor relying on previous records. Those drugs that are no longer needed or are contraindicated can be discontinued.

Other problems in old age

There is a vast range of other presenting problems in older people and they present to many medical specialties. End-of-life care is an important facet of clinical practice in old age and is discussed on page 290. Relevant sections in other chapters are referenced in Box 7.12.

Within each chapter, 'In Old Age' boxes highlight the areas in which presentation or management differs from that in younger individuals. These are listed on page 178.

7.12 Other presenting problems in old age

• Hypothermia	p. 104
• Under-nutrition	p. 120
• Dementia	p. 250
• Infection	pp. 296 and 306
• Fluid balance problems	p. 439
• Heart failure	p. 546
• Hypertension	p. 606
• Dizziness and blackouts	pp. 554 and 1157
• Atrial fibrillation	p. 564
• Diabetes mellitus	p. 806
• Peptic ulceration	p. 872
• Anaemia	p. 1001
• Painful joints	p. 1069
• Bone disease and fracture	pp. 1120 and 1071
• Stroke	p. 1231

REHABILITATION

Rehabilitation aims to improve the ability of people of all ages to perform day-to-day activities, and to restore their physical, mental and social capabilities as far as possible. Acute illness in older people is often associated with loss of their usual ability to walk or care for themselves, and common disabling conditions such as stroke, fractured neck of femur, arthritis and cardiorespiratory disease become increasingly prevalent with advancing age.

Disability is an interaction between factors intrinsic to the individual and the context in which they live, and both medical and social interventions are needed to address this (Box 7.13). Doctors tend to focus on health conditions and impairments, but patients are more concerned with the effect on their activities and ability to participate in everyday life.

7.13 International classification of functioning and disability

Factor	Intervention required
Health condition Underlying disease, e.g. stroke, osteoarthritis	Medical or surgical treatment
Impairment Symptoms or signs of the condition, e.g. hemiparesis, visual loss	Medical or surgical treatment
Activity limitation Resultant loss of function, e.g. walking, dressing	Rehabilitation, assistance, aids
Participation restriction Resultant loss of social function, e.g. cooking, shopping	Adapted accommodation Social services

7.14 How to assess rehabilitation needs using the Modified Barthel Index (20-point version)

Mobility
Independent = 3 Needs help = 2 Wheelchair independent = 1 Immobile = 0
Stairs
Independent = 2 Needs help = 1 Unable = 0
Transfers (e.g. from bed to chair)
Independent = 3 Needs minor help = 2 Needs major help = 1 Unable = 0
Bladder
Continent = 2 Occasional incontinence = 1 Incontinent = 0
Bowels
Continent = 2 Occasional incontinence = 1 Incontinent = 0
Grooming
Independent = 1 Needs help = 0
Toilet use
Independent = 2 Needs help = 1 Unable = 0
Feeding
Independent = 2 Needs help = 1 Unable = 0
Dressing
Independent = 2 Needs some help = 1 Completely dependent = 0
Bathing
Independent = 1 Needs help = 0

The total score reflects the degree of dependency; scores of 14 and above are usually consistent with living in the community; scores below 10 suggest the patient is heavily dependent on carers.

The rehabilitation process

Rehabilitation is a problem-solving process focused on improving the patient's physical, psychological and social function. It entails:

- *Assessment.* The nature and extent of the patient's problems can be identified using the framework in Box 7.13. Specific assessment scales, such as the Elderly Mobility Scale or Barthel Index of Activities of Daily Living (Box 7.14), are useful to quantify components of disability, but additional assessment is needed to determine the underlying causes or the interventions required in individual patients.
- *Goal-setting.* Goals should be specific to the patient's problems, realistic, and agreed between the patient and the rehabilitation team.
- *Intervention.* This includes the active treatments needed to achieve the established goals and to maintain the patient's health and quality of life. Interventions include hands-on treatment by therapists using a functional, task-orientated approach to improve day-to-day activities, and also psychological support and education. The emphasis on the type of intervention will be individualised, according to the patient's disabilities, psychological status and progress. The patient and carer(s) must be active participants.
- *Re-assessment.* There is ongoing re-evaluation of the patient's function and progress towards the goals by the rehabilitation team, the patient and the carer. Interventions may be modified as a result.

Multidisciplinary team working

The core rehabilitation team includes all members of the multidisciplinary team (p. 167). Others may be involved, e.g. audiometry to correct hearing impairment, podiatry for foot problems, and orthotics where a prosthesis or splinting is required. Good communication and mutual respect are essential. Regular team meetings allow sharing of assessments, agreement of rehabilitation goals and interventions, evaluation of progress and planning for the patient's discharge home. Rehabilitation is *not* when the doctor orders 'physio' or 'a home visit', and takes no further role.

Rehabilitation outcomes

There is evidence that rehabilitation improves functional outcomes in older people following acute illness, stroke and hip fracture. It also reduces mortality after stroke and hip fracture. These benefits accrue from complex multi-component interventions, but occupational therapy to improve personal ADLs and individualised exercise interventions have now been shown to be effective in improving functional outcome in their own right.

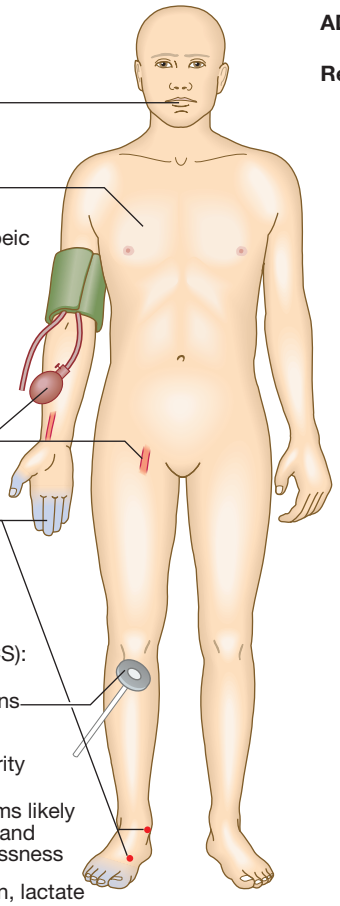
CLINICAL EXAMINATION OF THE CRITICALLY ILL PATIENT

2 Referral

FIRST RESPONDER

1 Initial assessment and resuscitation

A Airway clear
No: head tilt, chin lift
Yes: take presenting history



B Breathing
Distressed? Yes: oxygen
Respiratory rate: oxygen if tachypnoeic
Auscultation: nebulised salbutamol if wheeze
Monitor SpO_2
Obtain arterial blood gases and chest X-ray

C Circulation
Pulse rate, rhythm and volume
Blood pressure
ECG monitor
Check peripheral perfusion
Establish IV access and ?give fluid
Obtain immediate bloods* and 12-lead ECG

D Disability
Establish Glasgow Coma Score (GCS): if reduced, exclude hypoglycaemia
Check pupils and limbs for focal signs

E Evidence
Look for information to assess severity and establish diagnosis
Examination: target initially to systems likely to give most information, e.g. chest and heart if presentation is with breathlessness

*ABG, potassium, glucose, haemoglobin, lactate

ADVANCED RESPONDER/INTENSIVIST

Re-assessment and further management 3

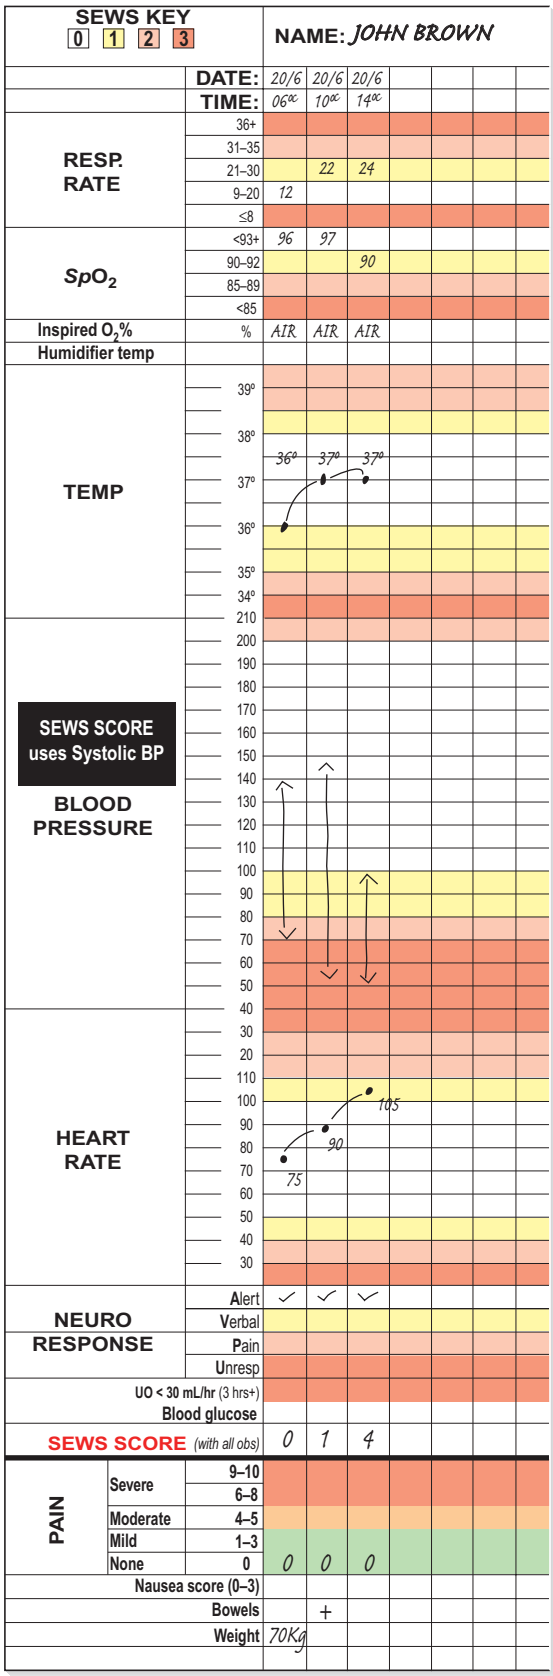
A Airway compromised
Consider intubation and ventilation
Give more oxygen

B Breathing
Oxygenation failure: give more oxygen; continuous positive airways pressure (CPAP)
Respiratory failure: non-invasive ventilation (NIV); intubation and ventilation

C Shock
Large-bore IV access
Volume resuscitation
Arterial line insertion
Central line insertion
Monitoring
Vasoactive drugs

D Reduced GCS
A + B + C and
Is CT scan required?

E Extricate
To ICU or HDU as appropriate
Plan safe transport



F Further investigations and full examination
FBC, acute biochemistry, coagulation, cultures, targeted specialist investigations

RECOGNISING THE CRITICALLY ILL PATIENT

Respiratory signs
- Respiratory arrest
- Threatened or obstructed airway
- Stridor, intercostal recession, paradoxical breathing (seesaw pattern)
- Respiratory rate < 8 or > 35/min
- Respiratory distress: use of accessory muscles; unable to speak in complete sentences
- SpO_2 < 90% on high-concentration oxygen
- Rising $PaCO_2$ > 7 kPa (52.5 mmHg) or > 2 kPa (> 15 mmHg) above 'normal' with acidosis

Cardiovascular signs
- Cardiac arrest
- Pulse rate < 40 or > 140 bpm
- Systolic blood pressure < 100 mmHg
- Poor peripheral perfusion
- Evidence of inadequate oxygen delivery
  Metabolic acidosis
  Hyperlactataemia
- Poor response to volume resuscitation
- Oliguria < 0.5 mL/kg/hr (check urea, creatinine, K^+)

Neurological signs
- Threatened or obstructed airway
- Absent gag or cough reflex
- Failure to maintain normal PaO_2 and $PaCO_2$
- Failure to obey commands
- GCS < 10
- Sudden fall in level of consciousness (GCS by > 2 points)
- Repeated or prolonged seizures

Standard Early Warning System (SEWS) chart. (UO = urine output)

Recognition of critical illness: early warning scores

- Record standard observations:
  - Respiratory rate
  - SpO_2
  - Temperature
  - Blood pressure (BP)
  - Heart rate
  - Neurological response
- Note whether the observation falls in a shaded 'at-risk zone' (see SEWS key)
- Add the points scored and record total SEWS score on chart
- Do not add 'Pain' score to SEWS score

If SEWS score ≥ 4, a doctor should assess the patient within 20 mins.

If SEWS score ≥ 6, a senior doctor should assess the patient within 10 mins.

Clinical features of shock

Low-flow shock, e.g. hypovolaemia, cardiogenic shock

- Rapid, shallow respiration
- Cold, clammy skin
- Tachycardia (> 100/min)
- Hypotension (systolic BP < 100 mmHg)
- Drowsiness, confusion, irritability (usually occurs late)
- Oliguria
- Multi-organ failure

Vasodilated shock, e.g. sepsis, anaphylaxis

- Rapid, shallow respiration (very early)
- Warm peripheries*
- Tachycardia (> 100/min)
- Hypotension (systolic BP < 100 mmHg and disproportionately low diastolic BP – early)
- Drowsiness, confusion, irritability (can occur early)
- Oliguria
- Multi-organ failure

*Peripheries may be cool in sepsis with hypovolaemia, or if myocardial depression is present.

A critically ill patient is at imminent risk of death. Recognition, assessment and management of critical illness are thus fundamental to clinical care in any area of medicine. The principle underpinning intensive care is the simultaneous assessment of illness severity and stabilisation of life-threatening physiological abnormalities. The goal is to prevent deterioration and effect improvements as the diagnosis is established, and treatment of the underlying definitive disease process(es) is initiated. Blinkered attention to either resuscitation or diagnosis in isolation results in worse outcomes and increased mortality; the two processes are inextricably interlinked. Appropriate physiological monitoring is required to allow continuing assessment and re-assessment of response to therapy, wherever the clinical environment.

PHYSIOLOGY OF CRITICAL ILLNESS

Oxygen transport

The principal function of the heart, lungs and circulation is the provision of oxygen (and other nutrients) to the various organs and tissues of the body. During this process, carbon dioxide and other metabolic waste products are removed. The rate of supply and removal should match the specific metabolic requirements of the individual tissues. This requires adequate oxygen uptake in the lungs, global matching of delivery and consumption, and regional control of the circulation. Failure to supply sufficient oxygen to meet the metabolic requirements of the tissues is the cardinal feature of circulatory failure or 'shock', and optimisation of tissue oxygen delivery and consumption is the goal of resuscitation.

Atmospheric oxygen moves down a partial pressure gradient from air, through the respiratory tract, from alveoli to arterial blood and then to the capillary beds and cells, diffusing into the mitochondria, where it is utilised at cytochrome a_3 (Fig. 8.1). The movement of oxygen from the left ventricle to the systemic tissue capillaries is known as oxygen delivery (DO_2), and is the product of cardiac output (flow) × arterial oxygen content (CaO_2) The latter is the product of haemoglobin (Hb) × arterial oxygen saturation of haemoglobin (SaO_2) × 1.34. By increasing cardiac output, arterial oxygen saturation or haemoglobin concentration, DO_2 will be increased.

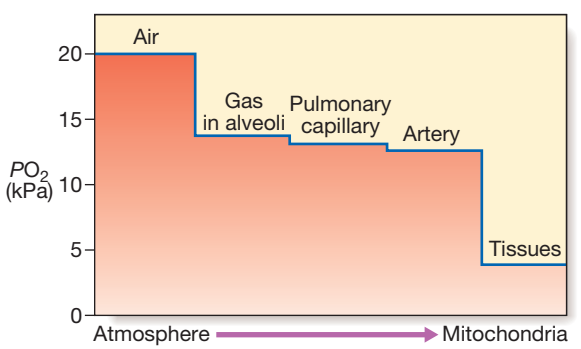


Fig. 8.1 The oxygen cascade in the transport of oxygen from inspired gas to the cell. Gas containing oxygen is entrained into the lungs by inspiratory flow. The partial pressure of O_2 falls as it moves from lungs to blood and then to the tissues. The partial pressure gradient between capillary blood and the intracellular environment is pivotal to oxygen reaching the mitochondria. (PO_2 = oxygen partial pressure (kPa) 1 kPa = 7.5 mmHg).

The regional distribution of oxygen delivery is important. If skin and muscle receive high blood flows but the splanchnic bed does not, the gut will become hypoxic even if overall DO_2 is high.

The movement of oxygen from tissue capillary to cell occurs by diffusion and depends on the gradient of oxygen partial pressures, diffusion distance and the ability of the target cell to take up and use oxygen. Microcirculatory, tissue diffusion and cellular factors thus also influence the oxygen status of the cell.

Cardiovascular component of oxygen delivery: flow

A key determinant of DO_2 is cardiac output, which is determined by the ventricular 'preload' and 'afterload', myocardial contractility and heart rate.

Preload

The atrial filling pressures, or preload, determine the end-diastolic ventricular volume, which, according to Starling's Law and depending on myocardial contractility, defines the force of cardiac contraction and the stroke volume (see Fig. 18.22, p. 547). The principal determinant of preload is venous return, determined by the intravascular volume, venous 'tone' and intrathoracic pressure. This can be measured as the central venous pressure (CVP), as described on page 185 (Box 8.1).

When volume is lost (e.g. in major haemorrhage), venous 'tone' increases and this helps to offset the consequent fall in atrial filling pressure and stroke volume. If the equivalent volume is restored gradually by intravenous fluid administration, the right atrial pressure will return to normal as the intravascular volume is normalised and the reflex increase in venous tone abates. However, if fluid is infused too rapidly, there is insufficient time for the venous and arteriolar tone to fall and pulmonary oedema may occur, even though the intravascular volume has only been restored to the premorbid level.

If the preload is low, volume loading with intravenous fluids is the priority and is the most appropriate means of improving cardiac output and tissue perfusion. The choice of fluid for volume loading is controversial, but as there is no clear advantage of colloid over crystalloid, sodium chloride is used. Fluid challenges of 200–250 mL should be administered rapidly over a couple of minutes, and titrated against heart rate, blood pressure (BP), peripheral circulation, and measurements of CVP (Fig. 8.2). Red cells have traditionally been transfused to

8.1 Central venous pressure measurements

• Normal	0–5 mmHg
• Target (usual) of volume resuscitation	6–10 mmHg
• Normal if ventilated	5–10 mmHg
• Target of volume resuscitation if ventilated	10–15 mmHg

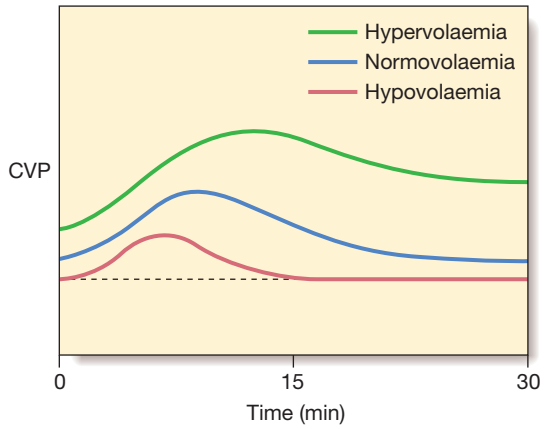

Fig. 8.2 Responses observed in central venous pressure (CVP) after a fluid challenge of 250 mL, depending on the intravascular volume status of the patient.

achieve and maintain a haemoglobin concentration of 100 g/L, but in the absence of significant heart disease, the target is 70–90 g/L (p. 184).

When the preload is high due to excessive intravascular volume or impaired myocardial contractility, removing volume from the circulation by using diuretics or haemofiltration, or increasing the capacity of the vascular bed by using venodilator therapy (glyceryl trinitrate, morphine) often improves stroke volume.

Afterload

Afterload is the tension in the ventricular myocardium during systole, and is determined by the resistance to ventricular outflow, which is a function of the peripheral arteriolar resistance.

Understanding the reciprocal relationship between pressure, flow and resistance is crucial for appropriate circulatory management. High resistances produce lower flows at higher pressures for a given amount of ventricular work. Therefore, a systemic vasodilator (see below) will allow the same cardiac output to be maintained for less ventricular work but with a reduced arterial BP. In hyperdynamic sepsis, the peripheral arteriolar tone and BP are low but the cardiac output is often high; therefore the vasoconstrictor noradrenaline (norepinephrine) is appropriate to restore BP, usually at the price of some reduction in cardiac output.

Myocardial contractility

This determines the stroke volume that the ventricle can generate against a given afterload for a particular preload. The ventricular stroke work is the external work performed by the ventricle with each beat. The relationship between stroke work and filling pressure is shown in Figure 18.22 (p. 547). Myocardial contractility is frequently reduced in critically ill patients due to pre-existing cardiac disease (usually ischaemic), drugs (e.g. β-blockers, verapamil) or to the disease process itself (particularly sepsis, as the associated low diastolic BP may compromise coronary arterial perfusion). It is thus important to maintain satisfactory perfusion and oxygen delivery to all organs at maximum cardiac efficiency, to minimise myocardial ischaemia.

Oxygenation component of oxygen delivery: content

The major determinants of the oxygen content of arterial blood (CaO_2) are the arterial oxygen saturation of haemoglobin (SaO_2) and the haemoglobin concentration. Over 95% of oxygen carried in the blood is bound to haemoglobin.

The oxyhaemoglobin dissociation curve (Fig. 8.3) describes the relationship between the saturation of haemoglobin (SO_2) and the partial pressure (PO_2) of oxygen in the blood. A shift in the curve will influence the uptake and release of oxygen by the haemoglobin molecule. If the curve moves to the right, the haemoglobin saturation will be lower for any given oxygen tension: less oxygen will be taken up in the lungs but more will be released to the tissues. As capillary PCO_2 rises, the curve moves to the right, increasing the unloading of oxygen in the tissues – a phenomenon known as the Bohr effect. Thus a shift to the right increases capillary PO_2 and hence cellular oxygen supply.

Due to the shape of the curve, a small drop in arterial PO_2 (PaO_2) below 8 kPa (60 mmHg) will cause a marked fall in SaO_2. Its position and the effect of various physicochemical factors are defined by the PO_2 at which 50% of the haemoglobin is saturated (P_{50}), which is normally 3.5 kPa (26 mmHg). The shape of the curve also means that increases in PaO_2 beyond the level that ensures SaO_2 is greater than 90% produce relatively small additional increases in CaO_2 (Fig. 8.3). Thus, in a patient who is both anaemic (Hb 60 g/L or 6 g/dL) and hypoxaemic (SaO_2 75%) when breathing air (fractional inspired oxygen concentration (FiO_2) 20%), supplementary oxygen at FiO_2 40% will increase SaO_2 to 93% and CaO_2 by 24%. However, further increases in FiO_2, while raising PaO_2, cannot produce any further useful increases in SaO_2 or CaO_2. However, increasing haemoglobin to 90 g/L

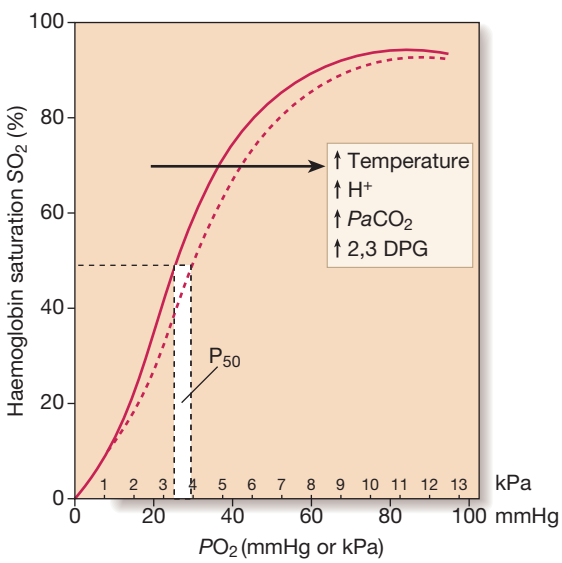

Fig. 8.3 Oxyhaemoglobin dissociation curve: the relationship between oxygen tension (PO_2) and percentage saturation of haemoglobin with oxygen (SO_2). The dotted line illustrates the rightward shift of the curve (i.e. P_{50} increases) caused by increases in temperature, $PaCO_2$, metabolic acidosis and 2,3 diphosphoglycerate (DPG).

(9 g/dL) by blood transfusion will result in a further 50% increase in CaO_2.

Traditionally, the optimum haemoglobin concentration for critically ill patients was considered to be approximately 100 g/L (10 g/dL), representing a balance between maximising the oxygen content of the blood and avoiding regional microcirculatory problems due to increased viscosity. However, improved outcomes have been demonstrated when the haemoglobin is maintained between 70 and 90 g/L (7–9 g/dL). A target haemoglobin of 100 g/L remains appropriate in the elderly and in patients with coronary artery disease, cardiogenic shock, significant aortic stenosis or acute brain trauma.

Oxygen consumption

The sum of the oxygen consumed by the various organs represents the global oxygen consumption (VO_2), and is approximately 250 mL/min for an adult of 70 kg undertaking normal daily activities.

The oxygen saturation in the pulmonary artery, or 'mixed venous oxygen saturation' (SvO_2), is a measure of the oxygen not consumed by the tissues ($DO_2 - VO_2$). The saturation of venous blood from different organs varies considerably; the hepatic venous saturation usually does not exceed 60% but the renal venous saturation may reach 90%, reflecting the difference in the metabolic requirements of these organs, and the oxygen content of the blood delivered to them. The SvO_2 is a flow-weighted average measured in the mixed effluent blood from all perfused tissues, and is influenced by changes in both oxygen delivery (DO_2) and consumption (VO_2). Provided the microcirculation and the mechanisms for cellular oxygen uptake are intact, it can be used to monitor whether global oxygen delivery is adequate to meet overall demand, so its measurement is particularly useful in low-flow situations such as cardiogenic shock. Central venous oxygen saturation ($ScvO_2$) is used in the same way, but as it does not reflect hepatosplanchnic oxygen consumption, it may be less helpful than SvO_2.

The re-oxygenation of the blood that returns to the lungs and the resulting arterial saturation (SaO_2) will depend on how closely pulmonary ventilation and perfusion are matched. If part of the pulmonary blood flow perfuses non-ventilated parts of the lung ('shunting'), the blood entering the left atrium will be desaturated in proportion to the size of the shunt and the level of SvO_2.

Relationship between oxygen consumption and delivery

The tissue oxygen extraction ratio (OER) is 20–25% in a normal individual at rest, but rises as consumption increases or supply diminishes. The maximum OER is approximately 60% for most tissues; at this point, no further increase in extraction can occur and any further increase in oxygen consumption or decline in oxygen delivery will cause tissue hypoxia, anaerobic metabolism and increased lactic acid production. This ultimately results in multiple organ failure and an increased risk of death.

In practice, if there is a metabolic acidosis, hyperlactataemia and/or oliguria that could be due to inadequate oxygen delivery, a therapeutic trial of increased oxygen delivery (while maintaining an adequate BP) may be helpful clinically. If oxygen consumption rises, it can indicate an oxygen debt that is being repaid.

Pathophysiology of the inflammatory response

The mediators and clinical manifestations of the inflammatory response are described on page 82. In critically ill patients, these have important consequences (Box 8.2).

Fever, tachycardia with warm peripheries, tachypnoea and a raised white cell count prompt a diagnosis of sepsis, with the presentation caused by invading microorganisms and their breakdown products. Other conditions, such as pancreatitis, trauma, malignancy, tissue necrosis (e.g. burns), aspiration syndromes, liver failure, blood transfusion and drug reactions, can also present in this way in the absence of infection.

Local inflammation

The body's initial response to a noxious local insult is to produce a local inflammatory response, with sequestration and activation of white blood cells and the release of a

8.2 Terminology in the inflammatory state

Infection
- Invasion of normally sterile tissue by microorganisms

Bacteraemia
- Viable bacteria in the blood

Systemic inflammatory response syndrome (SIRS)
- Defined by the presence of two or more of
  - Respiratory rate > 20/min
  - Heart rate > 90/min
  - White blood count > 12×10^9/L or < 4×10^9/L
  - Temperature > 38.0°C or < 36.0°C
  - $PaCO_2$ < 4.3 kPa (< 32 mmHg) or ventilated
- A wide pulse pressure, e.g. 115/42 mmHg, may be an early pointer to systemic sepsis
- Cause may be infection or a non-infective condition, e.g. pancreatitis, trauma, cardiopulmonary bypass, vasculitis etc.
- Hypothermia and septic neutropenia indicate more severe infection

Sepsis
- Systemic inflammatory response caused by documented infection

Severe sepsis/SIRS
- Sepsis/SIRS with evidence of early organ dysfunction *or* hypotension

Septic/SIRS shock
- Sepsis associated with organ failure *and* hypotension (systolic BP < 90 mmHg or > 40 mmHg fall from baseline) unresponsive to fluid resuscitation

Multiple organ dysfunction syndrome (MODS)
- Development of impaired organ function in a patient with SIRS
- Multiple organ failure (MOF) ensues unless there is prompt treatment of the underlying cause and appropriate organ support

variety of mediators to overcome the primary 'insult' and prevent further damage locally or in distant organs.

Normally, a delicate balance is achieved between pro- and anti-inflammatory mediators. However, if the response is excessive, a large array of pro-inflammatory mediators may be released into the circulation (p. 74). The inflammatory and coagulation cascades are intimately linked, as the latter cause not only platelet activation and fibrin deposition, but also activation of leucocytes and endothelial cells. Conversely, leucocyte activation induces tissue factor expression and initiates coagulation pathways. The natural anticoagulants, antithrombin (AT III), activated protein C (APC) and tissue factor pathway inhibitor (TFPI), inhibit pro-inflammatory cytokines. Deficiency of AT III and APC (features of disseminated intravascular coagulation (DIC), p. 1056) facilitates thrombin generation and promotes further endothelial cell dysfunction.

Systemic inflammation

In a severe inflammatory response, systemic release of cytokines and other mediators triggers widespread interaction between the coagulation pathways, platelets, endothelial cells and monocytes, tissue macrophages, and neutrophils. Activated neutrophils express adhesion factors, which make them adhere to and initially roll along the endothelium, before adhering firmly and migrating through the damaged and disrupted endothelium into the extravascular interstitial space (together with fluid and proteins), resulting in tissue oedema and inflammation. A vicious circle of endothelial injury, intravascular coagulation, microvascular occlusion, tissue damage and further release of inflammatory mediators ensues. This can occur in all organs, manifesting in the lungs as acute lung injury and in the kidneys as acute tubular necrosis (ATN). Similar processes probably account for damage to other organs, including the heart.

The endothelium itself produces mediators that control local blood vessel tone. The profound vasodilatation that characterises septic shock and some other acute systemic inflammatory states, such as pancreatitis, results from excessive production of nitric oxide (NO, p. 82), due to activation of inducible NO synthase enzymes.

Systemic inflammatory processes also have important effects on mitochondrial function, resulting in impaired oxidative phosphorylation and aerobic energy generation. This block to oxygen utilisation by cells is sometimes called cytopathic hypoxia. Patients typically have a reduced arteriovenous oxygen difference, a low oxygen extraction ratio, a raised plasma lactate and a paradoxically high mixed venous oxygen saturation (SvO_2), despite normal or supranormal oxygen delivery. This is associated with the development of multiple organ failure (MOF) and reduced survival.

MONITORING

Monitoring in intensive care includes a combination of clinical and automated recordings. Electrocardiogram (ECG), SpO_2 (oxygen saturation), BP and usually CVP recordings are taken at least hourly, using either a 24-hour chart or a computerised system. Urine output measurement requires early catheterisation. All invasive haemodynamic monitoring should be referenced to the mid-axillary line as 'zero'. Clinical monitoring of physical signs, such as respiratory rate, the appearance of the patient, restlessness, conscious level and indices of peripheral perfusion (pale, cold skin; delayed capillary refill in the nailbed), is just as important as a set of blood gases or monitor readings.

Monitoring the circulation

Electrocardiogram

Standard monitors display a single-lead ECG, record heart rate and identify rhythm changes. More sophisticated machines can print out rhythm strips and monitor ST segment shift, which is useful in patients with ischaemic heart disease.

Blood pressure

In critically ill patients, continuous intra-arterial monitoring is necessary using a line placed in the radial artery (or the femoral in vasoconstricted patients or where access is difficult). The brachial artery should be avoided, as it is an end artery of relatively small calibre and occlusion leads to ischaemia of the hand. When there is systemic vasoconstriction, the mean arterial pressure (MAP) may be normal or even high, although the cardiac output is low. Conversely, if there is peripheral vasodilatation, as in sepsis, the MAP may be low, although the cardiac output is high.

Central venous pressure

CVP or right atrial pressure (RAP) is monitored using a catheter inserted via either the internal jugular or the subclavian vein, with the distal end sited in the upper right atrium. The CVP may help in assessing the need for intravascular fluid replacement and the rate at which this should be given (see Box 8.1, p. 182). If the CVP is low in the presence of a low MAP or cardiac output, fluid resuscitation is necessary. However, a raised level does not necessarily mean that the patient is adequately volume-resuscitated. Right heart function, pulmonary artery pressure, intrathoracic pressure and venous 'tone' also influence CVP, and may lead to a raised CVP even when the patient is hypovolaemic (Box 8.3). In addition, positive pressure ventilation raises intrathoracic pressure and causes marked swings in atrial pressures and systemic BP in time with respiration. Pressure measurements should be recorded at end-expiration.

In severe hypovolaemia, the RAP may be sustained by peripheral venoconstriction, and transfusion may initially produce little or no change in the CVP (see Fig. 8.3, p. 183).

Pulmonary artery catheterisation and pulmonary artery 'wedge' pressure

The CVP is usually an adequate guide to the filling pressures of both sides of the heart. However, certain conditions, such as pulmonary hypertension or right ventricular dysfunction, may lead to raised CVP levels even in the presence of hypovolaemia. In these circumstances, it may be appropriate to insert a pulmonary artery flotation catheter (Fig. 8.4) so that pulmonary artery pressure and pulmonary artery 'wedge' pressure

8.3 Factors affecting central venous pressure

Physiological

- Cardiac function
- Blood volume
- Venoconstriction
- Intrathoracic pressure

Pathological

All increase CVP:

- Superior vena cava occlusion
- Chronic obstructive pulmonary disease (COPD)/ cor pulmonale
- Pulmonary embolism
- Cardiac tamponade

Interventions

Increase CVP:

- Positive pressure ventilation and positive end-expiratory pressure (PEEP)
- Fluid resuscitation
- Vasopressors

Reduce CVP:

- Venodilators

Artefacts caused by technical problems

- Line malpositioning: tip in right ventricle, internal jugular line in axillary vein, or subclavian line in internal jugular vein
- Transducer not in alignment with phlebostatic axis (mid-axillary line)
- Inaccurate calibration of transducer system
- Infusion attached to monitoring line
- Clot/occlusion in line

(PAWP), which approximates to left atrial pressure, can be measured.

The mean PAWP normally lies between 6 and 12 mmHg (measured from the mid-axillary line) but in left heart failure it may be grossly elevated, exceeding 30 mmHg. Provided the pulmonary capillary membranes are intact, the optimum PAWP when managing acute circulatory failure in the critically ill patient is generally 12–15 mmHg, because this will ensure good left ventricular filling without risking hydrostatic pulmonary oedema.

Pulmonary artery catheters also allow measurement of cardiac output and sampling of blood from the pulmonary artery ('mixed venous' samples), permitting continuous monitoring of the mixed venous oxygen saturation ($S\bar{v}O_2$) by oximetry. Measurement of $S\bar{v}O_2$ gives an indication of the adequacy of cardiac output (and hence DO_2) in relation to the body's metabolic requirements. It is especially useful in low cardiac output states.

Cardiac output

Measurement of cardiac output is important, particularly when large doses of a vasopressor are being administered, when there is underlying cardiac disease (acute or chronic), and when volume resuscitation and vasoactive drug therapy are not achieving resolution of lactic acidosis or oliguria. It is most accurately measured by indicator dilution methods. Most PA catheters incorporate a heating element, which raises blood temperature at frequent intervals, and the resultant temperature change is detected by a thermistor at the tip of the catheter.

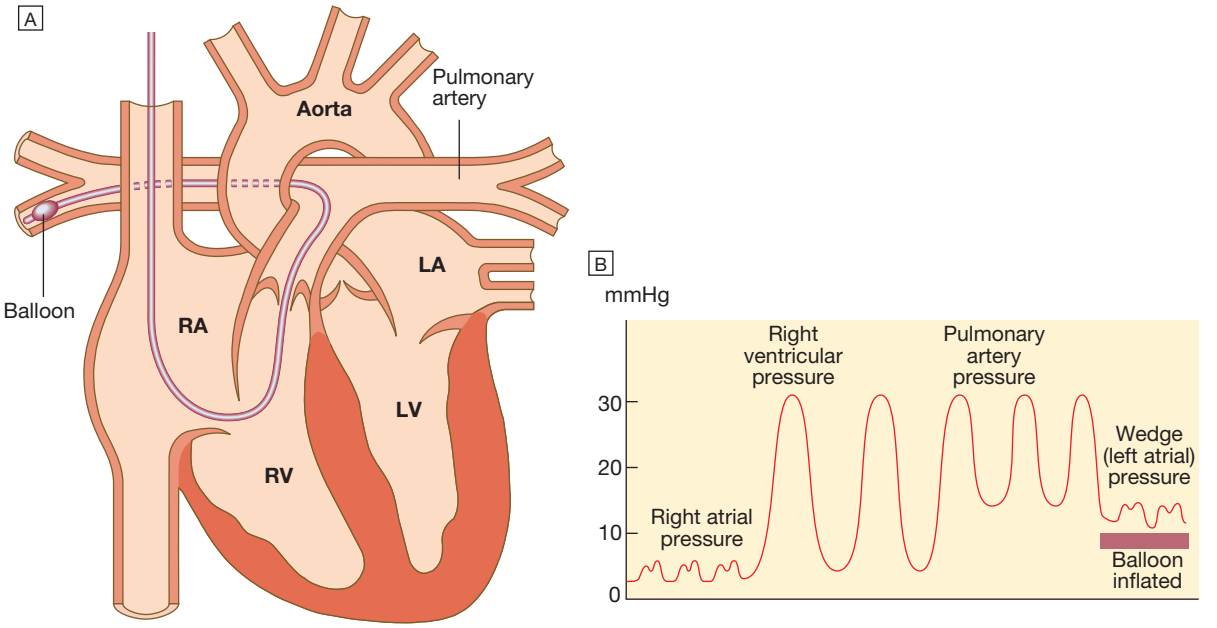

Fig. 8.4 A pulmonary artery catheter. A There is a small balloon at the tip of the catheter and pressure can be measured through the central lumen. The catheter is inserted via an internal jugular, subclavian or femoral vein and advanced through the right heart until the tip lies in the pulmonary artery. When the balloon is deflated, the pulmonary artery pressure can be recorded. B Advancing the catheter with the balloon inflated will 'wedge' the catheter in the pulmonary artery. Blood cannot then flow past the balloon, so the tip of the catheter will now record the pressure transmitted from the pulmonary veins and left atrium (known as the pulmonary artery wedge pressure), which provides an indirect measure of the left atrial pressure. (LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle).

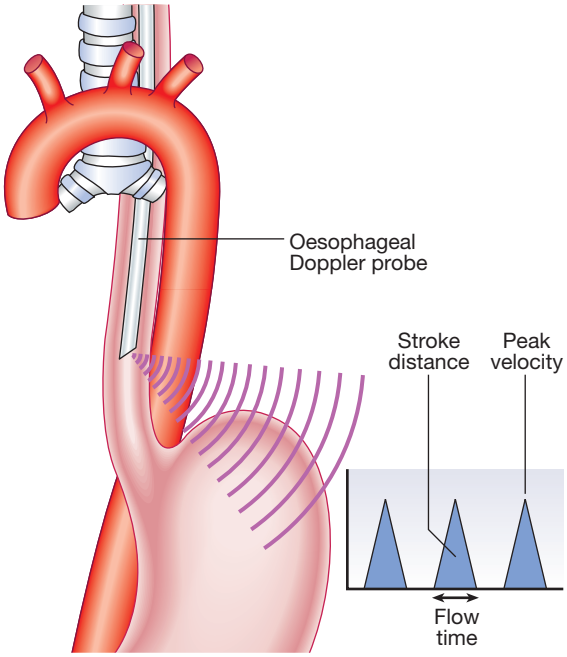

Fig. 8.5 Oesophageal Doppler ultrasonography.

Oesophageal Doppler ultrasonography provides a rapid and useful assessment of volume status and cardiac performance to guide early fluid and vasoactive therapy. A 6 mm probe is inserted into the distal oesophagus, allowing continuous monitoring of the aortic flow signal from the descending aorta (Fig. 8.5). Using the stroke distance (area under the velocity/time waveform) and a correction factor that incorporates the patient's age, height and weight, an estimate of left ventricular stroke volume and hence cardiac output can be made. Peak velocity is an indicator of left ventricular performance, while flow time is an indicator of left ventricular filling and peripheral resistance.

Analysis of arterial pressure waveform is another means of continuously estimating cardiac output, and can be calibrated either by transpulmonary thermodilution (PiCCO) or lithium dilution methods (LidCO). The Vigileo/Flotrac system derives cardiac output from arterial pressure waveform analysis with no external calibration.

Echocardiography

In many centres, echocardiography is increasingly being used for rapid assessment of myocardial function and volume status at the bedside. Continuous transoesophageal echocardiography allows direct assessment of cardiac filling status and ventricular function in real time.

Urine output

This is a sensitive measure of renal perfusion, provided that the kidneys are not damaged (e.g. in ATN) or affected by drugs such as diuretics or dopamine. Output is measured hourly and a lower limit of normal of 0.5 mL/hr/kg body weight is widely used. It reflects renal perfusion over the hours preceding measurement rather than in real time.

Peripheral skin temperature

In general, resuscitation is not complete until the patient's feet are warm and well perfused.

Blood lactate, hydrogen ion and base excess/deficit

Acid–base balance is discussed on page 443. Base excess or deficit is calculated as the difference between the patient's bicarbonate and the normal bicarbonate after the PCO_2 has been maintained in a blood gas machine at 5.33 kPa (40 mmHg). This is particularly useful, as it describes patients' underlying metabolic status independently of their current respiratory status. A metabolic acidosis with base deficit of more than 5 mmol/L requires investigation (p. 445). It often indicates increased lactic acid production in poorly perfused, hypoxic tissues, and impaired lactate metabolism and clearance due to poor hepatic perfusion. Serial lactate measurements may therefore be helpful in monitoring tissue perfusion and response to treatment. Other conditions, such as acute renal failure, ketoacidosis and poisoning, may be the cause, and infusions of large volumes of fluids containing sodium chloride may lead to a hyperchloraemic acidosis.

Monitoring respiratory function

Oxygen saturation

Oxygen saturation (SpO_2) is measured by a probe attached to a finger or earlobe. Spectrophotometric analysis determines the relative proportions of saturated and desaturated haemoglobin. It is unreliable if peripheral perfusion is poor, in the presence of nail polish, excessive movement or high ambient light. It is not useful in carbon monoxide poisoning, as it does not detect carboxy-haemoglobin. If this is suspected, PO_2 must be measured in an arterial blood gas sample. In general, arterial oxygenation is safe if SpO_2 is above 90%. Box 8.4 lists the causes of sudden falls in SpO_2.

Arterial blood gases

Arterial blood gases (ABGs) are measured several times a day in a ventilated patient so that inspired oxygen (FiO_2) and minute volume can be adjusted to achieve the

8.4 Causes of sudden changes in oxygen saturation

Patient factors

- Bronchospasm
- Lung collapse due to thick secretions blocking the proximal bronchial tree
- Pneumothorax
- Impaired peripheral perfusion

Equipment factors

- Displacement of the endotracheal tube (extubation, endobronchial intubation)
- Blockage of the endotracheal tube
- Disconnection from the ventilator
- Oxygen supply failure
- Detached probe

desired PaO_2 and $PaCO_2$ respectively. ABG results are also used to monitor disturbances of acid–base balance.

Lung function

In ventilated patients, lung function is monitored by:

- arterial PO_2 taken in relation to the fractional inspired oxygen concentration (PO_2/FiO_2 ratio) and level of end-expiratory pressure
- arterial and end-tidal CO_2, reflecting alveolar ventilation
- airway pressures and tidal volumes, reflecting lung compliance and airways resistance.

Capnography

The CO_2 concentration in inspired gas is zero, but during expiration, after clearing the physiological dead space, it rises progressively to reach a plateau that represents the alveolar or end-tidal CO_2 concentration. This cyclical change in CO_2 concentration, or capnogram, is measured using an infrared sensor inserted between the ventilator tubing and the endotracheal tube (Fig. 8.6). In normal lungs, the end-tidal CO_2 closely mirrors $PaCO_2$, and can be used to assess the adequacy of alveolar ventilation. However, its use is limited as there may be marked discrepancies in the presence of lung disease or impaired pulmonary perfusion (e.g. due to hypovolaemia). In combination with the gas flow and respiratory cycle data from the ventilator, CO_2 production and hence metabolic rate may be calculated. In clinical practice, end-tidal CO_2 is used to confirm correct placement of an endotracheal tube, in the management of head injury, and during the transport of ventilated patients. Continuous measurement of end-tidal CO_2 is important in the minute-to-minute monitoring of any patient ventilated through an endotracheal tube or tracheostomy in the acute setting.

Transcutaneous PCO_2

Monitors that measure transcutaneous PCO_2 are now available with an earlobe probe that incorporates a pulse oximeter and CO_2 electrode. The transcutaneous PCO_2 closely approximates to $PaCO_2$ and gives continuous monitoring. This is useful in patients with no arterial cannula but who require close monitoring: for example, during ventilatory weaning (see below).

RECOGNITION OF CRITICAL ILLNESS

The immediate appearance of the patient yields a wealth of information. Introducing yourself, shaking hands and asking 'How are you?' allow assessment of:

- the airway (for patency and noises, e.g. stridor, snoring, gurgling, none)
- breathing (rate, symmetry, work of breathing, including accessory muscle use, paradoxical chest/abdominal movement or see-saw pattern)
- peripheral circulation (temperature of the extremities)
- conscious level (the response of the patient).

Tachypnoea is often the earliest abnormality to appear and the most sensitive sign of a worsening clinical state, but it is the least well documented. In the UK, the use of early warning scores, such as the Standard Early Warning System chart (SEWS, p. 181), has been adopted to improve the recognition of critical illness. These alert staff to severely ill patients, complement clinical judgement and facilitate the prioritisation of clinical care. A patient with a SEWS score of 4 or more requires urgent review and appropriate interventions. An elevated score correlates with increased mortality.

Assessment and initial resuscitation of the critically ill patient

Airway and breathing

If the patient is talking, the airway is clear and breathing is adequate. A rapid history should be obtained whilst initial assessment is undertaken.

Assess breathing as described above. Supplemental oxygen should be administered to patients who are breathless, tachypnoeic or bleeding, or who have chest pain or reduced conscious level. The clinical status of the patient determines how much oxygen to give, but the critically ill should receive at least 60% oxygen initially. High-concentration oxygen is best given using a mask with a reservoir bag, which, at 15 L/min, can provide nearly 90% oxygen. ABGs should be checked early to assess oxygenation, ventilation ($PaCO_2$) and metabolic state (pH or H^+, HCO_3 and base deficit). Oxygen therapy should be adjusted in light of the ABGs, remembering

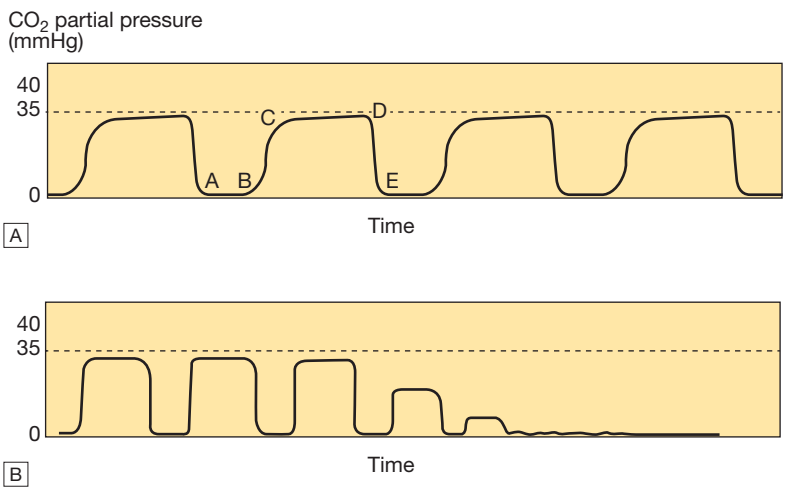

Fig. 8.6 Capnography traces for normal and pathological states. A The normal capnogram represents the varying CO_2 level throughout the breath cycle. A–B = baseline, B–C = expiratory upstroke, C–D = expiratory plateau, D = end-tidal concentration, D–E = inspiration. B Loss of the capnograph can occur with loss of cardiac output, as well as airway displacement. (1 kPa = 7.5 mmHg)

that oxygen requirements may subsequently increase or decrease. Early application of pulse oximeter monitoring is ideal, although this may not be reliable if the patient is peripherally shut down. Intubation, while often essential, may be hazardous in a patient with cardiorespiratory failure, and full monitoring and resuscitation facilities must be available.

Circulation

The carotid pulse should be sought in the collapsed or unconscious patient, but peripheral pulses checked in the conscious. The radial, brachial, foot and femoral pulses may disappear as shock progresses, and this indicates the severity of circulatory compromise.

Venous access for the administration of drugs and/or fluids is vital but often difficult in sick patients. The gauge of cannula needed is dictated by its purpose. Wide-bore cannulae are required for rapid fluid administration. Ideally, two 16G or larger cannulae should be inserted, one in each arm, in the severely hypovolaemic patient. If the two cannulae are of different sizes, the pulse oximeter should be placed on the same side as the larger one, and the BP cuff on the same side as the smaller one. This facilitates unimpeded volume resuscitation and uninterrupted oxygen saturation monitoring. Pressure infusors and blood warmers should be utilised for rapid, high-volume fluid resuscitation, particularly of blood products. An 18G cannula is adequate for drug administration.

Machine-derived cuff BP measurement is inaccurate at extremes of BP and in tachycardia, especially atrial fibrillation. Manual sphygmomanometer BP readings tend to be more accurate in hypotension. If severe hypotension is not readily corrected with fluid, early consideration should be given to arterial line insertion and vasoactive drug therapy.

Disability

Conscious level should be assessed using the Glasgow Coma Scale (GCS; see Box 26.15, p. 1160). Best eye, verbal and motor responses should be assessed and documented. Appropriate painful stimuli include supraorbital pressure and trapezius pinch. A score of 8 or less denotes coma with associated airway compromise and loss of airway protection, which necessitates intervention. Focal neurological signs may indicate unilateral cerebral pathology. Abnormal pupil size, symmetry or reaction to light may indicate primary cerebral disease or global cerebral insults induced by drugs (e.g. opioids), hypoxia or hypoglycaemia.

Exposure, evidence and examination

'Exposure' indicates the need for targeted clinical examination, and 'evidence' may be gathered from any recent investigations, prescription or monitoring charts.

Clinical decision-making and referral to critical care

During the initial assessment and resuscitation, several decisions must be made (Box 8.5), but particularly whether referral to the critical care service is necessary.

8.5 Clinical decisions in the critically ill

- How ill is the patient?
- How much help is needed and how quickly?
- Where would the patient be best managed?
- When should the patient be moved?
  - All critically ill patients require an appropriately trained escort during transfer
- What is required before transporting the patient?
  - ABCDE resuscitation ± endotracheal intubation and ventilation
  - Monitoring, including invasive arterial ± CVP
  - Volume resuscitation and vasoactive support
  - Imaging/diagnostic processes
- Is specialist involvement required?
  - E.g. transfer to specialist liver, burns, neurosurgical or cardiac surgical units or for specialised investigations
  - The urgency of specialist treatment needs balanced against the patient's condition; it may be necessary to stabilise the patient in the ICU first

8.6 Admission criteria for intensive care (ICU) and high-dependency units (HDU)

ICU

- Patients requiring/likely to require endotracheal intubation and invasive mechanical ventilatory support
- Patients requiring support of two or more organ systems (e.g. inotropes and haemofiltration)
- Patients with chronic impairment of one or more organ systems (e.g. COPD *or* severe ischaemic heart disease) who require support for acute reversible failure of another organ

HDU

- Patients requiring detailed observation or monitoring that cannot be provided at ward level
  - Direct arterial BP monitoring
  - CVP monitoring
  - Fluid balance
  - Neurological observations, regular GCS recording
- Patients requiring support for a single failing organ system, excluding invasive ventilatory support:
  - CPAP *or* NIV – see p. 193
  - Moderate inotropic or vasopressor support
  - Renal replacement therapy in an otherwise stable patient
- Step down from intensive care

(BP = blood pressure; CPAP = continuous positive airway pressure; COPD = chronic obstructive pulmonary disease; CVP = central venous pressure; GCS = Glasgow Coma Scale; NIV = non-invasive (mask) ventilation)

This requires local knowledge about the clinical areas providing enhanced care, whether intermediate high-dependency or advanced intensive care, and the mechanism of referral.

- *Intensive care units* allow management of the sickest patients who require invasive ventilation, multimodal monitoring and multiple organ system support (Box 8.6).
- *High-dependency care* allows a greater degree of monitoring, physiological support and nursing/medical input than the standard ward, for patients following major surgery, or for the septic patient requiring invasive haemodynamic monitoring and

circulatory support alone, or for the patient with respiratory failure manageable with non-invasive ventilation (NIV) or continuous positive airway pressure (CPAP).

The mechanism of referral to critical care varies between hospitals, and all clinical staff must be aware of the local system and how to access it. Many hospitals have medical emergency or outreach teams that facilitate this. A clear understanding of what is available in critical care and what is achievable allows early referral of appropriate patients, which will improve their survival and reduce length of stay. It prevents referral of patients who have no realistic prospect of meaningful survival, due to either the overwhelming nature of their acute condition or the lack of definitive therapy for the underlying disease process.

PRESENTING PROBLEMS/MANAGEMENT OF MAJOR ORGAN FAILURE

As the diagnosis and management of presenting problems take place simultaneously in critical care, these are described together.

Circulatory failure: 'shock'

The defining feature of 'shock' is a level of oxygen delivery (DO_2) that fails to meet the metabolic requirements of the tissues. 'Shock' is not synonymous with hypotension, which is often a late manifestation. The cardiac output and oxygen delivery may be critically low, even though the BP remains normal, and the underlying problem should be identified and treated before the BP falls. Objective markers of inadequate tissue oxygen delivery, such as increasing base deficit, elevated blood lactate and reduced urine output, can aid earlier identification of shock.

The causes of circulatory failure or 'shock' may be categorised as either low flow or stroke volume, or low peripheral arteriolar resistance (vasodilatation).

Low stroke volume

- *Hypovolaemic:* any condition provoking a major reduction in blood volume, e.g. internal or external haemorrhage, severe burns, salt and water depletion.
- *Cardiogenic:* severe cardiac impairment, e.g. myocardial infarction, acute mitral regurgitation. Subarachnoid haemorrhage may cause catecholamine-mediated myocardial stunning that can result in pulmonary oedema or cardiogenic shock.
- *Obstructive:* obstruction to blood flow around the circulation, e.g. major pulmonary embolism, cardiac tamponade, tension pneumothorax.

Vasodilatation

- *Sepsis/SIRS:* infection or other causes of a systemic inflammatory response that produce widespread endothelial damage with vasodilatation, arteriovenous shunting, microvascular occlusion, capillary leak and tissue oedema.
- *Anaphylactic:* inappropriate vasodilatation triggered by an allergen (e.g. bee sting), often associated with endothelial disruption and capillary leak.
- *Neurogenic:* caused by major brain or spinal injury, which disrupts brainstem and neurogenic vasomotor control. High cervical cord trauma may result in disruption of the sympathetic outflow tracts, leading to inappropriate bradycardia due to a combination of loss of noradrenaline (norepinephrine)-mediated vasoconstriction and adrenaline (epinephrine)-mediated chronotropy. Guillain–Barré syndrome (p. 1224) involves the autonomic as well as the sensorimotor systems, which may result in periods of severe hypo- or hypertension.

Clinical assessment and complications

Clinical features depend on the primary pathophysiology (p. 180). Hypovolaemic, cardiogenic and obstructive causes of circulatory failure produce the 'classical' image of shock with cold peripheries, reduced or absent peripheral pulses, weak central pulses and evidence of a low cardiac output. In early haemorrhagic shock, a narrowed pulse pressure, i.e. a raised diastolic (DBP) and reduced systolic (SBP) blood pressure, such as 105/95 mmHg, indicates the combination of hypovolaemia (reduced stroke volume, hence SBP) and activation of the sympathetic nervous system, with noradrenaline (norepinephrine) inducing vasoconstriction and so raising the DBP.

In contrast, sepsis/SIRS and anaphylactic shock are usually associated with warm peripheries, bounding pulses and features of a high cardiac output. The BP pattern is again distinctive (e.g. 115/42 mmHg), with a low DBP in the early stages due to peripheral vasodilatation, but a normal systolic BP, as the left ventricular afterload is reduced and stroke volume thus maintained, These patients are usually warm peripherally, but in more advanced septic or anaphylactic shock, SBP falls and the peripheries become cool. This is usually due to the hypovolaemia associated with capillary leak and will respond to fluid resuscitation. If there is no improvement with this, myocardial depression may be present.

Neurogenic shock often results in vasodilated hypotension with a paradoxically slow heart rate.

All forms of shock require early identification and treatment because, if inadequate regional tissue perfusion and cellular dysoxia persist, MOF will develop. Early institution of invasive haemodynamic monitoring is required.

Circulatory support

The primary goals (Box 8.7) are to:

- Restore global oxygen delivery (DO_2) by ensuring adequate cardiac output.
- Maintain an MAP that ensures adequate perfusion of vital organs. The target pressure will be patient-specific, depending on pre-morbid factors (e.g. hypertension or coronary artery disease), and may range from 60 to 90 mmHg.

The first objective is to ensure that an 'appropriate' ventricular preload is restored, initially by adequate volume resuscitation. Vasoactive drugs may then have to be considered.

8.7 Immediate management of circulatory collapse

Correct hypoxaemia

- Oxygen therapy
- Consider ventilation
  - Intractable hypoxaemia
  - Hypercapnia: $PaCO_2$ > 6.7 kPa (50 mmHg)
  - Respiratory distress
  - Impaired conscious level

Assess circulation

- Heart rate
- BP: direct arterial pressure
- CVP
- Peripheral perfusion

Optimise volume status

- Fluid challenge(s):
  - CVP < 6 mmHg: 250 mL 0.9% saline or colloid
  - CVP > 6 mmHg or poor ventricular function suspected: 100 mL boluses and consider measuring cardiac output by PA catheter or oesophageal Doppler

Optimise haemoglobin concentration

- Transfuse red cells to maintain Hb at 70–90 g/L (or 100 g/L if ischaemic heart disease)
- Septic patients can become profoundly anaemic with crystalloid/colloid resuscitation due to haemodilution

Achieve target BP

- Use vasopressor/inotrope once hypovolaemia is corrected

Achieve adequate CO and DO_2

- Inotropic agent if fluid alone is inadequate

Other measures

- Establish monitoring, including invasive measures, at once
- Trends in haemodynamics, ABG, H^+, base deficit and lactate guide further treatment

8.8 Actions of commonly used vasoactive agents

Drug	Action		
	Vasoconstrictor	Inotrope	Chronotrope
Adrenaline (epinephrine)	++	++	+
Noradrenaline (norepinephrine)	++++	+	(+)
Dobutamine	*	++++	++

*In most patients dobutamine acts as a vasodilator but in some it causes vasoconstriction.

Therapeutic options to optimise cardiac function

If the cardiac output is inadequate and myocardial contractility is poor, the available treatment options are to:

- *Reduce afterload*. Reduction can be achieved by using an arteriolar dilator (e.g. nitrates), but this may be limited by the consequent fall in systemic pressure. A counterpulsation intra-aortic balloon pump offers the ideal physiological treatment because it reduces left ventricular afterload while increasing cardiac output, diastolic pressure and coronary perfusion. It is particularly valuable in treating myocardial ischaemia.
- *Increase preload*. If there is significant impairment of myocardial contractility, giving fluids to increase filling pressures will only produce a small increase in stroke volume and cardiac output, and risks precipitating pulmonary oedema.
- *Improve myocardial contractility*. An inotrope may be required to ensure adequate cardiac output and peripheral blood flow sufficient to secure adequate oxygen delivery. Box 8.8 lists some characteristics of the commonly used vasoactive agents.
- *Control heart rate and rhythm*. The optimum heart rate is usually between 90 and 110 beats per minute. Correction of low serum potassium and magnesium concentrations should be the first step in treating tachyarrhythmias in the critically ill. Atrial fibrillation is particularly common; intravenous amiodarone (300 mg over 30–60 minutes, followed by 900 mg over 24 hours) can be successful in controlling ventricular rate and in restoring and maintaining sinus rhythm. Other anti-arrhythmic agents are described on page 573.

The management of cardiac tamponade and pulmonary embolism is described on pages 545 and 723, respectively. Circulatory support in the context of sepsis is described below.

Prognosis

If the precipitating cause and accompanying circulatory failure are dealt with promptly, before significant organ failure occurs ('early' shock), the prognosis is good. If not, there is progressive deterioration in organ function and MOF ensues ('late' shock). The mortality of MOF is high and increases with the number of organs that have failed, the duration of organ failure and the patient's age. Failure of four or more organs is associated with a mortality of more than 80%.

Respiratory failure and acute respiratory distress syndrome

Respiratory failure may be the primary problem or could constitute a secondary complication (Box 8.9). The pattern of respiratory failure is classified using ABG analysis:

- *type 1*: hypoxaemia (PaO_2 < 8 kPa (< 60 mmHg) when breathing air) without hypercapnia
- *type* 2: hypoxaemia with hypercapnia ($PaCO_2$ > 6.5 kPa (> 49 mmHg)) due to alveolar hypoventilation.

Acute hypoxaemia results from an increase in ventilation–perfusion mismatch within the lung and this can be caused by almost any pulmonary disease. The most extreme form of mismatch is pulmonary shunting, which occurs when an area of lung is not ventilated at all – for example, due to collapse or consolidation.

8.9 Common causes of respiratory failure in critically ill patients

Type 1 respiratory failure

- Pneumonia
- Pulmonary oedema*
- Pulmonary embolism
- Pulmonary fibrosis
- ARDS*
- Aspiration
- Lung collapse*, e.g. retained secretions
- Asthma
- Pneumothorax
- Pulmonary contusion (blunt chest trauma)

Type 2 respiratory failure

- Reduced respiratory drive*, e.g. drug overdose, head injury
- Upper airway obstruction (oedema, infection, foreign body)
- Late severe acute asthma
- COPD
- Peripheral neuromuscular disease*, e.g. Guillain–Barré syndrome, myasthenia gravis
- Flail chest injury
- Exhaustion* (includes all type 1 causes)

*Secondary complications of other conditions.
(ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease)

Acute or chronic hypercapnia usually results from alveolar hypoventilation. Causes include:

- central depression of respiratory drive
- impaired nerve transmission between the central nervous system and muscle (especially the diaphragm)
- reduced chest wall movements (including diaphragmatic movements)
- reduced alveolar ventilation due to pathology within the lungs.

The primary respiratory conditions causing acute respiratory failure are detailed in Chapter 19. Critically ill patients may have both type 1 and 2 respiratory failure at some point, and the pattern and severity can change rapidly. Close monitoring and review are thus essential in order to decide which form of respiratory support is required, as this may change rapidly as the patient deteriorates and/or improves. Both the disease causing the illness *and* its effect on the patient's physiology over time must be taken into consideration. A combination of clinical examination and investigation helps to determine the most appropriate interventions (Box 8.10). The best method for assessing hypoxaemia is the ratio of the PaO_2 (measured by blood gas) to the fractional inspired oxygen delivered (PaO_2/FiO_2). This 'PF' ratio is lower, the more severe the disease. For example, a patient receiving 60% oxygen with a PaO_2 of 10.0 kPa (75.2 mmHg) on blood gas has a PF ratio of 10.0/0.6 = 16.7 kPa (125.6 mmHg).

Acute lung injury and the acute respiratory distress syndrome

A range of conditions (Box 8.11) can result in a diffuse acute inflammatory process in the lungs called acute lung injury (ALI); when severe (as defined by hypoxaemia), this is termed the acute respiratory distress syndrome (ARDS; Box 8.12). Inflammation occurs throughout the lungs, affecting both endothelial and epithelial surfaces. Activated neutrophils are sequestered into the lungs and capillary permeability is increased, with damage to type I and II alveolar cells.

8.10 How to assess respiratory failure

Respiratory pattern

- Inspiratory stridor: typically caused by partial airway obstruction
- Tachypnoea: often the first indicator of critical illness
- Rapid shallow breathing: indicates more severe respiratory failure
- Prolonged expiratory efforts: indicates severe bronchospasm

Conscious level

- Worsening drowsiness or agitation: indicates more severe respiratory failure as a result of hypoxaemia and/or hypercapnia

Pulse oximetry

- Oxygen saturations < 94%: indicate arterial hypoxaemia
- Failure to respond to supplemental oxygen therapy, especially FiO_2 > 60%: indicates severe ventilation–perfusion mismatch and/or shunt

Arterial blood gases

- Calculate the PF ratio (see text): lower values indicate more severe disease

Imaging

- Chest X-ray, CT scan or chest ultrasound: information about the underlying pathology and treatable conditions, e.g. pleural effusion

8.11 Conditions predisposing to ARDS

Inhalation (direct)

- Aspiration of gastric contents
- Toxic gases/burn injury
- Pneumonia
- Blunt chest trauma
- Near-drowning

Blood-borne (indirect)

- Sepsis
- Necrotic tissue (particularly bowel)
- Multiple trauma
- Pancreatitis
- Cardiopulmonary bypass
- Drugs (heroin, barbiturates, thiazides)
- Severe burns
- Major transfusion reaction
- Anaphylaxis
- Fat embolism
- Carcinomatosis
- Obstetric crises (amniotic fluid embolus, eclampsia)

This results in exudation and accumulation of protein-rich cellular fluid within alveoli and the formation of characteristic 'hyaline membranes'. Local release of cytokines and chemokines by activated macrophages and neutrophils results in progressive recruitment of inflammatory cells. Secondary effects include loss of surfactant and impaired surfactant production.

The net effect is alveolar collapse and reduced lung compliance, which are most marked in dependent regions of the lung, where airspaces become fluid-filled (Fig. 8.7). The combination of loss of surfactant and fluid accumulation makes these areas difficult to ventilate, which results in hypoxaemia due to ventilation–perfusion mismatch and increased pulmonary shunt. ALI and ARDS can be difficult to distinguish from fluid overload or cardiac failure.

8.12 Berlin definition of ARDS

- Onset within 1 week of a known clinical insult, or new or worsening respiratory symptoms
- Bilateral opacities on chest X-ray, not fully explained by effusions, lobar/lung collapse or nodules
- Respiratory failure not fully explained by cardiac failure or fluid overload. Objective assessment (e.g. by echocardiography) must exclude hydrostatic oedema if no risk factor is present
- Impaired oxygenation:
  Mild: 26.6 kPa (200 mmHg) < PaO_2/FiO_2 ≤ 39.9 kPa (300 mmHg) with PEEP or CPAP ≤ 5 cmH_2O
  Moderate: 13.3 kPa (100 mmHg) < PaO_2/FiO_2 ≤ 26.6 kPa (200 mmHg) with PEEP ≤ 5 cmH_2O
  Severe: PaO_2/FiO_2 ≤ 13.3 kPa (100 mmHg) with PEEP ≤ 5 cmH_2O

(CPAP = continuous positive airway pressure; PEEP = positive end expiratory pressure – see text for explanation)

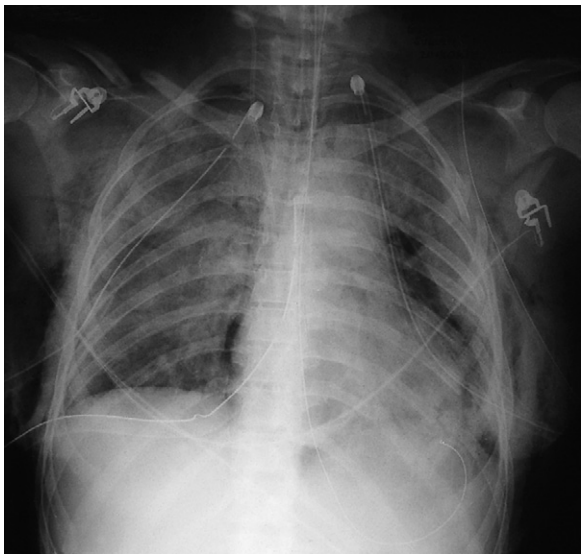

Fig. 8.7 Chest X-ray in acute respiratory distress syndrome (ARDS). Note bilateral lung infiltrates, pneumomediastinum, pneumothoraces with bilateral chest drains, surgical emphysema, and fractures of the ribs, right clavicle and left scapula.

Respiratory support

The aims of respiratory support are to maintain the patency of the airway, correct hypoxaemia and hypercapnia, and reduce the work of breathing.

Oxygen therapy

Oxygen is given to ensure adequate arterial oxygenation (SpO_2 > 90%), initially by facemask or nasal cannulae. The inspired oxygen concentration (FiO_2) is adjusted, depending on pulse oximetry and ABG analysis. If this results in unacceptable hypercapnia, the patient requires some form of mechanical respiratory support. The risk of progressive hypercapnia in patients with chronic obstructive pulmonary disease (COPD) who are dependent on hypoxic drive has been overstated. Hypoxic cerebral damage is irreversible, so the theoretical risks of oxygen toxicity are not relevant if the patient is acutely hypoxaemic, as the maintenance of cerebral oxygenation takes precedence. More detail on oxygen therapy is given on page 664.

Non-invasive respiratory support

Non-invasive respiratory support includes techniques that do not require sedation or an endotracheal or tracheostomy tube. This helps preserve the patient's respiratory muscle activity and reduces complications such as nosocomial infection. It can be used to support selected patients with type 1 or 2 respiratory failure, but the patient's conscious level must be adequate to ensure airway protection from aspiration. Non-invasive respiratory support is classified as continuous positive airway pressure (CPAP) alone or CPAP plus additional support, in the form of pressure applied to the breathing circuit during inspiration (non-invasive ventilation, or NIV).

CPAP therapy

CPAP therapy involves the application of a continuous positive airway pressure throughout the patient's breathing cycle, typically between 5 and 10 cmH_2O. CPAP recruits collapsed alveoli and can enhance clearance of alveolar fluid. It is particularly effective for treating pulmonary atelectasis (which may be post-operative) and pulmonary oedema, and helps correct hypoxaemia in some patients with pneumonia, especially the immunocompromised. CPAP therapy is most effective in correcting hypoxaemia in type 1 respiratory failure, but if it improves pulmonary compliance (by clearing fluid or improving lung volume), it can reduce the work of breathing and improve hypercapnia in type 2. However, many patients with the latter require NIV or invasive ventilation. CPAP therapy can be delivered using tight-fitting facial masks, high-flow nasal cannulae, and hoods (Fig. 8.8). Usually, a CPAP mask is tried first, but different systems can be trialled until the most comfortable for the patient is found. Patients must be cooperative,

Fig. 8.8 CPAP delivery with a Castar hood.

able to protect their airway, and have the strength to breathe spontaneously and cough effectively. Failure to improve over 24–48 hours, or a further deterioration in conscious level or blood gases, indicates that invasive ventilation should be considered.

Non-invasive ventilation

Non-invasive ventilation (NIV) is ventilatory support by nasal or full facemask. It can be delivered by a simple bi-level (BiPAP) turbine ventilator, which delivers a higher pressure (approximately 15–25 cmH_2O) for inspiration and a lower pressure (4–10 cmH_2O) to allow expiration. If hypoxaemia is severe, a complex ICU ventilator is employed that allows higher oxygen concentrations to be administered. A simple breathing circuit with a leak rather than an expiratory valve is generally used, and ventilation can be spontaneous (triggered by the patient's breaths) or timed (occurring at set intervals and/or frequency). Systems that synchronise with the patient's efforts are better tolerated and more effective. NIV is the first-line therapy in patients with type 2 respiratory failure secondary to acute exacerbation of COPD because it reduces the work of breathing and offloads the diaphragm, allowing it to recover strength. It should be initiated early, especially when severe respiratory acidosis and/or decreased consciousness secondary to hypercapnia are present. Unless there is an improvement in acidosis within 4–6 hours, invasive ventilation is indicated. NIV can also be used to support selected patients with hypercapnia secondary to pulmonary oedema or pneumonia, or during weaning from invasive ventilation, but its effectiveness in these conditions is less certain. As with mask CPAP, NIV requires the patient to be conscious and cooperative.

Emergency endotracheal intubation and mechanical ventilation

Many patients admitted to ICU require endotracheal intubation and mechanical ventilation, mostly for respiratory failure (Boxes 8.13 and 8.14). The final decision to undertake these is based on clinical judgement rather than the results of ABGs in isolation. If possible, the patient's relatives should be given the chance to visit prior to anaesthesia and intubation, as this may be the last opportunity they have to speak together.

In the conscious patient, intubation requires induction of anaesthesia and muscle relaxation, while in more obtunded patients, sedation alone may be adequate. Intubation can be hazardous in the critically ill patient, particularly if there is associated cardiovascular failure. Patients should be pre-oxygenated and cricoid pressure applied, with continuous monitoring of heart rate, ECG and BP (preferably invasively), together with capnography (and subsequently a chest X-ray) to confirm correct endotracheal tube placement. Complications are common, and intubation is ideally performed in a critical care environment, or with expert assistance, resuscitation facilities and appropriate medication immediately available. Hypotension may follow sedation or anaesthesia due to the direct cardiovascular effects of the anaesthetic agent and loss of sympathetic drive. Positive pressure ventilation may compound this by increasing intrathoracic pressure, thereby reducing venous return and thus cardiac output.

Tracheostomy is usually performed electively when endotracheal intubation is likely to be required for more than 7–10 days (Box 8.15). The timing is determined by individual patient factors and clinical judgement. Tracheostomy is usually carried out percutaneously in the ICU, to avoid transfer to an operating theatre. The passage of a smaller (4.5 mm internal diameter) 'mini-tracheostomy' tube through the cricothyroid membrane is a useful technique for clearing airway secretions in spontaneously breathing patients with a poor cough effort, particularly in the HDU and in post-operative patients.

General considerations in the management of the ventilated/intubated patient

Modern ventilators allow enormous flexibility in the way ventilator support is provided. The terminology used to describe ventilation modes can be confusing,

8.13 Indications for tracheal intubation and mechanical ventilation

- Protection of airway
- Respiratory arrest or rate < 8 breaths/min
- Tachypnoea > 35 beats/min
- Inability to tolerate oxygen mask/CPAP/NIV, e.g. agitation, confusion
- Removal of secretions
- Hypoxaemia (PaO_2 < 8 kPa (< 60 mmHg); SpO_2 < 90%) despite CPAP with FiO_2 > 0.6
- Hypercapnia if conscious level is impaired or risk of raised intracranial pressure
- Worsening respiratory acidosis
- Vital capacity falling below 1.2 L in patients with neuromuscular disease
- Removing the work of breathing in exhausted patients

8.14 Conditions requiring mechanical ventilation*

Post-operative	
• After major abdominal or cardiac surgery	
Respiratory failure	
• ARDS • Pneumonia • COPD	• Acute severe asthma • Aspiration • Smoke inhalation, burns
Circulatory failure	
• Low cardiac output: cardiogenic shock	• Pulmonary oedema • Post-cardiac arrest
Neurological disease	
• Coma of any cause • Status epilepticus • Drug overdose • Respiratory muscle failure (see Box 8.9, p. 192)	• Head injury: to avoid hypoxaemia and hypercapnia, and reduce intracranial pressure • Bulbar abnormalities causing risk of aspiration (e.g. stroke, myasthenia gravis)
Multiple trauma	

*Additional considerations:
Metabolic rate: ventilatory requirements rise as metabolic rate increases.
Nutritional reserve: low potassium or phosphate reduces respiratory muscle power.
Abdominal distension due to surgery or tense ascites: causes discomfort and splinting of the diaphragm, compromising spontaneous respiratory effort and promoting bilateral basal lung collapse.

8.15 Advantages and disadvantages of tracheostomy

Advantages	
• Patient comfort • Improved oral hygiene • Access for tracheal toilet • Enables speech with cuff deflated and a speaking valve attached	• Earlier weaning and ICU discharge • Reduced sedation requirement • Reduces vocal cord damage
Disadvantages	
• Immediate complications: hypoxia, haemorrhage • Tracheostomy site infection	• Tracheal damage; late stenosis

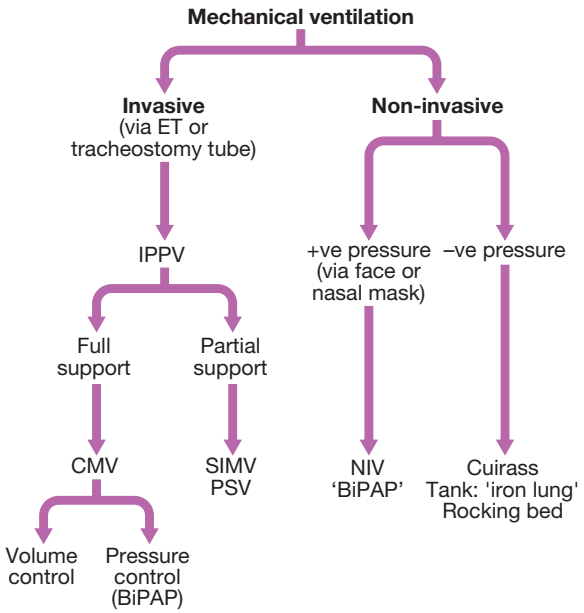

Fig. 8.9 Types of invasive and non-invasive ventilatory support. (BiPAP = bi-level positive airway pressure; CMV = controlled mandatory ventilation; ET = endotracheal; IPPV = intermittent positive pressure ventilation; NIV = non-invasive ventilation; PSV = pressure support ventilation; SIMV = synchronised intermittent mandatory ventilation)

because of subtle differences between modes, and the use of different names by different manufacturers. Figure 8.9 gives a classification of the different types of invasive ventilation support, and Box 8.16 outlines the terminology used and the parameters that are set on any ventilator. The inspired gas should always be humidified and warmed, usually achieved with a heat and moisture exchanger, but occasionally with hot water humidification systems.

Initial settings

Following intubation, the ventilator is set to deliver a safe mandatory mode of ventilation that will achieve oxygenation and carbon dioxide clearance in the majority of patients. Regular re-assessment of the patient's parameters will show if modification is required. Hyperoxia is avoided, as it is associated with adverse outcomes.

8.16 Ventilator parameter settings on initiating mechanical ventilation

Parameter	Setting
FiO_2	Initially set to achieve SpO_2 > 92% based on pulse oximetry Subsequently adjusted to achieve PaO_2 of 8–12 kPa (60.2–90.2 mmHg) on ABGs
Positive end expiratory pressure (PEEP)	The pressure maintained by the ventilator at the end of expiration: important for recruiting and maintaining alveoli for gas exchange Initially set at ~5 cmH_2O, except in patients with severe gas trapping (e.g. acute asthma), but increased in patients with severe hypoxaemia
Tidal volume	Set low in ARDS to minimise pulmonary barotrauma and volutrauma In patients with normal lungs, higher volumes are safe
Respiratory rate	Typically set at 12–15 breaths/min Adjusted according to $PaCO_2$ on ABGs to achieve adequate CO_2 clearance
Mode of ventilation	The safest initial mode is SIMV (see text): synchronises breaths with efforts made by patient, but ventilates at the set rate and tidal volume in the absence of respiratory effort
Breath trigger	Initiates a breath in response to patient's efforts, triggered by flow towards the patient on attempts to breathe Set at the appropriate sensitivity for the patient
Inspired to expired time ratio (I–E ratio)	In most patients, the I–E ratio should be 1 : 2 to 1 : 3 Sometimes altered in expiratory airway obstruction (e.g. lengthened in asthma) or difficult oxygenation (e.g. shortened or reversed in ARDS)
Alarms	Disconnection Low or high tidal volumes Low FiO_2 Excessively high or low airway pressures A range of other parameters can also be selected Adjust default settings to optimise safety for the individual patient

Mandatory modes of ventilation

Volume-controlled modes. These are set to deliver a preset tidal volume at a set frequency to guarantee a specified minute ventilation. Synchronised intermittent mandatory ventilation (SIMV) is the most widely used, which also synchronises breaths with any efforts made by the patient. Volume-controlled modes will deliver the set volume, but the pressures generated in the patient's lungs can be excessively high if the pulmonary compliance is low – for example, in ARDS – thus precipitating lung barotrauma or volutrauma, which could cause pneumothorax.

Pressure-controlled modes. These deliver a set pressure for a specified duration. Pressure-controlled ventilation (PCV) and bi-level positive airway pressure ventilation (BiPAP) are examples. The tidal and minute volumes achieved are determined by the pulmonary compliance; in patients with stiff lungs, only small tidal volumes may

be achieved, whereas in patients with normal compliance, excessive volumes may result. An advantage of these modes is that airway pressures are controlled, but the effect on blood gases needs to be regularly assessed to identify changes in pulmonary compliance. Tidal volume is a useful safety alarm as it falls with increased resistance, such as with bronchospasm. In difficult-to-ventilate cases, several modes can be attempted sequentially to identify which is most effective.

Weaning or spontaneously breathing modes. Most modern ventilators can detect whether a patient is making breathing efforts, and use a flow trigger to augment each breath. Assisting breathing with additional pressure is more comfortable than fixed tidal volumes and allows sedation to be reduced. The most common mode applies additional pressure during inspiration, assisting the work of breathing and increasing tidal volume. The pressure is removed when the ventilator detects an expiratory effort. These modes are usually called pressure support ventilation (PSV) or assisted spontaneous breathing (ASB).

Mixed modes. Different modes can be applied simultaneously, tailored to meet individual requirements. For example, it is possible to specify a frequency of SIMV or PCV breaths, but also provide PSV for any additional efforts the patient makes.

Advanced ventilation strategies

In patients with severe acute lung disease, especially those resulting in reduced lung compliance such as ARDS, the ventilator can worsen lung injury as a result of overstretch and shearing forces in parts of the lung that continually open and collapse. The aim of advanced ventilation is to minimise further damage due to pressure (barotrauma), volume stretch (volutrauma), and the additional inflammatory mediators released into the body from ongoing lung injury (biotrauma) (Box 8.17). Tidal volumes and airway pressures are kept as low as possible while achieving adequate oxygenation. In many cases, it is best to accept hypercapnia rather than apply higher pressure to clear CO_2. Often, higher levels of positive end expiratory pressure (PEEP) are required to achieve adequate alveolar recruitment and oxygenation.

Several other strategies can be used.

Prone ventilation. Oxygenation will often improve in patients turned on their front, as a result of improved lung recruitment and better ventilation–perfusion matching. Prone ventilation has not reduced mortality in controlled trials, but is a useful 'rescue therapy' in cases where oxygenation is difficult.

High-frequency oscillatory ventilation (HFOV). This uses a specialised ventilator to provide gas exchange with high-frequency oscillating gas movements (> 150/min). Conventional breaths and tidal volumes are not set, but effective oxygenation and CO_2 clearance are achieved by adjusting the frequency and power of the oscillations, and the mean airway pressure.

Nitric oxide. Nitric oxide is a very short-acting pulmonary vasodilator. When delivered to the airway, it improves blood flow to ventilated alveoli, thus improving ventilation–perfusion matching. Oxygenation can be improved markedly in some patients but there is evidence that this lasts for only 48 hours, and rebound effects can occur when it is withdrawn. No improvement in mortality has been shown in controlled trials. Its role is limited to rescue therapy when other interventions have failed, and it may be useful in patients with severe pulmonary hypertension.

Extracorporeal membrane oxygenation therapy (ECMO). ECMO involves connecting the patient to an external bypass circuit. Oxygenation and CO_2 clearance are achieved using a membrane oxygenator. The patient's lungs are usually 'rested' and ventilation reduced to low levels. Advances in technology have dramatically improved the safety of these devices, although their use is restricted to specialised centres. Controlled trials indicate improved survival in appropriately selected cases, and patients with severe ARDS should be considered for treatment.

Corticosteroids. There is conflicting evidence regarding the use of steroids as anti-inflammatory agents in acute lung injury. Uncertainty remains about patient selection and the timing of therapy, and use of corticosteroids may be complicated by secondary infection and muscle weakness. However, they are often tried after 7–10 days of ARDS, if the patient remains severely unwell.

Weaning from respiratory support

Patients usually require most mechanical ventilation in the period following intubation when they are most unwell, following which support is gradually reduced as the underlying condition resolves and the patient is able to breathe with less assistance. This is the process of 'weaning' from ventilation. Sufficient support is provided to correct hypoxaemia and hypercapnia, but the level is decreased as quickly as possible to reduce the chance of secondary complications, such as infection and muscle weakness. Rapid weaning, often with reduction in sedation levels (see below), shortens length of ICU stay and improves patient outcomes. Patients who have required long-term ventilatory support for severe lung disease such as ARDS may be unable to sustain even a modest degree of respiratory work initially because of poor lung compliance, high work of breathing and respiratory muscle weakness. They require more prolonged weaning, until respiratory muscle strength improves.

Several criteria can be used to assess whether a patient is ready to start reducing respiratory support (Box 8.18). Approaches include:

EBM 8.17 Mechanical ventilation in ARDS

- Low tidal volumes (4–6 mL/kg ideal body weight) reduce mortality from ARDS.[1]
- High levels of PEEP should be avoided in patients with less severe ARDS, in whom it may be harmful. In severe ARDS, high level of PEEP to recruit the lungs and improve oxygenation may decrease mortality.[2]
- Early use of neuromuscular relaxing drugs to facilitate mechanical ventilation reduces mortality in severe ARDS.[3]
- Minimised fluid administration and accumulation reduce the duration of mechanical ventilation in ARDS.[4]

- [1]ARDS Clinical Trials Network. N Engl J Med 2000; 342:1301–1308.
- [2]Briel M, et al. JAMA 2010; 303:865–873.
- [3]Papazian L, et al. N Engl J Med 2010; 363:1107–1116.
- [4]ARDS Clinical Trials Network. N Engl J Med 2006; 354:2564–2575.

(PEEP = positive end-expiratory pressure)

8.18 Factors to consider in deciding to wean and extubate a ventilated patient

- Has the original indication for mechanical ventilation resolved?
- Is the patient conscious and able to cough and protect his/her airway?
- Is the circulation stable, without signs of cardiac failure or excessive fluid overload?
- Is gas exchange satisfactory (PaO_2 > 10 kPa (> 75 mmHg) on FiO_2 < 0.5; $PaCO_2$ < 6 kPa (< 45 mmHg))?
- Is analgesia adequate?
- Are any metabolic problems well controlled?

Spontaneous breathing trials (SBTs). These involve removing all respiratory support, typically on a daily basis, and observing how long the patient is able to breathe unassisted. This is particularly effective when linked to sedation breaks. Signs of failure include rapid shallow breathing, hypoxaemia, rising $PaCO_2$, sweating and agitation. Patients who pass an SBT are assessed for extubation.

Progressive reduction in pressure support ventilation. Progressive reduction in the PSV is applied for each breath over a period of hours or days, according to patient response. When patients are strong enough to achieve stable ABGs without distress while receiving minimal or no support, they are likely to be ready for extubation. This can take from several hours to many weeks, according to the severity of illness.

Weaning protocols. The process of weaning is best undertaken as a continuous process. Protocols that empower nursing staff to initiate and progress weaning within agreed guidelines reduce ventilation times. Patients requiring prolonged mechanical ventilation typically require individualised weaning plans, with regular periods of training followed by rest, to enable respiratory muscles to regain strength.

The timing of extubation relies on clinical judgement. Patients must have stable ABGs with resolution of hypoxaemia and hypercapnia despite withdrawal of ventilator support. Conscious level must be adequate to protect the airway, comply with physiotherapy, and cough. The need for re-intubation following extubation is associated with poorer outcomes.

Acute kidney injury

Acute kidney injury (AKI) is defined as an abrupt and sustained decrease in kidney function (Box 8.19). AKI in the critically ill patient is often due to pre-renal problems such as hypovolaemia, hypotension and ischaemia resulting in reduced renal DO_2. However, it may also be due to acute tubular necrosis (ATN, p. 479), which may result from ischaemia, or nephrotoxicity caused by chemical or bacterial toxins, or a combination of these. Potentially nephrotoxic drugs include non-steroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, radiological contrast media and some antibiotics.

Oliguria (< 0.5 mL/kg/hr for several hours) is an important early sign of systemic problems in critical illness. It requires investigation and early intervention to correct hypoxaemia, hypovolaemia, hypotension and renal hypoperfusion. Successful resuscitation is associated with restoration of good urine output, an improving acid–base balance and correction of plasma potassium, urea and creatinine.

8.19 Diagnostic criteria for acute kidney injury*

An abrupt (within 48 hrs) decline in kidney function defined as:

- An absolute increase in serum creatinine of ≥ 26.4 μmol/L (0.3 mg/dL)
- A percentage increase in serum creatinine of ≥ 50% (1.5-fold from baseline)
- A reduction in urine output (documented oliguria of < 0.5 mL/kg for > 6 consecutive hrs)

*Mehta R, et al. http://ccforum.eom/content/11/2/R31.

Oliguria is an integral part of the normal stress response to major surgery, and care should be taken not to overfill the post-operative patient who has oliguria but is otherwise well from a cardiovascular and biochemical point of view.

Renal support

Sepsis is frequently implicated in the development of AKI, and the source must be promptly identified and adequately treated. Obstruction of the renal tract (including catheter blockage) should always be excluded and is most easily identified with abdominal ultrasound. It must be relieved at once. Acute glomerulonephritis and vasculitis must also be considered, and appropriate specialist referral, with investigations such as urine microscopy and immunopathological tests (p. 480), carried out early.

The mainstay of management is aggressive haemodynamic resuscitation to achieve normovolaemia, normotension and an appropriate cardiac output. There is little evidence that specific treatments aimed at inducing a diuresis, such as low-dose dopamine, furosemide or mannitol, have any renoprotective action or other benefit in restoring renal function.

If renal function cannot be restored following resuscitation, renal replacement therapy (p. 488) is indicated (Box 8.20). The preferred renal replacement therapy in ICU patients is pumped venovenous haemofiltration. This is associated with fewer osmotic fluid shifts and hence greater haemodynamic stability than haemodialysis. It is carried out using a double-lumen central venous catheter placed percutaneously. Haemofiltration should

8.20 Indications for renal replacement therapy

- Hyperkalaemia: potassium > 6 mmol/L despite medical treatment
- Fluid overload: pulmonary oedema
- Metabolic acidosis: H^+ > 56 nmol/L (pH < 7.25)
- Uraemia:
  - Urea > 30–35 mmol/L (180–210 mg/dL)
  - Creatinine > 600 μmol/L (> 6.78 mg/dL)
- Drug removal in overdose
- Sepsis: tentative evidence for mediator removal

be continuous in the early phase of treatment. Intermittent treatment may be used when the patient is recovering from the primary insult and return of normal renal function is expected. Provided the precipitating cause can be successfully treated, renal failure due to ATN usually recovers between 5 days and several weeks later.

Survival rates from MOF, including AKI, have been around 50% for many years, but modern haemofiltration techniques are being shown to produce better outcomes.

Gastrointestinal and hepatic disturbance

Gastrointestinal symptoms, such as nausea, vomiting and large nasogastric aspirates, may be the earliest signs of regional circulatory failure, and when associated with a tender, distended, silent abdomen, indicate that this is the probable site of the primary pathology. The gut has a rapid cell turnover rate and fasting alone can produce marked changes in mucosal structure and function. In hypovolaemia and frank shock states, splanchnic vasoconstriction produces gut mucosal ischaemia, damaging the mucosal barrier and allowing toxins to enter the portal circulation and lymphatics. Splanchnic ischaemia may contribute to the progression of MOF, possibly as a source of bacteraemia or systemic inflammation. Manifestations of MOF within the gastrointestinal tract include loss of gastric acid production, erosive gastritis, stress ulceration, bleeding, ischaemia, pancreatitis and acalculous cholecystitis. These occur less frequently when adequate circulatory resuscitation occurs early. Ischaemic bowel is difficult to diagnose in the critically ill patient, but in the context of otherwise unexplained lactic acidosis, hyperkalaemia and coagulopathy, abdominal imaging by contrast-enhanced computed tomography (CT) and laparotomy should be considered.

Three distinctive hepatic dysfunction syndromes can occur in the critically ill:

- *Shock liver or ischaemic hepatitis* results from extreme hepatic tissue hypoxia and is characterised by centrilobular hepatocellular necrosis. Transaminase levels are often massively raised (> 1000–5000 U/L) at an early stage, followed by moderate hyperbilirubinaemia (< 100 µmol/L or < 5.8 mg/dL). There is often associated hypoglycaemia, coagulopathy and lactic acidosis. Following successful resuscitation, hepatic function generally returns to normal.
- *Hyperbilirubinaemia* ('*ICU jaundice*') frequently develops following trauma or sepsis, particularly if there is inadequate control of the inflammatory process. There is a marked rise in bilirubin (predominantly conjugated), but only mild elevation of transaminase and alkaline phosphatase. This results from failure of bilirubin transport within the liver and produces the histological appearance of intrahepatic cholestasis. Extrahepatic cholestasis must be excluded by abdominal ultrasound and potentially hepatotoxic drugs should be stopped. Treatment is non-specific and should include early institution of enteral feeding. Therapy that compromises splanchnic blood flow, particularly high doses of vasoconstrictor agents, should be avoided.
- *Transaminitis* is most commonly due to drug toxicity: for example, antibiotics.

Gastrointestinal and hepatic support

Early institution of enteral nutrition is the most effective strategy for protecting the gut mucosa and providing nutritional support. The optimum use of enteral nutrition involves simple protocols that initiate nutrition as early as possible, and progressively increase feeding volumes until nutritional targets are met. Current evidence supports early enteral nutrition using standard feeds, with the addition of prokinetic agents such as metoclopramide or low-dose erythromycin when gastric aspirates are high. The evidence for early supplementation with total parenteral nutrition (TPN) is weak, and it is not routinely indicated until enteral feeding attempts have been unsuccessful for approximately 7 days. Nutritional support is further considered on page 122.

Hyperglycaemia is common during critical illness and is associated with poor outcomes. Tight glycaemic control, using insulin infusions, has been studied in several controlled trials in the critically ill. The benefit was greatest in surgical patients at low risk of death, but the risk-to-benefit profile in the mixed critically ill population is uncertain. Inadvertent hypoglycaemia is associated with adverse patient outcomes. In most ICUs, the current target is for modestly elevated blood glucose concentrations: for example, 5.5–8 mmol/L (100–144 mg/dL).

Stress ulcer prophylaxis is best achieved with H_2-receptor antagonists (e.g. ranitidine), which are both safe and effective. Although stress ulcer bleeding is rare with modern resuscitation, evidence supports routine use in mechanically ventilated patients and those with renal failure or coagulopathy. H_2-receptor antagonists are associated with an increased incidence of nosocomial pneumonia, and treatment should be stopped following extubation in the absence of other indications. Withdrawal can also be considered when full enteral nutrition has been established, unless the patient has a history of peptic ulcer disease. Proton pump inhibitors are only required in upper gastrointestinal bleeding due to ulceration, and they should also be continued when the patient has been taking them long-term.

The management of liver failure is discussed on page 934.

Neurological failure (coma)

Impaired consciousness or coma is often an early feature of severe systemic illness (Box 8.21). Prompt assessment of consciousness level and management of airway, breathing and circulation are essential to prevent further brain injury, to allow diagnosis and to permit definitive treatment to be instituted. Any patient with confusion or reduced conscious level should have blood sugar measured and hypoglycaemia corrected.

Impairment of conscious level is graded using the Glasgow Coma Scale (GCS, p. 1160), which is also used to monitor progress. A targeted neurological examination is very important. Pupil size and reaction to light,

8.21 Causes of coma

Systemic causes

Cerebral hypoxia or hypercapnia
- Respiratory failure

Cerebral ischaemia
- Cardiac arrest
- Hypotension

Metabolic disturbance
- Diabetes mellitus
  - Hypoglycaemia
  - Ketoacidosis
  - Hyperosmolar coma
- Hyponatraemia
- Myxoedema coma
- Uraemia
- Hepatic failure
- Hypothermia
- Drugs
- Sepsis

Primary neurological causes

Trauma
- Cerebral contusion
- Extradural haematoma
- Subdural haematoma

Infection
- Cerebral abscess
- Encephalitis
- Meningitis

Cerebrovascular disease
- Intracerebral haemorrhage
- Brainstem infarction
- Subarachnoid haemorrhage
- Cerebral venous sinus thrombosis

Cerebral tumour

Epilepsy

Hydrocephalus

presence or absence of neck stiffness, focal neurological signs and evidence of other organ impairment should be noted. After cardiorespiratory stability is achieved, the cause of the coma must be sought from the history (family, witness, general practitioner), examination and investigation, particularly CT of brain. The possibility of drug overdose should always be considered.

Neurological support

A diverse range of neurological conditions require management in the ICU. These include not only the various causes of coma, but also spinal cord injury, peripheral neuromuscular disease and prolonged seizures. The goals are to:

- protect the airway, if necessary by endotracheal intubation
- provide respiratory support to correct hypoxaemia and hypercapnia
- treat circulatory problems, e.g. neurogenic pulmonary oedema in subarachnoid haemorrhage, autonomic disturbances in Guillain–Barré syndrome, and spinal shock following high spinal cord injuries
- manage acute brain injury with control of raised intracranial pressure (ICP)
- manage status epilepticus using anaesthetic agents such as thiopental or propofol.

The aim of management in acute brain injury is to optimise cerebral oxygen delivery by maintaining a normal arterial oxygen content and a cerebral perfusion pressure of more than 60 mmHg. Avoiding secondary insults to the brain, such as hypoxaemia and hypotension, improves outcome. ICP rises in acute brain injury as a result of haematoma, contusions, oedema or ischaemic swelling. Raised ICP causes direct damage to the cerebral cortex and, as a result of downward pressure on the brainstem, indirect damage by reducing cerebral perfusion pressure, thereby threatening cerebral blood flow and oxygen delivery:

Cerebral perfusion pressure (CPP) = mean BP – ICP

ICP is measured by pressure transducers that are inserted directly into the brain tissue. The normal upper limit for ICP is 15 mmHg and management should be directed at keeping it below 20 mmHg (Box 8.22). Sustained pressures of more than 30 mmHg are associated with a poor prognosis.

CPP should be maintained above 60 mmHg by ensuring adequate fluid replacement and, if necessary, by treating hypotension with a vasopressor such as noradrenaline (norepinephrine).

Complex neurological monitoring must be combined with frequent clinical assessment of GCS, pupil response to light, and focal neurological signs. The motor response to pain is an important prognostic sign. No response or extension of the upper limbs is associated with severe injury, and unless there is improvement within a few days, prognosis is very poor. A flexor response is encouraging and indicates that a good outcome is still possible.

8.22 Strategies to control intracranial pressure

- Prevent coughing with sedation, analgesia and occasionally paralysis
- Nurse with 30° head-up tilt and avoid excessive flexion of the head or pressure around the neck that may impair cerebral venous drainage
- Control epileptiform activity with appropriate anticonvulsant therapy: an electroencephalogram (EEG) may be necessary to ensure that this is achieved
- Maintain blood glucose between 5.5 and 8 mmol/L (99–144 mg/dL)
- Aim for a core body temperature of between 36 and 37°C
- Maintain sodium > 140 mmol/L using IV 0.9% saline
- Avoid volume depletion or overload
- Ventilate aiming to reduce the $PaCO_2$ to 4–4.5 kPa (~30–34 mmHg) for the first 24 hrs
- Osmotic diuretic: mannitol 20% 100–200 mL (0.25–0.5 g/kg), coupled with volume replacement
- Hypnotic infusion: thiopental, titrated to 'burst suppression' on EEG
- Surgery: drainage of haematoma or ventricles; lobectomy, decompressive craniectomy

Neurological complications in intensive care

Neurological complications may occur as a result of systemic critical illness. Sepsis may be associated both with an encephalopathy characterised by delirium, and with cerebral oedema and loss of vasoregulation. Hypotension and coagulopathy may provoke cerebral infarction or haemorrhage. Neurological examination is very

difficult if patients are sedated or paralysed, and it is important to stop sedation regularly to re-assess their underlying level of consciousness. If there is evidence of a focal neurological deficit or a markedly declining level of consciousness, CT of brain should be performed.

Critical illness polyneuropathy is another potential complication in patients with sepsis and MOF. It is due to peripheral nerve axonal loss and can result in areflexia, gross muscle wasting and failure to wean from the ventilator, thus prolonging the duration of intensive care. Recovery can take many weeks.

Sepsis

Sepsis can occur in many clinical situations. It may be due to a primary infection (e.g. pneumonia) or it may be the result of clinical interventions for other conditions (e.g. immunosuppressive drugs, chemotherapy, invasive lines). Patients who are in hospital are at increased risk of certain specific infections, such as meticillin-resistant *Staphylococcus aureus* (MRSA). Sepsis usually originates from a localised infection that progresses to an uncontrolled systemic response. It can rapidly lead to acute physiological deterioration with the risk of MOF and death. Early identification of sepsis and appropriate intervention with oxygen, fluids, antibiotics, and more advanced resuscitation where indicated, has been shown to improve survival.

The incidence of sepsis is thought to be increasing, possibly as a result of a growing elderly population, increased use of invasive surgery, higher bacterial resistance, and greater numbers of immunocompromised patients. Important comorbidities and risk factors for sepsis are shown in Box 8.23. These conditions not only increase risk of development of sepsis but also can exaggerate the severity of the process. However, sepsis can affect healthy people at any age.

Box 8.24 gives the common sites of infection in critically ill patients and appropriate investigations to consider. Any pathogen, including aerobic Gram-positive and negative bacteria, anaerobes and fungi, may cause sepsis but in nearly 45% of cases microbiological confirmation of the organism is lacking.

Any or all of the features of SIRS (see Box 8.2, p. 184) may be present, together with an obvious focus of infection, such as purulent sputum with chest X-ray shadowing, or erythema around an intravenous line. However, severe sepsis may present with unexplained hypotension (i.e. septic shock), and the speed of onset may mimic a major pulmonary embolus or myocardial infarction.

Nosocomial infections are an increasing problem in critical care units. Risk factors are similar to those in Box 8.23, but also include prolonged ICU stay, invasive ventilation and stress ulcer prophylaxis with H_2 antagonists. Cross-infection is a major concern, particularly with MRSA, multidrug-resistant Gram-negative organisms and *Clostridium difficile*. If cross-infection occurs frequently, it should prompt a review of the unit's infection

8.23 Risk factors for sepsis

- Diabetes mellitus
- Immunodeficiency
- Trauma
- Burns
- Alcohol and substance abuse
- Chronic disease (heart, lungs, kidneys, liver)
- Haematological disorders
- Recent surgery/invasive procedure
- Invasive lines: intravenous or arterial, urinary catheters, nasogastric tubes

8.24 Sites of infection in critically ill patients

Sites of infection	Investigations and comments
Major	
Intravenous lines (particularly central)	If the patient develops sepsis, replace any lines that have not been changed for > 4 days
Lungs	High risk of nosocomial pneumonia in intubated patients. After ICU stay > 3–4 days, particularly if antibiotics are given, the nasopharynx becomes colonised with Gram-negative bacteria, which migrate to the lower respiratory tract. Prophylaxis with parenteral and enteral antibiotics (selective decontamination of the digestive tract) reduces the incidence of nosocomial pneumonia
Abdomen	Consider intra-abdominal abscess or necrotic gut in patients who have had abdominal surgery Pancreatitis, acute cholecystitis or perforated peptic ulcer may develop as a complication of critical illness. Ultrasound, CT, aspiration of collections of fluid/pus and laparotomy may be required
Urinary tract	Urine culture (but this is a relatively unusual source in unexplained sepsis)
Other	
Heart valves	Transthoracic or transoesophageal echocardiogram
Meninges	Lumbar puncture after checking coagulation and platelet count
Joints and bones	X-ray, gallium or technetium white cell scan
Nasal sinuses, ears, retropharyngeal space	Clinical examination, plain X-ray, CT
Genitourinary tract (particularly post-partum)	PV examination, ultrasound
Gastrointestinal tract	PR examination, stool culture, *Clostridium difficile* toxin, sigmoidoscopy

control policies (p. 145). Limiting antibiotic use helps to prevent the emergence of multidrug-resistant bacteria.

Management

Prompt resuscitation, with early cultures, administration of appropriate antibiotics and eradication of the source of infection (if necessary by surgical drainage), is required (Box 8.25). Antibiotics should have a spectrum wide enough to cover probable causative organisms, based on the likely site of infection, whether community-acquired or nosocomial, previous antibiotic therapy and known local resistance patterns.

Other investigations required include:

- cultures of sputum, intravascular lines, urine and any wound discharge
- ABGs and coagulation profile
- urinalysis and chest X-ray.

Only 10% of ICU patients with a clinical diagnosis of 'septic' shock will have positive blood cultures, due to prior antibiotic treatment and the fact that an inflammatory state is not always due to infection. More specific investigations are driven by the history and examination (see Box 8.24).

The haemodynamic changes in septic shock are very variable and not specific for the Gram status of the infecting organism. The first feature is often tachypnoea and the early stages are frequently dominated by hypotension with relative volume depletion due to vasodilatation. Sufficient intravenous fluid should be given to ensure that the intravascular volume is not the limiting factor in determining global oxygen delivery. The type of fluid that should be administered and what constitutes 'adequate' volume resuscitation remain controversial. The response to therapy is crucial when deciding this and is frequently unpredictable, so rigid protocols cannot be used. Depending on haemoglobin concentration, blood or synthetic colloid should be given as 100–200 mL boluses to assess BP response to volume (see Fig. 8.2, p. 183).

Although ventricular function is frequently impaired, the characteristically low systemic vascular resistance (SVR) usually ensures a high cardiac output (once the patient is adequately volume-resuscitated), albeit with low BP.

The choice of the most appropriate vasoactive drug to use should be based on a full assessment of the circulation and the different inotropic, dilating or constricting properties of these drugs (see Box 8.8, p. 191). In most cases, a vasoconstrictor such as noradrenaline (norepinephrine) is necessary to increase SVR and BP, while an inotrope (dobutamine) may be necessary to maintain cardiac output. In the later stages of severe sepsis, the fundamental problem is at the microcirculatory level. Oxygen uptake and utilisation are impaired due to failure of the regional distribution of flow and direct cellular toxicity despite adequate global oxygen delivery. Tissue oxygenation may be improved and aerobic metabolism sustained by reducing demand, i.e. metabolic rate (Box 8.26). This can be achieved with sedatives and muscle relaxants (see below).

8.25 Immediate management of severe sepsis

- Give high-concentration oxygen
- Take blood cultures
- Give intravenous antibiotics (appropriate to likely organism)
- Volume-resuscitate
- Measure Hb and lactate
- Measure urine output
- Control source of infection

8.26 Factors increasing the metabolic rate in critical illness

- Fever
- Sepsis
- Trauma
- Burns
- Sympathetic activation due to pain, shivering or agitation
- Surgery
- Drugs, e.g. β-blockers, amphetamines, tricyclics
- Nursing procedures, visitors or physiotherapy

Corticosteroids

Assessment of the pituitary–adrenal axis is difficult in the critically ill but in some series up to 30% of patients have adrenal insufficiency, as assessed by a short Synacthen test (p. 778). Corticosteroid replacement therapy is controversial. Recent evidence suggests that, although it is associated with earlier resolution of shock, it has no effect on survival.

Disseminated intravascular coagulation

Also known as consumptive coagulopathy, disseminated intravascular coagulation (DIC) is an acquired disorder of haemostasis (p. 1055); it is common in critically ill patients and often heralds the onset of MOF. It is characterised by an increase in prothrombin time, partial thromboplastin time and fibrin degradation products, and a fall in platelets and fibrinogen. The clinically dominant feature may be widespread bleeding from vascular access points, gastrointestinal tract, bronchial tree and surgical wound sites, or widespread microvascular and even macrovascular thrombosis. Management is supportive with infusions of fresh frozen plasma and platelets, while the underlying cause is treated.

GENERAL PRINCIPLES OF CRITICAL CARE MANAGEMENT

Essential aspects of the management of critically ill patients on admission to the ICU are shown in Box 8.27.

8.27 Management of patients on admission to ICU

- Handover from transferring team to ICU staff
- Full clinical assessment
- Ongoing resuscitation/stabilisation
- Establishment of monitoring
- Review of medical and social history
- Communication with and explanation to relatives
- Investigations to establish or confirm the definitive diagnosis
- Formulation and implementation of a management plan

Daily clinical management in the ICU

Regular clinical examination is essential to identify any changes in a patient's condition. Detailed clinical examination is performed at least daily, with additional focused and systematic assessment on ward rounds at least twice daily. Ward rounds are also an opportunity to ensure the reliable application of evidence-based measures to reduce complications; the mnemonic FAST HUG provides a useful checklist of feeding, analgesia, sedation, thromboprophylaxis, head of bed elevation, ulcer prophylaxis, glucose control.

Patient review should include:

- Review of progress reports from nursing and medical staff, and any specialist opinions.
- Review of 24-hour charts.
- Examination: general (including skin, line sites, wounds etc.).
- System reviews:
  - *Cardiovascular*: haemodynamics, fluids and inotropes
  - *Respiratory*: ventilator settings and ABGs
  - *Gastrointestinal*: nutrition (calorie, protein intake, route), nasogastric aspirate and bowel function
  - *Renal*: urine output, overall fluid balance, urea and electrolytes, and renal replacement therapy
  - *Neurological*: sedation level, GCS and pupil responses.
- Laboratory results: haematology, coagulation and biochemistry.
- Microbiology: temperature, white blood count, line sites and other possible sources of infection, results of cultures, antibiotic therapy.
- Drug therapy: review with pharmacist, consider adverse effects and interactions, and identify drugs that can be discontinued. Medicines required for long-term conditions should be continued in the context of the acute illness. An accurate record of the patient's usual medicines must be obtained.
- Imaging: review X-rays and other specialist investigations with radiologists.
- Monitoring: are all measures still required? In particular, remove central venous catheters, arterial lines and peripheral venous catheters as soon as no longer needed, in order to avoid infection.
- Management plan: formulate an integrated plan, with specific goals for each organ system and goals for the patient, e.g. mobilising out of bed. Involve the family in the patient's care.

Sedation and analgesia

Intensive care is an extremely stressful experience for the patient, with pain, discomfort and anxiety related to endotracheal intubation, invasive monitoring and other procedures.

Most patients require sedation and analgesia to ensure comfort, relieve anxiety, and allow tolerance of an endotracheal tube, mechanical ventilation and invasive procedures. Some conditions, especially severe neurological conditions that cause brain swelling and raised ICP, require deep sedation to reduce tissue oxygen requirements and protect organs from ischaemic damage. Excessive sedation is common in ICU patients, and is associated with longer ICU stays, a higher prevalence of delirium, prolonged requirement for mechanical ventilation, and more ICU-acquired infections. The optimally sedated patient is comfortable and tolerates treatments, but is awake and lucid.

8.28 Richmond Agitation Sedation Scale (RASS)

Score	Term	Description
+4	Combative	Overtly combative, or violent or immediate danger to staff
+3	Very agitated	Pulls on/removes tubes or catheters, or aggressive to staff
+2	Agitated	Frequent non-purposeful movement or patient–ventilator dyssynchrony
+1	Restless	Anxious or apprehensive but no aggressive or vigorous movements
0	Alert and calm	
–1	Drowsy	Not fully alert but sustained awakening (>10 secs) with eye opening/contact to voice
–2	Light sedation	Brief awakening (< 10 secs) with eye contact to voice
–3	Moderate sedation	Movement but no eye contact to voice
–4	Deep sedation	Movement to physical stimulation but no response to voice
–5	Unrousable	No response to voice or physical stimulation

Sedation and analgesia are usually provided via continuous infusions of sedative and/or analgesic drugs. As many critically ill patients have impaired liver and renal function, the potential for drugs to accumulate is high and the patient's sedation must be regularly monitored. The sedative agents used ideally have predictable short half-lives that are not affected by liver or renal impairment. Short-acting intravenous agents, such as propofol, are usually employed. Analgesia can be provided using morphine infusions, but in patients with MOF, especially renal failure, active metabolites can accumulate. Opiates such as fentanyl or alfentanil, which are not renally metabolised or excreted, are commonly chosen.

Sedation is monitored via clinical sedation scales (Box 8.28) that record responses to voice and physical stimulation. Regular use of these to adjust sedation is associated with a shorter ICU stay. Many ICUs also have a daily 'sedation break', when all sedation is stopped in appropriate cases for a period, in order to re-assess the patient. This approach reduces the chance of oversedation and shortens ICU stay.

Muscle relaxants

Muscle relaxants are avoided whenever possible in ICU patients. Their use is associated with a higher prevalence of critical illness neuropathy and myopathy, resulting in muscle weakness. Sedation use also tends to be higher when muscle relaxants are employed. They are required to facilitate endotracheal intubation and to facilitate ventilation in patients with critical oxygenation and/or poor

lung compliance. Patients with critically increased ICP often receive intravenous infusions of muscle relaxant drugs such as atracurium, to help control it and to prevent coughing and high intrathoracic pressures, which increase ICP.

Delirium

Delirium is extremely common in critically ill patients. It often becomes apparent as sedation is reduced and stopped. About 60–80% of patients have hypoactive delirium, which is often missed unless formal testing is undertaken. Between 5 and 10% of patients have agitated delirium, and 10–20% a mixed pattern. Delirium of any type is associated with poorer outcome. Management is focused on reducing or avoiding precipitating factors, such as benzodiazepines and metabolic disturbances. Patients with agitated delirium should be managed with haloperidol in 2.5 mg increments, rather than additional sedatives. Some sedative drugs are associated with a lower incidence of delirium, such as α_2-adrenergic agonists (clonidine and dexmedetomidine). These have a central sedative action and can be useful in difficult cases. There is no evidence that pharmacological interventions are useful as prophylaxis or in hypoactive delirium. Additional information about diagnosis and management of delirium is given on page 1161.

DISCHARGE FROM INTENSIVE CARE

Discharge is appropriate when the original indication for admission has resolved and the patient has sufficient physiological reserve to continue recovery without the facilities of intensive care. Many ICUs and HDUs function as combined units, which allows stepdown to HDU care without a change of clinical team. Critically ill patients often have complex medical histories, multiple ongoing medical problems, and family and social issues. Many also have the emotional problems associated with survival from a life-threatening event or illness. Discharge from the ICU is stressful for patients and families, and communication with the clinical team accepting responsibility is vital. A key issue is that nursing care changes from one-to-one or one-to-two to much lower staffing levels. Discharges from ICU/HDU to standard wards should take place within normal working hours to ensure adequate medical and nursing support and detailed handover, as discharge outside normal working hours (and early discharge) are associated with higher ICU re-admission rates and increased mortality.

The receiving team should be provided with a written summary, including relevant recent investigations, and the critical care team should remain available for advice. Many ICU teams provide an outreach service to furnish advice and ensure continuity. Irrespective of the reason for admission to the ICU, many patients suffer problems (Box 8.29). These can last from weeks to many months and require ongoing support and rehabilitation.

Withdrawal of intensive support

Withdrawal of support must be considered when it is clear that the patient has no realistic prospect of recovery or of surviving with a quality of life that he or she would value. In these situations, intensive care will only prolong the dying process and is therefore futile. When intensive support is withdrawn, management remains active and is aimed at allowing the patient to die with dignity and as free from distress as possible (p. 290). Patients' views are paramount and increasing use is being made of advance directives or 'living wills'. Communication with the patient, if possible, and with the family, the referring clinicians, and between members of the critical care team is crucial (p. 165). Failure in this area causes stress and unrealistic expectations, damages working relations and leads to subsequent unhappiness, anger and litigation.

8.29 Common problems after ICU discharge

Physical

- Fatigue: almost universal and can last for many weeks
- Breathlessness
- Muscle weakness: a combination of muscle wasting from inadequate nutritional intake, muscle breakdown associated with inflammation/infection, and damage to nerves and muscle associated with severe systemic illness (critical illness polyneuropathy and polymyopathy – p. 1230)
- Altered taste and poor appetite: can result in weight loss
- Joint stiffness
- Itch
- Hair loss

Psychological

- Anxiety
- Depression
- Traumatic memories: including delusional memories (often unpleasant), dreams, flashbacks and hyperarousal. Worse in more severe and prolonged illness, more prolonged deep sedation and after delirium. Recovery occurs over weeks/months, but can persist and affect quality of life

Brainstem death

Recent advances in the resuscitation and intensive care management of brain-injured patients have inevitably increased the survival of patients who remain ventilated on ICU, in whom progression of brain injury results in brainstem death. The preconditions for considering brainstem death and the criteria for establishing the diagnosis are listed on page 1160.

When the formal criteria for brainstem death are met, it is clearly inappropriate to continue supporting life with mechanical ventilation, and the possibility of organ donation should be considered. All intensive care clinicians have a responsibility to approach relatives to seek consent for organ donation, provided there is no contraindication to their use. This can be very difficult, but is easier if the patient carried an organ donor card or was registered with an organisation such as the UK Organ Donor Register. In the UK, each region has a team of specialist nurses in organ donation who provide help with the process and with care of the potential organ donor.

OUTCOME OF INTENSIVE CARE

The measure used most widely to assess outcome from intensive care is mortality. Mortality is strongly influenced by the case mix of an ICU (the type of patients and their illness severity at admission). Typically, about 20% of ICU patients will die during their ICU stay despite treatment, and about 30% will die before leaving hospital. Some factors associated with higher mortality are shown in Box 8.30. Mortality in patients requiring HDU care is much lower. Many patients have pre-existing illnesses prior to ICU admission, which, combined with the effect of the illness that resulted in ICU admission and the subsequent complications, means that many who survive the ICU admission have reduced life expectancy compared to those of similar age in the general population. The long-term physical and psychological effects of critical illness can mean that surviving patients have a reduced quality of life for many months or years. Families often carry a heavy burden of care after critical illness. Many patients do not regain pre-illness health and may be unable to work, resulting in economic and social hardship.

Scoring systems

Admission and discharge criteria vary between ICUs, so it is important to define the characteristics of the patients admitted (case mix) in order to assess the effects of the care provided on the outcome achieved. Two systems are widely used to measure severity of illness:

- *'APACHE' II*: Acute Physiology Assessment and Chronic Health Evaluation
- *'SAPS' 2*: Simplified Acute Physiology Score.

These scores include assessment of certain admission characteristics (e.g. age and pre-existing organ dysfunction) and a variety of routine physiological measurements (e.g. temperature, BP, GCS) that reflect the response of the patient to his or her illness (Box 8.31). Patient age is included in many scoring systems (Box 8.32). When combined with the admission diagnosis, scoring systems have been shown to correlate well with the risk of hospital death. Such outcome predictions can never be 100% accurate and should be viewed as only one of many factors to be considered when deciding whether or not further intervention is appropriate.

Predicted mortality figures by diagnosis have been calculated from large databases generated from a range of ICUs. These allow a particular unit to evaluate its performance compared to the reference ICUs by calculating standardised mortality ratios (SMRs) for each diagnostic group, by dividing observed mortality by predicted mortality.

A value of unity indicates the same performance as the reference ICUs, while a value less than 1 indicates a better than predicted outcome. If a unit has a high SMR in a certain diagnostic category, it should prompt investigation into the management of patients with that diagnosis, in order to identify aspects of care that could be improved.

8.30 Factors associated with higher mortality from critical illness

- Older age
- Significant pre-existing comorbidities, especially liver disease, severe cardiorespiratory disease, malignancy, immunosuppression and chronic renal failure
- Poor pre-existing nutritional state and/or general physical condition
- Higher illness severity at ICU admission, measured with the APACHE or SAPS score (see text)
- Worse or multiple acute organ failures during ICU (especially shock, respiratory failure and acute renal failure)

8.31 Uses of critical care scoring systems

- Comparison of the performance of different units
- Assessment of new therapies
- Assessment of changes in unit policies and management guidelines
- Measurement of the cost-effectiveness of care

8.32 The critically ill older patient

- **ICU demography**: increasing numbers of critically ill older patients are admitted to the ICU; more than 50% of patients in many general ICUs are over 65 years old.
- **Outcome**: affected to some extent by age, as reflected in APACHE II, but age should not be used as the sole criterion for withholding or withdrawing ICU support.
- **Cardiopulmonary resuscitation (CPR)**: successful hospital discharge following in-hospital CPR is rare in patients over 70 years old in the presence of significant chronic disease.
- **Functional independence**: tends to be lost during an ICU stay and prolonged rehabilitation may subsequently be necessary.
- **Specific problems**:
  Skin fragility and ulceration
  Poor muscle strength: difficulty in weaning from ventilator and in mobilising
  Delirium: compounded by sedatives and analgesics
  High prevalence of underlying nutritional deficiency.

COMPREHENSIVE EVALUATION OF THE POISONED PATIENT

Insets (*Self-cutting*) From Douglas, et al. 2005; (*Burn*) www.firewiki.net; (*Needle tracks*) www.deep6inc.com; (*Pupil*) drugrecognition.com; (*Conjunctiva*) knol.google.com – see p. 230.

Taking a history in poisoning

- What toxin(s) have been taken and how much?
- What time were they taken and by what route?
- Has alcohol or any drug of misuse been taken as well?
- Obtain details from witnesses of the circumstances of the overdose (e.g. family, friends ambulance personnel)
- Ask the general practitioner for background and details of prescribed medication
- Assess suicide risk (full psychiatric evaluation when patient has physically recovered)
- Assess capacity to make decisions about accepting or refusing treatment
- Establish past medical history, drug history and allergies, social and family history
- Record all information carefully

Pupil size
Small: opioids, clonidine, organophosphorus compounds
Large: tricyclic antidepressants, amphetamines, cocaine

Respiratory rate
Reduced: opioids, benzodiazepines
Increased: salicylates

Blood pressure
Hypotension: tricyclic antidepressants, haloperidol
Hypertension: cocaine, α-adrenoceptor agonists

Right upper quadrant /renal angle tenderness
Paracetamol hepatotoxicity, renal toxicity

Epigastric tenderness
NSAIDs, salicylates

Rhabdomyolysis
Amphetamines, caffeine

Cerebellar signs
Some anticonvulsants, alcohol

Extrapyramidal signs
Phenothiazines, haloperidol, metoclopramide

Cyanosis
Any CNS depressant drug or agent (N.B. consider methaemoglobinaemia caused by dapsone, amyl nitrite)

Heart rate
Tachycardia or tachyarrhythmias: tricyclic antidepressants, theophylline, digoxin, antihistamines
Bradycardia or bradyarrhythmias: digoxin, β-blockers, calcium channel blockers, opioids

Needle tracks
Drugs of misuse: opioids etc.

Body temperature
Hyperthermia and sweating: ecstasy, serotonin re-uptake inhibitors, salicylates
Hypothermia: any CNS depressant drug, opioids, chlorpromazine

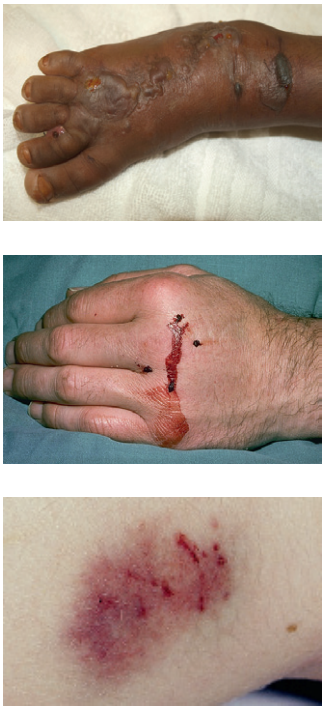
Clinical signs of poisoning by pharmaceutical agents and drugs of misuse.

EVALUATION OF THE ENVENOMED PATIENT

Assessment of type and extent of envenoming

Neurotoxic paralysis
- 'Sleepy' or drooping eyelids
- Difficulty swallowing, dysarthria and drooling
- Limb weakness
- Respiratory distress

Excitatory neurotoxicity
- Sweating, salivation, piloerection
- Tingling around mouth or tongue, muscle twitching
- Dyspnoea (pulmonary oedema)



Myolysis
- Muscle pain or weakness

Coagulopathy
- Blood oozing from bite site and/or gums
- Bruising
- Melaena, haematemesis

Local effects
- Pain, sweating, blistering, bruising etc.

Taking a history in envenoming

- When was the patient exposed to a bite/sting?
- Was the organism causing it seen and what did it look like (size, colour)?
- What were the circumstances (on land, in water etc.)?
- Was there more than one bite/sting?
- What first aid was used, when and for how long?
- What symptoms has the patient had (local and systemic)?
- Are there symptoms suggesting systemic envenoming (paralysis, myolysis, coagulopathy etc.)?
- Past medical history and medications?
- Past exposure to antivenom/venom and allergies?

Bites showing puncture marks, blistering, bruising and bleeding.

Acute poisoning is common, accounting for about 1% of hospital admissions in the UK. Common or otherwise important substances involved are shown in Box 9.1. In developed countries, the most frequent cause is intentional drug overdose in the context of self-harm and usually involves prescribed or 'over-the-counter' medicines. Accidental poisoning is also common, especially in children and the elderly (Box 9.2). Toxicity also may occur as a result of alcohol or recreational substance use, or following occupational or environmental exposure. Poisoning is a major cause of death in young adults, but most deaths occur before patients reach medical attention, and mortality is much lower than 1% in those admitted to hospital.

In developing countries, the frequency of self-harm is more difficult to estimate. Household and agricultural products, such as pesticides and herbicides, are more freely available, are common sources of poisoning and are associated with a much higher case fatality. In China and South-east Asia, pesticides account for about 300 000 suicides each year.

GENERAL APPROACH TO THE POISONED PATIENT

A general approach is shown on pages 206–207.

9.1 Important substances involved in poisoning

In the UK

- Analgesics: paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs)
- Antidepressants: tricyclic antidepressants (TCAs), selective serotonin re-uptake inhibitors (SSRIs) and lithium
- Cardiovascular agents: β-blockers, calcium channel blockers and cardiac glycosides
- Drugs of misuse: opiates, benzodiazepines, stimulants (e.g. amphetamines, MDMA, cocaine)
- Carbon monoxide
- Alcohol

In South and South-east Asia

- Organophosphorus and carbamate insecticides
- Aluminium and zinc phosphide
- Oleander
- Snake venoms
- Antimalarial drugs: chloroquine
- Antidiabetic medication

9.2 Poisoning in old age

- **Aetiology**: commonly results from accidental poisoning (e.g. due to confusion or dementia) or drug toxicity as a consequence of impaired renal or hepatic function or drug interaction. Toxic prescription medicines are more likely to be available.
- **Psychiatric illness**: self-harm is less common than in younger adults but more frequently associated with depression and other psychiatric illness, as well as chronic illness and pain. There is a higher risk of subsequent suicide.
- **Severity of poisoning**: increased morbidity and mortality result from reduced renal and hepatic function, reduced functional reserve, increased sensitivity to sedative agents and frequent comorbidity.

Triage and resuscitation

Patients who are seriously poisoned must be identified early so that appropriate management is not delayed. Triage involves:

- immediate assessment of vital signs
- identifying the poison(s) involved and obtaining adequate information about them
- identifying patients at risk of further attempts at self-harm and removing any remaining hazards.

Those with possible external contamination with chemical or environmental toxins should undergo appropriate decontamination (Fig. 9.1). Critically ill patients must be resuscitated (p. 180).

The Glasgow Coma Scale (GCS) is commonly employed to assess conscious level, although it has not been specifically validated in poisoned patients. The AVPU (alert/verbal/painful/unresponsive) scale is also a rapid and simple method. An electrocardiogram (ECG) should be performed and cardiac monitoring instituted in all patients with cardiovascular features or where exposure to potentially cardiotoxic substances is suspected. Patients who may need antidotes should be weighed when this is feasible, so that appropriate weight-related doses can be prescribed.

Substances that are unlikely to be toxic in humans should be identified so that inappropriate admission and intervention are avoided (Box 9.3).

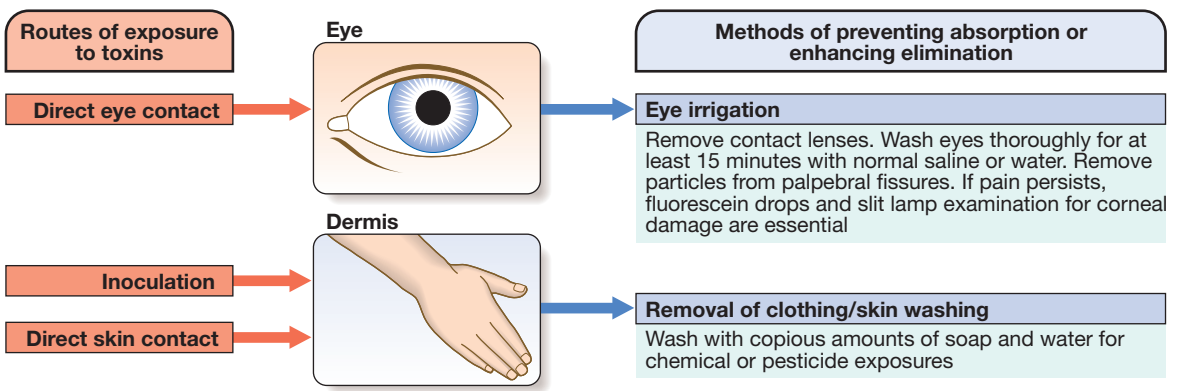


Fig. 9.1 Methods of external decontamination.

9.3 Substances of very low toxicity

- Writing/educational materials
- Decorating products
- Cleaning/bathroom products (except dishwasher tablets, which are corrosive)
- Pharmaceuticals: oral contraceptives, most antibiotics (but not tetracyclines and antituberculous drugs), H_2-blockers, proton pump inhibitors, emollients and other skin creams, baby lotion
- Miscellaneous: plasticine, silica gel, household plants, plant food

Clinical assessment and investigations

History and examination are described on page 206. Occasionally, patients may be unaware or confused about what they have taken, or may exaggerate (or less commonly underestimate) the size of the overdose, but rarely mislead medical staff deliberately. In regions of the world where self-poisoning is illegal, patients may be reticent about giving a history.

Toxic causes of abnormal physical signs are shown on page 207. The patient may have a cluster of clinical features ('toxidrome') suggestive of poisoning with a particular drug type, e.g. anticholinergic, serotoninergic (see Box 9.11, p. 213), stimulant, sedative, opioid (see Box 9.12, p. 217) or cholinergic (see Box 9.14, p. 221) feature clusters. Poisoning is a common cause of coma, especially in younger people, but it is important to exclude other potential causes (p. 1159), unless the aetiology is certain.

Urea, electrolytes and creatinine should be measured in all patients with suspected systemic poisoning. Arterial blood gases should be checked in those with significant respiratory or circulatory compromise, or when poisoning with substances likely to affect acid–base status is suspected (Box 9.4). Calculation of anion and osmolar gaps may help to inform diagnosis and management (Box 9.5).

For a limited number of specific substances, management may be facilitated by measurement of the amount of toxin in the blood (Box 9.6). Qualitative urine screens for potential toxins, including near-patient testing kits, have a limited clinical role.

9.4 Causes of acidosis in the poisoned patient

Cause	Normal lactate*	High lactate
Toxic	Salicylates Methanol Ethylene glycol Paraldehyde	Metformin Iron Cyanide Sodium valproate Carbon monoxide
Other	Renal failure Ketoacidosis Severe diarrhoea	Shock

*Unless circulatory shock is present, when it will be high in any case.

9.5 Anion and osmolal gaps in poisoning

	Anion gap	Osmolal gap
Calculation	$[Na^+ + K^+] - [Cl^- + HCO_3^-]$	[Osm (measured)] $[2 \times$ Na + Urea + Glucose (all mmol/L)][1]
Reference range	12–16 mmol/L	< 10 mOsm/kg
Common toxic causes of elevation[2]	Ethanol Ethylene glycol Methanol Salicylates Iron Cyanide	Ethanol Ethylene glycol Methanol

[1]Osm (measured) stands for measured osmolality. For non-SI units, the corresponding formula is [Osm (measured)] – [2 × Na (meq/L) + Urea/2.8 (mg/dL) + Glucose/18 (mg/dL)].
[2]Box 16.19 (p. 445) gives non-toxic causes.

9.6 Laboratory analysis in poisoning

Organophosphates

- Plasma cholinesterase is reduced more rapidly but is less specific than red cell cholinesterase (p. 222)
- Antidote use should not be delayed pending results

Carboxyhaemoglobin

- > 20% indicates significant carbon monoxide exposure

Digoxin

- Therapeutic range usually 1–2 ng/mL (1.28–2.46 mmol/L)
- Concentrations > 4 ng/mL (5.12 mmol/L) usually associated with toxicity, especially with chronic poisoning

Ethanol

- Toxicity at concentrations > 1.8 g/L

Iron

- Take sample ≥ 4 hrs after overdose or if clinical signs of toxicity
- Concentrations > 5 mg/L suggest severe toxicity

Lithium

- Take sample ≥ 6 hrs after overdose or if clinical signs of toxicity
- Usual therapeutic range 0.4–1.0 mmol/L

Methaemoglobin

- Poisoning with nitrites, benzocaine, dapsone, chloroquine and aniline dyes is associated with methaemoglobinaemia
- Concentrations > 20% may require treatment with methylthioninium chloride (methylene blue)

Paracetamol

- Take sample ≥ 4 hrs after overdose
- Use nomogram to determine need for antidotal treatment (see Fig. 9.2, p. 212)

Salicylate

- Take sample ≥ 2 hrs (symptomatic patients) or 4 hrs (asymptomatic patients) after overdose
- Concentrations > 500 mg/L suggest serious toxicity
- Repeat after 2 hrs if severe toxicity is suspected

Theophylline

- Take sample ≥ 4 hrs after overdose or if clinical signs of toxicity
- Repeat after 2 hrs if severe toxicity is suspected
- Concentrations > 60 mg/L suggest severe toxicity

Psychiatric assessment

All patients presenting with deliberate drug overdose should undergo psychiatric evaluation by a health professional with appropriate training prior to discharge (p. 238). This should take place once the patient has recovered from any features of poisoning, unless there is an urgent issue, such as uncertainty about their capacity to decline medical treatment.

General management

Patients presenting with eye/skin contamination should undergo local decontamination procedures (see Fig. 9.1).

Gastrointestinal decontamination

Patients who have ingested potentially life-threatening quantities of toxins may be considered for gastrointestinal decontamination if poisoning has been recent (Box 9.7). Induction of emesis using ipecacuanha is no longer recommended.

Activated charcoal

Given orally as slurry, activated charcoal absorbs toxins in the bowel as a result of its large surface area. If given sufficiently early, it can prevent absorption of an important proportion of the ingested dose of toxin. Efficacy decreases with time and current guidelines do not advocate use more than 1 hour after overdose in most circumstances (see Box 9.7). However, use after a longer interval may be reasonable when a delayed-release preparation has been taken or when gastric emptying may be delayed. Some toxins do not bind to activated charcoal (Box 9.8) so it will not affect their absorption. In patients with impaired swallowing or a reduced level of consciousness, activated charcoal, even via a nasogastric tube, carries a risk of aspiration pneumonitis, which can be reduced (but not eliminated) by protecting the airway with a cuffed endotracheal tube.

EBM 9.7 Use of gastric decontamination methods

'Single-dose activated charcoal may be considered if a patient has ingested a potentially toxic amount of a poison (known to be adsorbed to charcoal) up to 1 hr previously.'[1]

'Multiple-dose activated charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine or theophylline.'[2]

'Gastric lavage should not be employed routinely, if ever, in the management of poisoned patients.'[3]

'Whole bowel irrigation should be considered for:
- poisoning with sustained-release or emetic-coated drugs
- patients who have ingested substantial amounts of iron (as morbidity is high and other options are limited)
- removal of ingested packets of illicit drugs.

- [4]J Toxicol Clin Toxicol 2004; 42:843–42854.

9.8 Substances poorly adsorbed by activated charcoal

Medicines	
• Iron	• Lithium
Chemicals	
• Acids*	• Mercury
• Alkalis*	• Methanol
• Ethanol	• Petroleum distillates*
• Ethylene glycol	

*Gastric lavage contraindicated.

Multiple doses of oral activated charcoal (50 g 6 times daily in an adult) may enhance the elimination of some drugs at any time after poisoning and are recommended for serious poisoning with some substances (see Box 9.7). This interrupts enterohepatic circulation or reduces the concentration of free drug in the gut lumen, to the extent that drug diffuses from the blood back into the bowel to be absorbed on to the charcoal: so-called 'gastrointestinal dialysis'. A laxative is generally given with the charcoal to reduce the risk of constipation or intestinal obstruction by charcoal 'briquette' formation in the gut lumen.

Evidence suggests that single or multiple doses of activated charcoal do not improve clinical outcomes after poisoning with pesticides or oleander.

Gastric aspiration and lavage

Gastric aspiration and/or lavage is very infrequently indicated in acute poisoning, as it is no more effective than activated charcoal and complications are common, especially aspiration. Use may be justified for life-threatening overdoses of some substances that are not absorbed by activated charcoal (see Box 9.8).

Whole bowel irrigation

This is occasionally indicated to enhance the elimination of ingested packets of illicit drugs or slow-release tablets such as iron and lithium that are not absorbed by activated charcoal. It involves the administration of large quantities of osmotically balanced polyethylene glycol and electrolyte solution (1–2 L/hr for an adult), usually by a nasogastric tube, until the rectal effluent is clear. Contraindications include inadequate airway protection, haemodynamic instability, gastrointestinal haemorrhage, obstruction or ileus. Whole bowel irrigation may precipitate nausea and vomiting, abdominal pain and electrolyte disturbances.

Urinary alkalinisation

Urinary excretion of weak acids and bases is affected by urinary pH, which changes the extent to which they are ionised. Highly ionised molecules pass poorly through lipid membranes and therefore little tubular reabsorption occurs and urinary excretion is increased. If the urine is alkalinised (pH > 7.5) by the administration of sodium bicarbonate (e.g. 1.5 L of 1.26% sodium bicarbonate over 2 hrs), weak acids (e.g. salicylates, methotrexate and the herbicides 2,4-dichlorophenoxyacetic acid and mecoprop) are highly ionised, resulting in enhanced urinary excretion.

Urinary alkalinisation is currently recommended for patients with clinically significant salicylate poisoning when the criteria for haemodialysis are not met (see below). It is also sometimes used for poisoning with methotrexate. Complications include alkalaemia, hypokalaemia and occasionally alkalotic tetany (p. 447). Hypocalcaemia may occur but is rare.

Haemodialysis and haemoperfusion

These techniques can enhance the elimination of poisons that have a small volume of distribution and a long half-life after overdose, and are appropriate when poisoning is sufficiently severe to justify invasive elimination methods. The toxin must be small enough to cross the dialysis membrane (haemodialysis) or must bind to activated charcoal (haemoperfusion) (Box 9.9). Haemodialysis may also correct acid–base and metabolic disturbances associated with poisoning (p. 209).

9.9 Poisons effectively eliminated by haemodialysis or haemoperfusion

Haemodialysis	
• Ethylene glycol	• Salicylates
• Isopropanol	• Sodium valproate
• Methanol	• Lithium
Haemoperfusion	
• Theophylline	• Phenobarbital
• Phenytoin	• Amobarbital
• Carbamazepine	

Lipid emulsion therapy

Lipid emulsion therapy, or 'lipid rescue', is being used increasingly for the management of poisoning with lipid-soluble agents, such as local anaesthetics, tricyclic antidepressants, calcium channel blockers and lipid-soluble β-blockers such as propranolol. It involves intravenous infusion of 20% lipid emulsion (e.g. Intralipid®) at an initial dose of 1.5 mL/kg, followed by a continued infusion of 0.25 mL/kg/min until there is clinical improvement. It is thought that lipid-soluble toxins partition into the intravenous lipid, reducing target tissue concentrations. The elevated myocardial concentration of free fatty acid induced by Intralipid administration may also have beneficial effects on myocardial metabolism and performance by counteracting the inhibition of myocardial fatty acid oxidation produced by local anaesthetics and some other cardiotoxins. This reverses cardiac depression by enabling increased ATP synthesis and energy production. Animal studies have suggested efficacy and case reports of use in human poisoning have also been encouraging, with recovery of circulatory collapse reported in cases where other treatment modalities have been unsuccessful. No controlled trials of this technique have been performed, however, and as a result, its efficacy remains uncertain.

9.10 Complications of poisoning and their management

	Examples of causative agents	Management
Coma	Sedative agents	Appropriate airway protection and ventilatory support Pressure area and bladder care Identification and treatment of aspiration pneumonia
Seizures	NSAIDs Anticonvulsants TCAs Theophylline	Appropriate airway and ventilatory support IV benzodiazepine (e.g. diazepam 10–20 mg, lorazepam 2–4 mg) Correction of hypoxia, acid–base and metabolic abnormalities
Acute dystonias	Typical antipsychotics Metoclopramide	Procyclidine, benzatropine or diazepam
Hypotension		
Due to vasodilatation	Vasodilator antihypertensives Anticholinergic agents TCAs	IV fluids Vasopressors (rarely indicated; p. 191)
Due to myocardial suppression	β-blockers Calcium channel blockers TCAs	Optimisation of volume status Inotropic agents (p. 191)
Ventricular tachycardia		
Monomorphic, associated with QRS prolongation	Sodium channel blockers	Correction of electrolyte and acid–base abnormalities and hypoxia Sodium bicarbonate
Torsades de pointes, associated with QT_c prolongation	Anti-arrhythmic drugs (quinidine, amiodarone, sotalol) Antimalarials Organophosphate insecticides Antipsychotic agents Antidepressants Antibiotics (erythromycin)	Magnesium sulphate, 2 g IV over 1–2 mins, repeated if necessary

Supportive care

For most poisons, antidotes and methods to accelerate elimination are inappropriate, unavailable or incompletely effective. Outcome is dependent on appropriate nursing and supportive care, and on treatment of complications (Box 9.10). Patients should be monitored carefully until the effects of any toxins have dissipated.

Antidotes

Antidotes are available for some poisons and work by a variety of mechanisms: for example, by specific antagonism (isoprenaline for β-blockers), chelation (desferrioxamine for iron) or reduction (methylene blue for dapsone). The use of some antidotes is described in the management of specific poisons below.

POISONING BY SPECIFIC PHARMACEUTICAL AGENTS

Analgesics

Paracetamol

Paracetamol (acetaminophen) is the drug most commonly used in overdose in the UK. Toxicity results from formation of an intermediate reactive metabolite that binds covalently to cellular proteins, causing cell death. This results in hepatic and occasionally renal failure. In therapeutic doses, the toxic intermediate metabolite is detoxified in reactions requiring glutathione, but in overdose, glutathione reserves become exhausted.

Management

Management is summarised in Figure 9.2. Activated charcoal may be used in patients presenting within 1 hour. Antidotes for paracetamol act by replenishing hepatic glutathione and should be administered to all patients with paracetamol concentrations above the 'treatment line' provided on paracetamol poisoning nomograms. Acetylcysteine given intravenously (or orally in some countries) is highly efficacious if administered within 8 hours of the overdose. However, since efficacy declines thereafter, administration should not be delayed in patients presenting after 8 hours to await a paracetamol blood concentration result. The antidote can be stopped if the paracetamol concentration is shown to be below the nomogram treatment line.

The most important adverse effect of acetylcysteine is related to dose-related histamine release, the 'anaphylactoid' reaction, which causes itching and urticaria, and in occasional severe cases, bronchospasm and hypotension. Most cases can be managed by temporary discontinuation of acetylcysteine and administration of an antihistamine.

An alternative antidote is methionine 2.5 g orally (adult dose) every 4 hours to a total of 4 doses, but this is less effective, especially after delayed presentation. If a patient presents more than 15 hours after ingestion, liver function tests, prothrombin time (or international normalised ratio – INR), renal function tests and a venous bicarbonate should be measured, the antidote started, and a poisons information centre or local liver unit contacted for advice if results are abnormal. An arterial blood gas sample should be taken in patients with severe liver function abnormalities; metabolic acidosis indicates severe poisoning. Liver transplantation should be considered in individuals who develop life-threatening liver failure due to paracetamol poisoning (p. 932).

If multiple ingestions of paracetamol have taken place over several hours or days (i.e. a staggered overdose), acetylcysteine may be indicated. Recommended thresholds for treatment vary between countries.

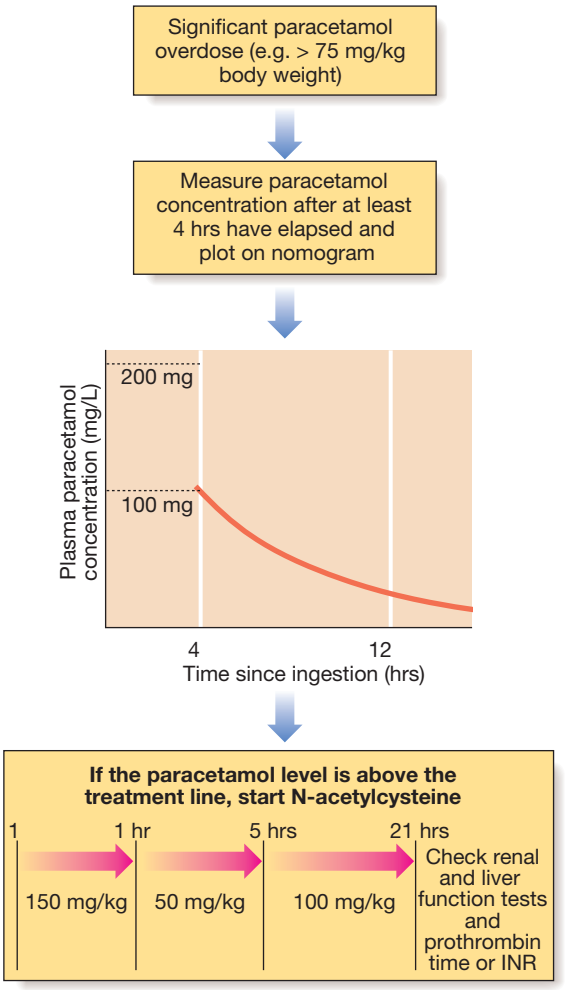

Fig. 9.2 The management of a paracetamol overdose.

Salicylates (aspirin)

Clinical features

Salicylate overdose commonly causes nausea, vomiting, sweating, tinnitus and deafness. Direct stimulation of the respiratory centre produces hyperventilation and respiratory alkalosis. Peripheral vasodilatation with bounding pulses and profuse sweating occurs in moderately severe poisoning. Serious salicylate poisoning is associated with metabolic acidosis, hypoprothrombinaemia, hyperglycaemia, hyperpyrexia, renal failure, pulmonary oedema, shock and cerebral oedema. Agitation, confusion, coma and fits may occur, especially in children. Toxicity is enhanced by acidosis, which increases salicylate transfer across the blood–brain barrier.

Management

Activated charcoal should be administered if the patient presents within 1 hour. Multiple doses of activated charcoal may enhance salicylate elimination but currently are not routinely recommended.

The plasma salicylate concentration should be measured at least 2 (in symptomatic patients) or 4 hours (asymptomatic patients) after overdose and repeated in suspected serious poisoning, since concentrations may continue to rise some hours after overdose. In adults, concentrations above 500 mg/L and 700 mg/L suggest serious and life-threatening poisoning respectively, although clinical status is more important than the salicylate concentration in assessing severity.

Dehydration should be corrected carefully, as there is a risk of pulmonary oedema, and metabolic acidosis should be identified and treated with intravenous sodium bicarbonate (8.4%), once plasma potassium has been corrected. Urinary alkalinisation is indicated for adults with salicylate concentrations above 500 mg/L.

Haemodialysis is very effective at removing salicylate and correcting acid–base and fluid balance abnormalities, and should be considered when serum concentrations are above 700 mg/L in adults with severe toxic features, or when there is renal failure, pulmonary oedema, coma, convulsions or refractory acidosis.

Non-steroidal anti-inflammatory drugs

Clinical features

Overdose of most non-steroidal anti-inflammatory drugs (NSAIDs) usually causes little more than minor abdominal discomfort, vomiting and/or diarrhoea, but convulsions can occur occasionally, especially with mefenamic acid. Coma, prolonged seizures, apnoea, liver dysfunction and renal failure can occur after substantial overdose but are rare. Features of toxicity are unlikely to develop in patients who are asymptomatic more than 6 hours after overdose.

Management

Electrolytes, liver function tests and a full blood count should be checked in all but the most trivial cases. Activated charcoal may be given if the patient presents sufficiently early. Symptomatic treatment for nausea and gastrointestinal irritation may be necessary.

Antidepressants

Tricyclic antidepressants

Tricyclic antidepressants (TCAs) are used frequently in overdose and carry a high morbidity and mortality relating to their sodium channel-blocking, anticholinergic and α-adrenoceptor-blocking effects.

Clinical features

Anticholinergic effects are common (Box 9.11). Life-threatening complications are frequent, including convulsions, coma, arrhythmias (ventricular tachycardia, ventricular fibrillation and, less commonly, heart block) and hypotension, which results from inappropriate vasodilatation or impaired myocardial contractility. Serious complications appear to be more common with dosulepin and amitriptyline.

9.11 Anticholinergic and serotonergic feature clusters

	Anticholinergic	Serotonin syndrome
Common causes	Benzodiazepines Antipsychotics TCAs Antihistamines Scopolamine Benzatropine Belladonna Jimson weed Mushrooms (some)	SSRIs Monoamine oxidase inhibitors (MAOIs) TCAs Amphetamines Buspirone Bupropion (especially in combination)
Clinical features		
Cardiovascular	Tachycardia, hypertension	Tachycardia, hyper- or hypotension
CNS	Confusion, hallucinations, sedation	Confusion, delirium, hallucinations, sedation, coma
Muscle	Myoclonus	Shivering, tremor, myoclonus, raised creatine kinase
Temperature	Fever	Fever
Eyes	Diplopia, mydriasis	Normal pupil size
Abdomen	Ileus, palpable bladder	Diarrhoea, vomiting
Mouth	Dry	
Skin	Flushing, hot, dry	Flushing, sweating
Complications	Seizures	Seizures Rhabdomyolysis Renal failure Metabolic acidosis Coagulopathies

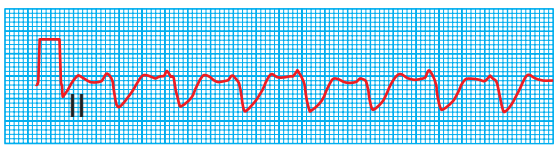

Fig 9.3 ECG in severe tricyclic antidepressant poisoning. This rhythm strip shows a broad QRS complex due to impaired conduction.

Management

Activated charcoal should be administered if the patient presents within 1 hour. All patients with possible TCA overdose should have a 12-lead ECG and ongoing cardiac monitoring for at least 6 hours. Prolongation of the QRS interval (especially if > 0.16 s) indicates severe sodium channel blockade and is associated with an increased risk of arrhythmia (Fig. 9.3). QT interval prolongation may also occur. Arterial blood gases should be measured in suspected severe poisoning.

In patients with arrhythmias, significant QRS or QT prolongation or acidosis, intravenous sodium bicarbonate (50 mL of 8.4% solution) should be administered and repeated to correct pH. The correction of the acidosis and the sodium loading that result is often associated with rapid improvement in ECG features and arrhythmias. Hypoxia and electrolyte abnormalities should also be corrected. Anti-arrhythmic drugs should only be given on specialist advice. Prolonged convulsions should be treated with intravenous benzodiazepines (see Box 9.10). There is anecdotal evidence of benefit

from lipid emulsion therapy in severe intractable poisoning.

Selective serotonin and noradrenaline re-uptake inhibitors

Selective serotonin re-uptake inhibitors (SSRIs) are a group of antidepressants that include fluoxetine, paroxetine, fluvoxamine, sertraline, citalopram and escitalopram. They are increasingly used to treat depression, partly because they are less toxic in overdose than TCAs. A related group of compounds termed serotonin–noradrenaline reuptake inhibitors (SNRIs), such as venlafaxine and duloxetine, are also in common use and are sometimes taken in overdose.

Clinical features and management

Overdose of SSRIs may produce nausea and vomiting, tremor, insomnia and sinus tachycardia. Agitation, drowsiness and convulsions occur infrequently and may be delayed for several hours after ingestion. Occasionally, features of serotonin syndrome may develop (see Box 9.11), especially if SSRIs are taken in combination or with other serotonergic agents. Cardiac arrhythmias occur infrequently and most patients require supportive care only. The toxic effects of SNRIs are similar but tachycardia, hypertension or hypotension and ECG changes (QRS and QT prolongation) may be more prominent and hypoglycaemia can also occur.

Lithium

Severe lithium toxicity is uncommon after intentional overdose and is more often encountered in patients taking therapeutic doses as the result of interactions with drugs such as diuretics or NSAIDs that can cause dehydration or renal impairment, or because an excessive dose has been prescribed. Severe toxicity is more common with acute overdose in patients taking chronic therapy ('acute on chronic' poisoning).

Clinical features

Nausea, diarrhoea, polyuria, dizziness and tremor may progress to muscular weakness, drowsiness, confusion, myoclonus, fasciculations, choreoathetosis and renal failure. Coma, convulsions, ataxia, cardiac dysrhythmias such as heart block, blood pressure disturbances and renal failure may all occur in severe poisoning.

Management

Activated charcoal is ineffective. Gastric lavage is of theoretical benefit if used early after overdose, but lithium tablets are likely to remain intact in the stomach and may be too large for aspiration via a lavage tube. Some advocate whole bowel irrigation after substantial overdose but efficacy is unknown.

Lithium concentrations should be measured immediately in symptomatic patients or after at least 6 hours in asymptomatic patients following acute overdose. Adequate hydration should be maintained with intravenous fluids. Convulsions should be treated as in Box 9.10.

In patients with features suggesting severe toxicity associated with high lithium concentrations (e.g. > 4.0 mmol/L after chronic or 'acute on chronic' poisoning, or > 7.5 mmol/L after acute poisoning), haemodialysis should be considered. Lithium concentrations are reduced substantially during dialysis but rebound increases occur after discontinuation, and multiple sessions may be required.

Cardiovascular medications

Beta-adrenoceptor blockers

These have negative inotropic and chronotropic effects. Some have additional properties that may increase toxicity, such as blockade of sodium channels with propranolol, acebutolol and carvedilol, and blockade of potassium channels with sotalol.

Clinical features

The major features of toxicity are bradycardia and hypotension. Heart block, pulmonary oedema and cardiogenic shock occur in severe poisoning. Beta-blockers with sodium channel-blocking effects may cause seizures, confusion and coma, while sotalol may be associated with repolarisation abnormalities (including QT_c prolongation) and torsades de pointes (p. 570).

Management

Intravenous fluids may reverse hypotension but care is required to avoid pulmonary oedema. Bradycardia and hypotension may respond to high doses of atropine (up to 3 mg in an adult). The adrenoceptor agonist isoprenaline may also be effective but high doses are often needed. Glucagon (5–10 mg over 10 mins, then 1–5 mg/hr by infusion), which counteracts the effect of β-blockers by stimulating intracellular production of cyclic adenosine monophosphate (cAMP), is now more commonly used. In severe cases, 'hyperinsulinaemia euglycaemic therapy' has been used, as described under calcium channel blockers. Lipid emulsion therapy may have a role in severe poisoning with lipid-soluble agents such as propranolol, carvedilol and oxprenolol.

Calcium channel blockers

Calcium channel blockers are highly toxic in overdose because of their inhibitory effects on L-type calcium channels. Dihydropyridines, such as nifedipine or amlodipine, affect vascular smooth muscle in particular, resulting in vasodilatation, whereas diltiazem and verapamil, which are used in the treatment of arrhythmias, have predominantly cardiac effects, including bradycardia and reduced myocardial contractility.

Clinical features

The usual presentation is with hypotension due to vasodilatation or myocardial depression. Bradycardias and heart block may also occur, especially with verapamil and diltiazem. Gastrointestinal disturbances, confusion, metabolic acidosis, hyperglycaemia and hyperkalaemia may also be present.

Management

Hypotension should be corrected with intravenous fluids, taking care to avoid pulmonary oedema. Persistent hypotension may respond to intravenous calcium gluconate (10 mg IV over 5 mins, repeated as required). Isoprenaline and glucagon may also be useful. Successful use of intravenous insulin with glucose (10–20%

dextrose with insulin initially at 0.5–2.0 U/kg/hr, increasing to 5–10 U/kg/hr according to clinical response), so-called 'hyperinsulinaemia euglycaemic therapy', has been reported in patients unresponsive to other strategies. The mechanism of action remains to be fully elucidated, but in states of shock myocardial metabolism switches from use of free fatty acids to glucose. Calcium channel blocker poisoning is also associated with hypoinsulinaemia and insulin resistance, impeding glucose uptake by myocytes. High doses of insulin inhibit lipolysis and increase glucose uptake and the efficiency of glucose utilisation. Cardiac pacing may be needed for severe unresponsive bradycardias or heart block. Lipid emulsion therapy has been used in severe poisoning with apparent benefit, although evidence is largely anecdotal.

Digoxin and oleander

Poisoning with digoxin is usually accidental, arising from prescription of an excessive dose, impairment of renal function or drug interactions. In South Asia, deliberate self-poisoning with yellow oleander (*Thevetia peruviana*), which contains cardiac glycosides, is common.

Clinical features

Characteristic cardiac effects of toxicity are tachyarrhythmias (either atrial or ventricular) and bradycardias, with or without atrioventricular block. Ventricular bigeminy is common and atrial tachycardia with evidence of atrioventricular block is highly suggestive of the diagnosis. Severe poisoning is associated with hyperkalaemia. Non-cardiac features include confusion, headache, nausea, vomiting, diarrhoea and (rarely) altered colour vision.

Management

Activated charcoal is commonly administered to patients presenting within 1 hour of ingestion of an acute overdose, although evidence of benefit is lacking. Urea, electrolytes and creatinine should be measured, a 12-lead ECG performed and cardiac monitoring instituted. Hypoxia, hypokalaemia (sometimes associated with concurrent diuretic use), hypomagnesaemia and acidosis increase the risk of arrhythmias and should be corrected. Significant bradycardias may respond to atropine, although temporary pacing is sometimes needed. Ventricular arrhythmias may respond to intravenous magnesium (see Box 9.10). If available, digoxin-specific antibody fragments should be administered when there are severe ventricular arrhythmias or unresponsive bradycardias. This antidote has been shown to be effective for both digitalis and yellow oleander poisoning.

Antimalarials

Chloroquine

Chloroquine is highly toxic in overdose and quantities of 5 g or more of chloroquine base are likely to be fatal in an adult.

Clinical features

Features of toxicity occur within 1 hour of ingestion and include nausea, vomiting, agitation, drowsiness, hypokalaemia, acidosis, headaches and blurred vision. Coma, convulsions and hypotension may occur in severe poisoning. ECG changes indicating conduction and repolarisation delay (prolonged QRS and QT_c intervals) occur and are associated with ventricular tachycardia (including torsades de pointes), ventricular fibrillation and sudden death.

Management

Activated charcoal should be given to all patients presenting within 1 hour of ingestion of chloroquine in amounts greater than 15 mg/kg. Cardiac rhythm should be monitored and dysrhythmias managed as outlined in Box 9.10. The arterial pH should be corrected, but hypokalaemia is thought to have a protective effect and should not be corrected in the first 8 hours after poisoning. High-dose diazepam (2 mg/kg body weight IV over 30 mins followed by an infusion of 2 mg/kg/hr) has been suggested to have a protective effect, especially if given in the early stages of severe chloroquine poisoning, but evidence is limited as yet. One controlled trial did not show beneficial effects on the ECG. Diazepam therapy requires intubation and mechanical ventilation to avoid pulmonary aspiration.

Quinine

Quinine salts are widely used for treating malaria and leg cramps. Deaths have been reported with ingestion of as little as 1.5 g in an adult and 900 mg in a child.

Clinical features

Features of toxicity include nausea, vomiting, tremor, tinnitus and deafness. Hypotension, haemolysis, renal failure, ataxia, convulsions and coma are features of serious poisoning. Conduction and repolarisation delay results in prolonged QRS and QT_c intervals on the ECG, and ventricular tachycardia (including torsades de pointes), ventricular fibrillation and sudden death may occur. Quinine-induced retinal photoreceptor cell toxicity may result in blurred vision and impaired colour perception. This usually develops a few hours after overdose and progresses to constriction of the visual field, scotoma and complete blindness associated with pupillary dilatation and unresponsiveness to light. Fundoscopy may show retinal artery spasm, disc pallor and retinal oedema. Although visual loss can be permanent, some degree of recovery, especially of central vision, often occurs over several weeks.

Management

Multiple-dose activated charcoal should be commenced in patients who have taken quinine in amounts greater than 15 mg/kg. Gastric lavage should be considered in patients who have taken a substantial overdose who present within 1 hour. All patients should have a 12-lead ECG and cardiac monitoring, and their urea, electrolytes and glucose checked. Dysrhythmias, hypotension, seizures and coma should be managed as outlined in Box 9.10.

There are no effective treatments for the visual effects of quinine. Stellate ganglion block and retrobulbar or intravenous injections of vasodilators such as nitrates were previously used but are ineffective, as are haemodialysis and haemoperfusion.

Iron

Overdose with iron can cause severe and sometimes fatal poisoning. The toxicity of individual iron preparations is related to their elemental iron content.

Clinical features

Early clinical features include gastrointestinal disturbance with the passage of grey or black stools. Hyperglycaemia and leucocytosis may occur. Haematemesis, rectal bleeding, drowsiness, convulsions, coma, metabolic acidosis and cardiovascular collapse may occur in severe poisoning.

Early symptoms may improve or even resolve within 6–12 hours, but hepatocellular necrosis may develop 12–24 hours after overdose and occasionally progresses to hepatic failure. Gastrointestinal strictures are late complications of iron poisoning.

Management

Gastric lavage may be considered in patients presenting within 1 hour of life-threatening overdose but efficacy has not been established. Activated charcoal is ineffective since iron is not bound. Serum iron concentration should be measured (see Box 9.6, p. 209). The antidote desferrioxamine chelates iron and should be administered immediately in patients with severe features, without waiting for serum iron concentrations to be available. Symptomatic patients with high serum iron concentrations (e.g. > 5 mg/L) should also receive desferrioxamine. Desferrioxamine may cause hypotension, allergic reactions and occasionally pulmonary oedema. Otherwise, treatment is supportive and directed at complications.

Antipsychotic drugs

Antipsychotic drugs (p. 248) are often prescribed for patients at high risk of self-harm or suicide, and are commonly encountered in overdose.

Clinical features

Drowsiness, tachycardia and hypotension are frequently found. Anticholinergic features (see Box 9.11) and acute dystonias, such as oculogyric crisis, torticollis and trismus, may occur after overdose with typical antipsychotics like haloperidol or chlorpromazine. QT interval prolongation and torsades de pointes can occur with typical antipsychotics such as thioridazine and haloperidol, as well as atypical antipsychotics like quetiapine, amisulpride and ziprasidone. Convulsions may occur with both groups of agent.

Management

Activated charcoal may be of benefit if given within 1 hour of overdose. Cardiac monitoring should be undertaken for at least 6 hours. Management is largely supportive, with treatment directed at complications (see Box 9.10, p. 211).

Antidiabetic agents

Antidiabetic agents commonly causing toxicity in overdose include sulphonylureas such as chlorpropamide, glibenclamide, gliclazide, glipizide and tolbutamide; biguanides like metformin and phenformin; and insulins. Overdose may also be encountered with some of the newer antidiabetic drugs, such as thiazolidinediones (pioglitazone), meglinides (nateglinide, repaglinide) and dipeptidyl peptidase (DPP)-IV inhibitors (sitagliptin).

Clinical features

Sulphonylureas, meglitinides and parenteral insulin cause hypoglycaemia when taken in overdose, although insulin is non-toxic if ingested by mouth. The duration of hypoglycaemia depends on the half-life or release characteristics of the preparation and may be prolonged over several days with long-acting agents such as chlorpropamide, insulin zinc suspension or insulin glargine.

Features of hypoglycaemia include nausea, agitation, sweating, aggression and behavioural disturbances, confusion, tachycardia, hypothermia, drowsiness, coma or convulsions (p. 814). Permanent neurological damage can occur if hypoglycaemia is prolonged. Hypoglycaemia can be diagnosed using bedside glucose strips but venous blood should also be sent for laboratory confirmation.

Metformin is uncommonly associated with hypoglycaemia. Its major toxic effect in overdose is lactic acidosis, which can have a high mortality, and is particularly common in older patients and those with renal or hepatic impairment, or when ethanol is co-ingested. Other features of metformin overdose are nausea and vomiting, diarrhoea, abdominal pain, drowsiness, coma, hypotension and cardiovascular collapse.

There is limited experience of overdose involving thiazolidinediones and DPP-IV inhibitors, but significant hypoglycaemia is unlikely.

Management

Activated charcoal should be considered for all patients who present within 1 hour of ingestion of a substantial overdose of an oral hypoglycaemic agent. Venous blood glucose and urea and electrolytes should be measured and tests repeated regularly. Hypoglycaemia should be corrected using oral or intravenous glucose (50 mL of 50% dextrose); an infusion of 10–20% dextrose may be required to prevent recurrence. Intramuscular glucagon can be used as an alternative, especially if intravenous access is unavailable. Failure to regain consciousness within a few minutes of normalisation of the blood glucose can indicate that a central nervous system (CNS) depressant has also been ingested, the hypoglycaemia has been prolonged, or that the coma has another cause (e.g. cerebral haemorrhage or oedema).

Arterial blood gases should be taken after metformin overdose to assess the extent of acidosis. If present, plasma lactate should be measured and acidosis should be corrected with intravenous sodium bicarbonate (250 mL 1.26% solution or 50 mL 8.4% solution, repeated as necessary). In severe cases, haemodialysis or haemodiafiltration is used.

DRUGS OF MISUSE

Cannabis

Cannabis is derived from the dried leaves and flowers of *Cannabis sativa*. When it is smoked, the onset of effect occurs within 10–30 minutes, whereas after ingestion

9.12 Stimulant, sedative and opioid feature clusters

	Stimulant	Sedative hypnotic	Opioid

[1]Especially barbiturates. [2]IV use.

the onset is 1–3 hours later. The duration of effect is 4–8 hours. Cannabis produces euphoria, perceptual alterations and conjunctival injection, followed by enhanced appetite, relaxation and occasionally hypertension, tachycardia, slurred speech and ataxia. High doses may produce anxiety, confusion, hallucinations and psychosis (Box 9.12). Psychological dependence is common but tolerance and withdrawal symptoms are unusual. Long-term use is thought to increase the lifetime risk of developing schizophrenia. Ingestion or smoking of cannabis rarely results in serious poisoning and supportive treatment is all that is required.

Benzodiazepines

Benzodiazepines may be prescribed or used illicitly. They are of low toxicity when taken alone in overdose but can enhance CNS depression when taken with other sedative agents, including alcohol. They may also cause significant toxicity in the elderly and those with chronic lung or neuromuscular disease.

Clinical features

Clinical features of toxicity include drowsiness, ataxia and confusion (see Box 9.12). Respiratory depression and hypotension may occur with severe poisoning in susceptible groups, especially after intravenous administration of short-acting agents.

Management

Activated charcoal may be useful after ingestion in susceptible patients or after mixed overdose, if given within 1 hour. Conscious level, respiratory rate and oxygen saturation should be monitored for at least 6 hours after substantial overdose.

The specific benzodiazepine antagonist flumazenil increases conscious level in patients with overdose but carries a risk of seizures, and is contraindicated in patients co-ingesting proconvulsant agents such as TCAs and in those with a history of seizures.

Stimulants and entactogens

This group includes amphetamines, ecstasy, cathinones such as mephedrone, piperazines and cocaine. These are sympathomimetic and serotonergic amines; as a result, they have clinical features of poisoning that overlap (see Box 9.12).

Cocaine

Cocaine is available as a water-soluble hydrochloride salt suitable for nasal inhalation ('snorting'), or as an insoluble free base ('crack' cocaine) that, unlike the hydrochloride salt, vaporises at high temperature and can be smoked, giving a more rapid and intense effect. Cocaine hydrochloride is usually purchased as a white crystalline powder, and crack cocaine in 'rocks'.

Clinical features

Effects appear rapidly after inhalation and especially after smoking. Sympathomimetic stimulant effects are common (see Box 9.12). Serious complications usually occur within 3 hours of use and include coronary artery spasm, which may result in myocardial ischaemia or infarction, even in patients with normal coronary arteries. This may lead to hypotension, cyanosis and ventricular arrhythmias. Cocaine toxicity should be considered in young adults who present with ischaemic chest pain. Hyperpyrexia may be associated with rhabdomyolysis, acute renal failure and disseminated intravascular coagulation.

Management

All patients should be observed with ECG monitoring for a minimum of 4 hours. A 12-lead ECG should be performed. Abnormalities are common, including ST segment elevation, which may occur even in the absence of myocardial infarction. Troponin T estimations are the most sensitive and specific markers of myocardial damage. Benzodiazepines and intravenous nitrates are useful for managing patients with chest pain or hypertension, but β-blockers are best avoided because of the risk of unopposed α-adrenoceptor stimulation. Coronary angiography should be considered in patients with myocardial infarction or acute coronary syndromes. Acidosis should be corrected. Physical cooling measures may be required for hyperthermia (p. 105).

Amphetamines and cathinones

These include amphetamine sulphate ('speed'), methylamphetamine ('crystal meth'), 3,4-methylenedioxymethamphetamine (MDMA, 'ecstasy') and mephedrone. Tolerance is common, leading regular users to seek progressively higher doses.

Clinical features

Toxic features usually appear within a few minutes of use and last 4–6 hours, or substantially longer after a large overdose. Sympathomimetic stimulant and serotonergic effects are common (see Boxes 9.11 and 9.12). A proportion of ecstasy users develop hyponatraemia as a result of excessive water drinking and inappropriate antidiuretic hormone secretion. Muscle rigidity, pain and bruxism (clenching of the jaw) may occur. Hyperpyrexia, rhabdomyolysis, metabolic acidosis, acute renal failure, disseminated intravascular coagulation, hepatocellular necrosis, acute respiratory distress syndrome (ARDS) and cardiovascular collapse have all been described following MDMA use but are rare. Cerebral infarction and haemorrhage have been reported, especially after intravenous amphetamine use.

Management

Management is supportive and directed at complications (see Box 9.10, p. 211).

Gammahydroxybutyrate and gamma butyrolactone

Gamma hydroxybuterate (GHB) and gamma butyrolactone (GBL) are sedative agents with psychedelic and body-building effects. They are easily manufactured from commonly available industrial chemicals, including 1,4 butanediol, which is metabolised to GHB in vivo and has similar effects after ingestion. GHB solution is drunk by users, who titrate the dose until the desired effects are achieved.

Clinical features

Toxic features are those of a sedative hypnotic (see Box 9.12). Nausea, diarrhoea, vertigo, tremor, myoclonus, extrapyramidal signs, euphoria, bradycardia, convulsions, metabolic acidosis, hypokalaemia and hyperglycaemia may also occur. As the drug may be produced in batches and shared amongst a number of individuals, several patients may present with coma at the same time. The sedative effects are potentiated by other CNS depressants, such as alcohol, benzodiazepines, opioids and neuroleptics. Coma usually resolves spontaneously and abruptly within a few hours but may occasionally persist for several days. Dependence may develop in regular users, who may experience severe prolonged withdrawal effects if use is discontinued abruptly.

Management

Activated charcoal is recommended within 1 hour for ingestion of GHB in amounts greater than 20 mg/kg. Urea, electrolytes and glucose should be measured in all but the most trivial of cases. All patients should be observed for a minimum of 2 hours, with monitoring of blood pressure, heart rate, respiratory rate and oxygenation. Patients who remain symptomatic should be observed in hospital until symptoms resolve, but require supportive care only. Withdrawal may require treatment with high doses of benzodiazepines.

d-Lysergic acid diethyamide

d-Lysergic acid diethylamide (LSD) is a synthetic hallucinogen usually ingested as small squares of impregnated absorbent paper (often printed with a distinctive design) or as 'microdots'. The drug causes perceptual effects, such as heightened visual awareness of colours, distortion of images, and hallucinations that may be pleasurable or terrifying ('bad trip') and associated with panic, confusion, agitation or aggression. Dilated pupils, hypertension, pyrexia and metabolic acidosis may occur and psychosis may sometimes last several days.

Patients with psychotic reactions or CNS depression should be observed in hospital, preferably in a quiet, dimly lit room to minimise external stimulation. Where sedation is required, diazepam is the drug of choice. Antipsychotics should be avoided if possible, as they may precipitate cardiovascular collapse or convulsions.

Opioids

Commonly encountered opioids are shown in Box 9.12. Toxicity may result from misuse of illicit drugs such as heroin or after overdose of medicinal opiates such as dextropropoxyphene. Intravenous use of heroin or morphine gives a rapid, intensely pleasurable experience, often accompanied by heightened sexual arousal. Physical dependence occurs within a few weeks of regular high-dose injection; as a result, the dose is escalated and the user's life becomes increasingly centred on obtaining and taking the drug. Withdrawal, which can start within 12 hours, presents with intense craving, rhinorrhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting, diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

Accidental overdose with prescribed strong opioid preparations is common, especially in the elderly.

Clinical features

These are shown in Box 9.12. Needle tracks may be visible in intravenous drug misusers and drug-related paraphernalia may be found amongst their possessions. Severe poisoning results in respiratory depression, hypotension, non-cardiogenic pulmonary oedema and hypothermia, leading to respiratory arrest or aspiration of gastric contents. Dextropropoxyphene (the opioid component of co-proxamol) may cause cardiac conduction effects, particularly QRS prolongation, ventricular arrhythmias and heart block, and has been withdrawn in the UK and other countries. Methadone may cause QT_c prolongation and torsades de pointes.

Symptoms of opioid poisoning can be prolonged for up to 48 hours after use of long-acting agents such as methadone, dextropropoxyphene and oxycodone.

Management

The airway should be cleared and, if necessary, respiratory support and oxygen given. Oxygen saturation monitoring and measurement of arterial blood gases should be performed. Prompt use of the specific opioid antagonist naloxone (0.4–2 mg IV in an adult, repeated if necessary) may obviate the need for intubation, although excessive doses may precipitate acute withdrawal in chronic opiate users. An infusion may be required in some cases because the half-life of the antidote is short compared to that of most opiates, especially those with prolonged elimination. Patients must be monitored for at least 6 hours after the last naloxone dose. Other complications of naloxone therapy include fits and ventricular arrhythmias, although these are rare. Box 9.10 (p. 211) describes the management of coma, fits and hypotension. Non-cardiogenic pulmonary oedema does not usually respond to diuretic therapy, and continuous positive airways pressure (CPAP) or positive end-expiratory pressure (PEEP) ventilatory support (p. 193) may be required.

Body packers and body stuffers

Body packers ('mules') attempt to smuggle illicit drugs (usually cocaine, heroin or amphetamines) by ingesting multiple small packages wrapped in several layers of clingfilm or in condoms. Body stuffers are those who have ingested unpackaged or poorly wrapped substances, often to avoid arrest. Both groups are at risk of severe toxicity if the packages rupture. This is more likely for body stuffers, who may start to develop symptoms of poisoning within 8 hours of ingestion. The risk of poisoning depends on the quality of the wrapping, and the amount and type of drug ingested. Cocaine, for example, presents a much higher risk than heroin because of its high toxicity and lack of a specific antidote.

Fig. 9.4 Abdominal X-ray of a body packer showing multiple drug-filled condoms.

Patients suspected of body packing or stuffing should be admitted for observation. A careful history taken in private is important, but for obvious reasons patients may withhold details of the drugs involved. The mouth, rectum and vagina should be examined as possible sites for concealed drugs. A urine toxicology screen performed at intervals may provide evidence of leakage, although positive results may reflect earlier recreational drug use. Packages may be visible on plain abdominal films (Fig. 9.4), but this is not always the case, and ultrasound and computed tomography (CT) are more sensitive methods of visualisation. One of these (preferably CT) should be performed in all suspected body packers.

Antimotility agents are often used by body packers to prevent premature passage of packages, so it can take a number of days for packages to pass spontaneously; during this period the carrier is at risk from package rupture. Whole bowel irrigation is commonly used to accelerate passage and is continued until all packages have passed. Surgery may be required for mechanical bowel obstruction or when evolving clinical features suggest package rupture, especially with cocaine.

CHEMICALS AND PESTICIDES

Carbon monoxide

Carbon monoxide (CO) is a colourless, odourless gas produced by faulty appliances burning organic fuels. It is also present in vehicle exhaust fumes and sometimes in smoke from house fires. It causes toxicity by binding with haemoglobin and cytochrome oxidase, which

reduces tissue oxygen delivery and inhibits cellular respiration. It is a common cause of death by poisoning and most patients who die of CO poisoning do so before reaching hospital.

Clinical features

Early clinical features of acute severe carbon monoxide poisoning include headache, nausea, irritability, weakness and tachypnoea. Because these are non-specific, the correct diagnosis will not be obvious if the exposure is occult, such as from a faulty domestic appliance. Subsequently, ataxia, nystagmus, drowsiness and hyperreflexia may develop, progressing to coma, convulsions, hypotension, respiratory depression, cardiovascular collapse and death. Myocardial ischaemia may occur and results in arrhythmias or myocardial infarction. Cerebral oedema is common and rhabdomyolysis may lead to myoglobinuria and renal failure. In those who recover from acute toxicity, longer-term neuropsychiatric effects are common, such as personality change, memory loss and concentration impairment. Extrapyramidal effects, urinary or faecal incontinence, and gait disturbance may also occur. Poisoning during pregnancy may cause fetal hypoxia and intrauterine death.

Management

Patients should be removed from exposure as soon as possible and resuscitated as necessary. Oxygen should be administered in as high a concentration as possible via a tightly fitting facemask, as this reduces the half-life of carboxyhaemoglobin from 4–6 hours to about 40 minutes. Measurement of carboxyhaemoglobin is useful for confirming exposure (see Box 9.6, p. 209) but levels do not correlate well with the severity of poisoning, partly because concentrations fall rapidly after removal of the patient from exposure, especially if supplemental oxygen has been given.

An ECG should be performed in all patients with acute poisoning, especially those with pre-existing heart disease. Arterial blood gas analysis should be checked in those with serious poisoning. Oxygen saturation readings by pulse oximetry are misleading since both carboxyhaemoglobin and oxyhaemoglobin are measured. Excessive intravenous fluid administration should be avoided, particularly in the elderly, because of the risk of pulmonary and cerebral oedema. Convulsions should be controlled with diazepam.

Hyperbaric oxygen therapy is controversial. At 2.5 atmospheres it reduces the half-life of carboxyhaemoglobin to about 20 minutes and increases the amount of dissolved oxygen by a factor of 10, but systematic reviews have shown no improvement in clinical outcomes. The logistical difficulties of transporting sick patients to hyperbaric chambers and managing them therein should not be underestimated.

Organophosphorus insecticides and nerve agents

Organophosphorus (OP) compounds (Box 9.13) are widely used as pesticides, especially in developing countries. The case fatality rate following deliberate ingestion of OP pesticides in developing countries in Asia is 5–20%.

9.13 Organophosphorus compounds

Nerve agents

- G agents: sarin, tabun, soman
- V agents: VX,VE

Insecticides

Dimethyl compounds
- Dichlorvos
- Fenthion
- Malathion
- Methamidophos

Diethyl compounds
- Chlorpyrifos
- Diazinon
- Parathion-ethyl
- Quinalphos

Nerve agents developed for chemical warfare are derived from OP insecticides but are much more toxic. They are commonly classified as G (originally synthesised in Germany) or V ('venomous') agents. The 'G' agents, such as tabun, sarin and soman, are volatile, absorbed by inhalation or via the skin, and dissipate rapidly after use. 'V' agents, such as VX, are contact poisons unless aerosolised, and contaminate ground for weeks or months.

The toxicology and management of nerve agent and pesticide poisoning are similar.

Mechanism of toxicity

OP compounds phosphonylate the active site of acetylcholinesterase (AChE), inactivating the enzyme and leading to the accumulation of acetylcholine (ACh) in cholinergic synapses (Fig. 9.5). Spontaneous hydrolysis of the OP–enzyme complex allows reactivation of the enzyme. However, loss of a chemical group from the OP–enzyme complex prevents further enzyme reactivation, a process termed 'ageing'. After ageing has taken place, new enzyme needs to be synthesised before function can be restored. The rate of ageing is an important determinant of toxicity and is more rapid with dimethyl compounds (3.7 hours) than diethyl (31 hours), and especially rapid after exposure to nerve agents (soman in particular), which cause ageing within minutes.

Clinical features and management

OP poisoning causes an acute cholinergic phase, which may occasionally be followed by the intermediate syndrome or organophosphate-induced delayed polyneuropathy (OPIDN). The onset, severity and duration of poisoning depend on the route of exposure and agent involved. Cholinergic features may be prolonged over several weeks with some lipid-soluble agents.

Acute cholinergic syndrome

The acute cholinergic syndrome usually starts within a few minutes of exposure. Nicotinic or muscarinic features may be present (Box 9.14). Vomiting and profuse diarrhoea are typical following oral ingestion. Bronchoconstriction, bronchorrhoea and salivation may cause severe respiratory compromise. Miosis is characteristic and the presence of muscle fasciculations strongly suggests the diagnosis, although this feature is often absent, even in serious poisoning. Subsequently, the patient may develop generalised flaccid paralysis which can affect respiratory and ocular muscles and result in respiratory failure. Ataxia, coma and convulsions may

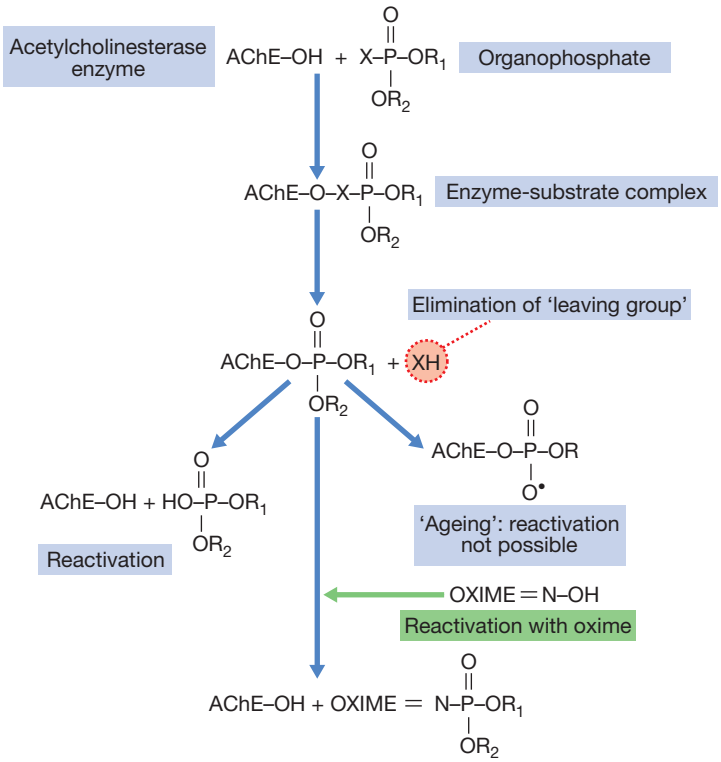

Fig. 9.5 Mechanism of toxicity of organophosphorus compounds and treatment with oxime.

9.14 Cholinergic features in poisoning*

	Cholinergic muscarinic	Cholinergic nicotinic
Respiratory	Bronchorrhoea, bronchoconstriction	Reduced ventilation
Cardiovascular	Bradycardia, hypotension	Tachycardia, hypertension
CNS	Confusion	–
Muscle	–	Fasciculation, paralysis
Temperature	Fever	–
Eyes	Diplopia, mydriasis	Lacrimation, miosis
Abdomen	Ileus, palpable bladder	Vomiting, profuse diarrhoea
Mouth	Dry	Salivation
Skin	Flushing, hot, dry	Sweating
Complications	Seizures	Seizures

*Both muscarinic and nicotinic features occur in OP poisoning. Nicotinic features occur in nicotine poisoning and black widow spider bites. Cholinergic features are sometimes seen with some mushrooms.

occur. In severe poisoning, cardiac repolarisation abnormalities and torsades de pointes may occur. Other early complications of OP poisoning include extrapyramidal features, pancreatitis, hepatic dysfunction and pyrexia.

Management

The airway should be cleared of excessive secretions, breathing and circulation assessed, high-flow oxygen administered and intravenous access obtained. In the event of external contamination, further exposure should be prevented, contaminated clothing and contact lenses removed, the skin washed with soap and water, and the eyes irrigated. Gastric lavage or activated charcoal may be considered if the patient presents within 1 hour of ingestion. Convulsions should be treated as described in Box 9.10 (p. 211). The ECG, oxygen saturation, blood gases, temperature, urea and electrolytes, amylase and glucose should be monitored closely.

Early use of sufficient doses of atropine is potentially life-saving in patients with severe toxicity. Atropine reverses ACh-induced bronchospasm, bronchorrhoea, bradycardia and hypotension. When the diagnosis is uncertain, a marked increase in heart rate associated with skin flushing after a 1 mg intravenous dose makes OP poisoning unlikely. In OP poisoning, atropine should be administered in doses of 0.6–2 mg IV, repeated every 10–25 mins until secretions are controlled, the skin is dry and there is a sinus tachycardia. Large doses may be needed but excessive doses may cause anticholinergic effects (see Box 9.11, p. 213).

In patients requiring atropine, an oxime such as pralidoxime chloride (or obidoxime), if available, should also be administered, as this may reverse or prevent muscle weakness, convulsions or coma, especially if given rapidly after exposure. The pralidoxime dose for an adult is 2 g IV over 4 mins, repeated 4–6 times daily. Oximes work by reactivating AChE that has not undergone 'ageing' and are therefore less effective with dimethyl compounds and nerve agents, especially soman. Oximes may provoke hypotension, especially if administered rapidly.

Ventilatory support should be instituted before the patient develops respiratory failure (p. 193).

Benzodiazepines may be used to reduce agitation and fasciculations, treat convulsions and sedate patients during mechanical ventilation.

Exposure is confirmed by measurement of plasma (butyrylcholinesterase) or red blood cell cholinesterase activity. These correlate poorly with the severity of clinical features, although values are usually less than 10% in severe poisoning, 20–50% in moderate poisoning and > 50% in subclinical poisoning.

The acute cholinergic phase usually lasts 48–72 hours, with most patients requiring intensive cardiorespiratory support and monitoring.

The intermediate syndrome

About 20% of patients with OP poisoning develop weakness that spreads rapidly from the ocular muscles to those of the head and neck, proximal limbs and the muscles of respiration, resulting in ventilatory failure. This 'intermediate syndrome' (IMS) generally develops quite rapidly between 1 and 4 days after exposure, often after resolution of the acute cholinergic syndrome, and may last 2–3 weeks. There is no specific treatment but supportive care, including maintenance of airway and ventilation, should be provided if necessary.

Organophosphate-induced delayed polyneuropathy

Organophosphate-induced delayed polyneuropathy (OPIDN) is a rare complication that usually occurs 2–3 weeks after acute exposure. It is a mixed sensory/motor polyneuropathy, especially affecting long myelinated neurons, and appears to result from inhibition of enzymes other than AChE. It is a feature of poisoning with some OPs such as trichlorocresylphosphate, but is less common with nerve agents,. Early clinical features are muscle cramps followed by numbness and paraesthesiae, proceeding to flaccid paralysis of the lower and subsequently the upper limbs. Paralysis of the lower limbs is associated with foot drop and a high-stepping gait, progressing to paraplegia. Paralysis of the arms leads to wrist drop. Sensory loss may also be present but is variable. Initially, tendon reflexes are reduced or lost but mild spasticity may develop later.

There is no specific therapy for OPIDN. Regular physiotherapy may limit deformity caused by muscle-wasting. Recovery is often incomplete and may be limited to the hands and feet, although substantial functional recovery after 1–2 years may occur, especially in younger patients.

Carbamate insecticides

Carbamate insecticides such as aldicarb, carbofuran and methomyl inhibit a number of tissue esterases, including AChE. The mechanism of action, clinical features and management are similar to those of OP compounds. However, clinical features tend to be less severe and of shorter duration, because the carbamate–AChE complex dissociates quickly, with a half-life of 30–40 minutes, and does not undergo ageing. Also, carbamates penetrate the CNS poorly. OPIDN and IMS are not common features of carbamate poisoning. Pancreatitis has been reported as a sequel, and deaths have occurred.

Atropine may be given intravenously in frequent small doses (0.6–2.0 mg IV for an adult) until signs of atropinisation develop. Diazepam may be used to relieve anxiety. The use of oximes is unnecessary.

Methanol and ethylene glycol

Ethylene glycol (1,2-ethanediol) is found in antifreeze, brake fluids and, in lower concentrations, windscreen washes. Methanol is present in some antifreeze products and commercially available industrial solvents, and in low concentrations in some screen washes and methylated spirits. It may also be an adulterant of illicitly produced alcohol. Both are rapidly absorbed after ingestion. Although methanol and ethylene glycol are not of high intrinsic toxicity, they are converted via alcohol dehydrogenase to toxic metabolites that are largely responsible for their clinical effects (Fig. 9.6).

Clinical features

Early features with either methanol or ethylene glycol include ataxia, drowsiness, dysarthria and nystagmus, often associated with vomiting. As the toxic metabolites are formed, metabolic acidosis, tachypnoea, coma and seizures may develop.

Toxic effects of ethylene glycol include ophthalmoplegia, cranial nerve palsies, hyporeflexia and myoclonus. Renal pain and acute tubular necrosis occur because of precipitation of calcium oxalate in the kidneys. Hypocalcaemia, hypomagnesaemia and hyperkalaemia are common.

Features of methanol poisoning include headache, confusion and vertigo. Visual impairment and photophobia develop, associated with optic disc and retinal oedema and impaired pupil reflexes. Blindness may be permanent, although some recovery may occur over several months. Pancreatitis and abnormal liver function have also been reported.

Management

Urea, electrolytes, chloride, bicarbonate, glucose, calcium, magnesium, albumin and plasma osmolarity and arterial blood gases should be measured in all

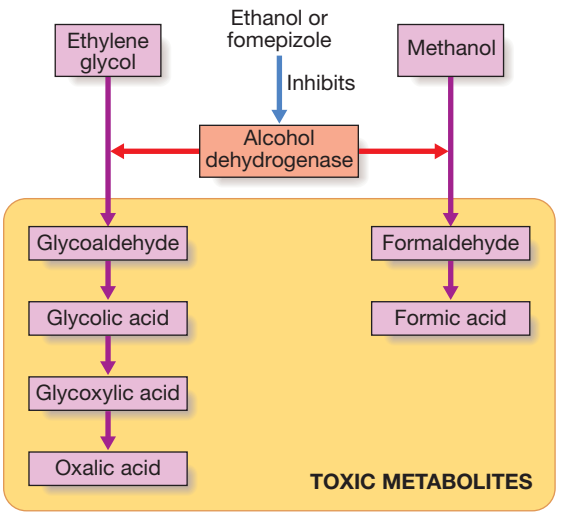

Fig. 9.6 Metabolism of methanol and ethylene glycol.

patients with suspected methanol or ethylene glycol toxicity. The osmolal and anion gaps should be calculated (see Box 9.5, p. 209). Initially, poisoning is associated with an increased osmolar gap, but as toxic metabolites are produced, an increased anion gap associated with metabolic acidosis will develop. The diagnosis can be confirmed by measurement of ethylene glycol or methanol concentrations, but assays are not widely available.

An antidote, either ethanol or fomepizole, should be administered to all patients with suspected significant exposure while awaiting the results of laboratory investigations. These block alcohol dehydrogenase and delay the formation of toxic metabolites until the parent drug is eliminated in the urine or by dialysis. The antidote should be continued until ethylene glycol or methanol concentrations are undetectable. Metabolic acidosis should be corrected with sodium bicarbonate (e.g. 250 mL of 1.26% solution, repeated as necessary). Convulsions should be treated with an intravenous benzodiazepine. In ethylene glycol poisoning, hypocalcaemia should only be corrected if there are severe ECG features or seizures occur, since this may increase calcium oxalate crystal formation.

Haemodialysis or haemodiafiltration should be used in severe poisoning, especially if renal failure is present or there is visual loss in the context of methanol poisoning. It should be continued until acute toxic features are no longer present and ethylene glycol or methanol concentrations are no longer detectable.

Aluminium and zinc phosphide

These rodenticides and fumigants are a common means of self-poisoning in northern India. The mortality rate for aluminium phosphide ingestion has been estimated at 60%; zinc phosphide ingestion appears less toxic, at about 2%. When ingested, both compounds react with gastric acid to form phosphine, a potent pulmonary and gastrointestinal toxicant. Clinical features include severe gastrointestinal disturbances, chest tightness, cough and breathlessness progressing to ARDS and respiratory failure, tremor, paraesthesiae, convulsions, coma, tachycardia, metabolic acidosis, electrolyte disturbances, hypoglycaemia, myocarditis, liver and renal failure, and leucopenia. Just a few tablets can be fatal.

Detection of phosphine in the exhaled air or stomach aspirate using either a silver nitrate-impregnated strip or specific phosphine detector tube is diagnostic, but gas chromatography provides the most sensitive indicator. Treatment is supportive and directed at correcting electrolyte abnormalities and treating complications; there is no specific antidote. Early gastric lavage is sometimes used, often with vegetable oil to reduce the release of toxic phosphine, but the benefit is uncertain.

ENVIRONMENTAL POISONING AND ILLNESS

Arsenism

Chronic arsenic exposure from drinking water has been reported in many countries, especially India, Bangladesh, Nepal, Thailand, Taiwan, China, Mexico and South America, where a large proportion of the drinking water (ground water) has a high arsenic content, placing large population groups at risk. The World Health Organization (WHO) guideline value for arsenic content in tube well water is 10 µg/L.

9.15 Clinical features of chronic arsenic poisoning

Gastrointestinal tract
• Anorexia, vomiting, weight loss, diarrhoea, increased salivation, metallic taste
Neurological
• Peripheral neuropathy (sensory and motor) with muscle wasting and fasciculation, ataxia
Skin
• Hyperpigmentation, palmar and plantar keratosis, alopecia, multiple epitheliomas, Mee's lines (transverse white lines on finger nails)
Eyes
• Conjunctivitis, corneal necrosis and ulceration
Bone marrow
• Aplastic anaemia
Other
• Low-grade fever, vasospasm and gangrene, jaundice, hepatomegaly, splenomegaly
Increased risk of malignancy
• Lung, liver, bladder, kidney, larynx and lymphoid system

Health effects associated with chronic exposure to arsenic in drinking water are shown in Box 9.15. In exposed individuals, high concentrations of arsenic are present in bone, hair and nails. Specific treatments are of no benefit in chronic arsenic toxicity and recovery from the peripheral neuropathy may never be complete. The emphasis should be on the prevention of exposure to arsenic in drinking water.

Fluorosis

Fluoride poisoning can result either from exposure to excessive quantities of fluoride (> 10 ppm) in drinking water or from industrial exposure to fluoride dust and consumption of brick teas. Clinical features include yellow staining and pitting of permanent teeth, osteosclerosis, soft tissue calcification, deformities (e.g. kyphosis) and joint ankylosis. Changes in the bones of the thoracic cage may lead to rigidity that causes dyspnoea on exertion. Very high doses of fluoride may cause abdominal pain, nausea, vomiting, seizures and muscle spasm. In calcium-deficient children, the toxic effects of fluoride manifest even at marginally high exposures to fluoride.

In endemic areas, such as Jordan, Turkey, Chile, India, Bangladesh, China and Tibet, fluorosis is a major public health problem. The maximum impact is seen in communities engaged in physically strenuous agricultural or industrial activities. Dental fluorosis is endemic in East Africa and some West African countries.

SUBSTANCES LESS COMMONLY TAKEN IN OVERDOSE

Boxes 9.16 and 9.17 respectively give an overview of the clinical features and management for some substances that are less often encountered in overdose.

9.16 Clinical features associated with substances taken less commonly in overdose

Anticonvulsants

Carbamazepine, phenytoin
- Cerebellar signs
- Convulsions
- Cardiac arrhythmias
- Coma

Sodium valproate
- Coma
- Metabolic acidosis

Isoniazid
- Peripheral neuropathy
- Convulsions

Theophylline
- Cardiac arrhythmias
- Convulsions
- Coma

Corrosives and bleach
- Injuries to stomach (esp. acids) and oesophagus (esp. alkali)
- GI perforation and late strictures
- Aspiration pneumonitis

Lead, e.g. chronic occupational exposure, leaded paint, water contaminated by lead pipes, use of kohl cosmetics
- Abdominal pain
- Microcytic anaemia with basophilic stippling
- Headache and encephalopathy
- Motor neuropathy
- Nephrotoxicity
- Hypertension
- Hypocalcaemia

Petroleum distillates, white spirit, kerosene
- Vomiting
- Aspiration pneumonitis

Paraquat
- Progressive respiratory fibrosis with respiratory failure
- Buccal ulceration
- Renal failure

Organochlorines, e.g. DDT, lindane, dieldrin, endosulfan
- Nausea, vomiting
- Agitation
- Fasciculation
- Paraesthesiae (face, extremities)
- Convulsions
- Coma
- Respiratory depression
- Cardiac arrhythmias
- Hyperthermia
- Rhabdomyolysis
- Pulmonary oedema
- Disseminated intravascular coagulation

Pyrethroid insecticides, e.g. cypermethrin, permethrin, imiprothrin
- Skin contact: dermatitis, skin paraesthesiae
- Eye contact: lacrimation, photophobia and oedema of the eyelids
- Inhalation: dyspnoea, nausea, headaches
- Ingestion: epigastric pain, nausea, vomiting, headache, coma, convulsions, pulmonary oedema

Anticoagulant rodenticides, (e.g. brodifacoum, bromodialone) and warfarin
- Abnormal bleeding (prolonged)

9.17 Specific management of poisoning by substances taken less commonly in overdose

Anticonvulsants

Carbamazepine, phenytoin
- Multiple-dose activated charcoal (carbamazepine)

Sodium valproate
- Haemodialysis for severe poisoning

Isoniazid
- Activated charcoal
- IV pyridoxine

Theophylline
- Multiple-dose activated charcoal

Corrosives and bleach
- Gastric lavage and neutralising chemicals are contraindicated
- Chest X-ray to exclude perforation
- Consider early endoscopy or Gastrografin studies to assess extent of damage and need for surgery

Lead
- Prevent further exposure
- Measure blood lead concentration, full blood count and blood film, urea and electrolytes, liver function tests and calcium
- Abdominal X-ray in children to detect pica
- Bone X-ray for 'lead lines'
- Chelation therapy with dimercaprol, DMSA, DMPS or sodium calcium edetate for severe poisoning (esp. in children)

Petroleum distillates, white spirit, kerosene
- Gastric lavage contraindicated
- Activated charcoal ineffective
- Oxygen and nebulised bronchodilators
- Chest X-ray to assess pulmonary effects

Paraquat
- Urine screen for paraquat
- Multiple-dose activated charcoal
- Check blood paraquat concentration and compare with survival curve for prognosis

Organochlorines
- Activated charcoal (with nasogastric aspiration for liquid preparations) within 1 hour of ingestion
- Cardiac monitoring

Pyrethroid insecticides
- Symptomatic and supportive care
- Washing contaminated skin makes irritation worse

Anticoagulant rodenticides and warfarin
- Monitor INR/prothrombin time
- Vitamin K_1 by slow IV injection if coagulopathy
- Fresh frozen plasma or specific clotting factors for bleeding

(DMPS = 2,3-dimercapto-1-propane sulphonate; DMSA = 2,3-dimercaptosuccinic acid)

ENVENOMING

Envenoming occurs when a venomous animal injects sufficient venom by a bite or a sting into a prey item or perceived predator to cause deleterious local and/or systemic effects. Venomous animals generally use their venom to acquire and in some cases predigest prey, with defensive use a secondary function. Accidental encounters between venomous animals and humans are

frequent, particularly in the rural tropics, where millions of cases of venomous bites and stings occur annually. Globally, an increasing number of exotic venomous animals are kept privately, so cases of envenoming may present to hospitals where doctors have insufficient knowledge to manage potentially complex presentations. Doctors everywhere should thus be aware of the basic principles of management of envenoming and how to seek expert support.

Venom

Venom is a complex mixture of diverse components, often with several separate toxins that can cause adverse effects in humans, and each potentially capable of multiple effects (Box 9.18). Venom is produced at considerable metabolic cost, so is used sparingly; thus only some bites/stings by venomous animals result in significant envenoming, the remainder being 'dry bites'. The concept of dry bites is important in understanding approaches to management.

Venomous animals

There are many animal groups that contain venomous species (Box 9.19). The epidemiology estimates shown reflect the importance of snakes and scorpions as causes of severe or lethal envenoming. Social insect stings from bees and wasps may also cause lethal anaphylaxis. Other venomous animals may commonly envenom humans but cause mostly non-lethal effects. A few rarely envenom humans, but have a high potential for severe or lethal envenoming. These include box jellyfish, cone shells, blue-ringed octopus, paralysis ticks and Australian funnel web spiders. Within any given group, particularly snakes, there may be a wide range of clinical presentations. Some are described here but for a more detailed discussion of the types of

9.18 Key venom effects*

Venom component	Clinical effects	Type of venomous animal
Neurotoxin		
Paralytic	Flaccid paralysis	Some snakes, paralysis ticks, cone shells, blue-ringed octopus
Excitatory	Neuroexcitation: autonomic storm, cardiotoxicity, pulmonary oedema	Some scorpions, spiders, jellyfish
Myotoxins	Systemic or local myolysis	Some snakes
Cardiotoxins	Direct or indirect cardiotoxicity; cardiac collapse, shock	Some snakes, scorpions, spiders, and jellyfish
Haemostasis system toxins	Vary from rapid coagulopathy and bleeding to thrombosis, deep venous thrombosis and pulmonary emboli	Many snakes and a few scorpions Brazilian caterpillars
Nephrotoxins	Renal damage	Some snakes, multiple bee, wasp stings
Necrotoxins	Local tissue injury/necrosis, shock	Some snakes, a few scorpions, spiders, jellyfish and stingrays
Allergic toxins	Induce acute allergic response (direct and indirect)	Almost all venoms but particularly those of social insects (bees, wasps, ants)

*All venom components have lethal potential.

9.19 Venomous animals and human envenoming

Phyla	Principal venomous animal groups	Estimated number of human cases/year	Estimated number of human deaths/year
Chordata	Snakes	> 2.5 million	> 100 000
	Spiny fish	? > 100 000	Close to 0
	Stingrays	? > 100 000	? < 10
Arthropoda	Scorpions	> 1 million	? < 5000
	Spiders	? > 100 000	? < 100
	Paralysis ticks	? > 1000	? < 10
	Insects	? > 1 million	? > 1000*
Mollusca	Cone shells	? < 1000	? < 10
	Blue-ringed octopus	? < 100	? < 10
Coelenterata	Jellyfish	? > 1 million	? < 10

*Social insect stings cause death by anaphylaxis rather than primary venom toxicity, except for massive multiple sting attacks.

venomous animal, their venoms and effects on humans see www.toxinology.com.

Clinical effects

With the exception of dry bites where no significant effects occur, venomous bites/stings can result in three broad classes of effect.

Local effects

These vary from trivial to severe (Box 9.20). There may be minimal or no local effects with some snakebites (not even pain), yet lethal systemic envenoming may still be present. For other species, local effects predominate over systemic, and for some species such as snakes, both are important.

General systemic effects

By definition, these are non-specific (see Box 9.20). Shock is an important complication of major local envenoming by some snake species and, if inadequately treated, can prove lethal, especially in children.

Specific systemic effects

These are important in both diagnosis and treatment.

- *Neurotoxic flaccid paralysis* can develop very rapidly, progressing from mild weakness to full respiratory paralysis in less than 30 minutes (blue-ringed octopus bite, cone shell sting), or may develop far more slowly, over hours (some snakes) to days (paralysis tick). For neurotoxic snakes, the cranial nerves are usually involved first, with ptosis a common initial sign (Fig. 9.7). From this, paralysis may extend to the limbs, with weakness and loss of deep tendon reflexes, then respiratory paralysis.
- *Excitatory neurotoxins* cause an 'autonomic storm', with profuse sweating, variable cardiac effects and cardiac failure, sometimes with pulmonary oedema (notably Australian funnel web spider bite, some scorpions such as Indian red scorpion). This type of envenoming can be rapidly fatal (many scorpions, funnel web spiders), or may cause distressing symptoms but constitute a lesser risk of death (widow spiders, banana spiders).

9.20 Local and systemic effects of envenoming

Local effects

- Pain
- Sweating
- Swelling
- Erythema
- Bleeding and bruising
- Blistering
- Necrosis
- Major direct tissue trauma (e.g. stingray injuries)

Non-specific systemic effects

- Headache
- Nausea
- Vomiting and diarrhoea
- Abdominal pain
- Hypertension or hypotension
- Tachycardia or bradycardia
- Dizziness
- Collapse
- Convulsions
- Shock
- Cardiac arrest

Fig. 9.7 Ptosis following neurotoxin envenomation.

- *Myotoxicity* can initially be silent, then present with generalised muscle pain, tenderness, myoglobinuria and huge rises in serum creatine kinase (CK). Secondary renal failure can precipitate potentially lethal hyperkalaemic cardiotoxicity.
- *Cardiotoxicity* is often secondary, but symptoms and signs are non-specific in most cases.
- *Haemostasis system toxins* cause a variety of effects, depending on the type of toxin, and the specific features can be diagnostic. Coagulopathy may present as bruising and bleeding from the bite site, gums and intravenous sites. Surgical interventions are high-risk in such cases. Other venoms cause thrombosis, usually presenting as deep venous thrombosis (DVT), pulmonary embolus or stroke (particularly Caribbean/Martinique vipers).
- *Renal damage* in envenoming is mostly secondary, although some species such as Russell's vipers can cause primary renal damage. The presentation is similar in both cases, with changes in urine output (polyuria, oliguria or anuria) or rises in creatinine and urea. In cases with intravascular haemolysis, secondary renal damage is likely. The clinical effects of specific animals in different regions of the world are shown in Boxes 9.21–9.23.

Management

It is important to determine an accurate diagnosis and the degree of risk, so that severe and potentially lethal cases are identified quickly and managed as a priority. With correct care, even severe cases are treatable, but delays in initiating effective treatment can severely compromise outcome. Expert advice should thus be sought at the earliest opportunity.

First aid

Pre-hospital first aid (Box 9.24) can be critical in major envenoming. It depends on the type of envenoming, but the key principles are to:

- support vital systems
- delay or prevent the onset of envenoming
- avoid harmful 'treatments' such as electric shock, cut and suck, tourniquets, and cryotherapy in snakebite.

Many preventable deaths occur prior to hospital transfer when ineffective cardiorespiratory resuscitation is given to patients with respiratory paralysis or cardiac arrest/failure, which can occur due to either primary envenoming or an anaphylactic reaction (p. 91).

9.21 Important venomous animals in Asia

Scientific name[1]	Common name	Clinical effects	Antivenom/antidote/treatment
Indian subcontinent			
Bungarus spp. (E)	Kraits	Flaccid paralysis[2,3], myolysis[4], hyponatraemia[4]	Indian PV or specific
Naja spp. (E)	Cobras	Flaccid paralysis[3], local necrosis/blistering, shock	Indian PV or specific
Ophiophagus hannah (E)	King cobra	Flaccid paralysis[3], local necrosis, shock	Indian PV or specific
Echis spp. (Vv)	Saw-scaled vipers	Procoagulant coagulopathy, local necrosis/blistering, renal failure	Indian PV or specific
Daboia russelli (Vv)	Russell's viper	Procoagulant coagulopathy, local necrosis/blistering, myolysis, renal failure, shock, flaccid paralysis[2]	Indian PV or specific
Hypnale spp. (Vc)	Hump-nosed vipers	Procoagulant coagulopathy, shock, renal failure	Try Indian PV
Trimeresurus[4] spp. (Vc)	Green pit vipers	Procoagulant coagulopathy, local necrosis, shock	Indian PV or specific
Mesobuthus spp. (Sc)	Indian scorpions	Neuroexcitation, cardiotoxicity	Indian specific AV, prazosin
East Asia			
Bungarus spp. (E)	Kraits	Flaccid paralysis[2,3]	Specific AV from country
Naja spp. (E)	Cobras (some spitters)	Flaccid paralysis[3], local necrosis/blistering, shock	Specific AV from country
Ophiophagus hannah (E)	King cobra	Flaccid paralysis[3], local necrosis, shock	King cobra AV
Calloselasma rhodostoma (Vc)	Malayan pit viper	Procoagulant coagulopathy, local necrosis/blistering, renal failure, shock	Specific AV from country
Daboia russelli (Vv)	Russell's viper	Procoagulant coagulopathy, local necrosis/blistering, renal failure, shock	Specific AV from country
Gloydius (Vc)	Mamushis, pit vipers	Procoagulant coagulopathy, local necrosis/blistering, shock, renal failure, flaccid paralysis[2]	Specific AV from country
Trimeresurus[5] (Vc)	Green pit vipers, habus	Procoagulant coagulopathy, local necrosis/blistering, shock	Specific AV from country

[1]Family names: A = Atractaspididae; C = 'Colubridae' (mostly 'non-venomous'; family subject to major taxonomic revisions); E = Elapidae (all venomous); Sc = scorpions; Vc = Viperidae crotalinae (New World and Asian vipers); Vv = Viperidae viperinae (Old World vipers). [2]Pre-synaptic. [3]Post-synaptic. [4]Only reported so far for *B. candidus* and *B. multicinctus*. [5]Genus is subject to major taxonomic change (split into at least eight genera).
(AV = antivenom; PV = polyvalent)
More information is available from WHO-SEARO Guidelines for the management of snakebite and www.toxinology.com.

Diagnosis

Envenoming is usually obvious but might not be on some occasions. Humans may be bitten or stung by an unseen organism, or may not be aware of a bite or sting having occurred at all. In such cases the patient may present with a variety of symptoms but with no linking history to indicate envenoming. Accordingly, envenoming should be considered as a possible diagnosis in cases of unexplained paralysis, myotoxicity, coagulopathy, nephrotoxicity, cardiotoxicity, pulmonary oedema, necrosis, collapse and convulsions.

History, examination and laboratory findings help to confirm or exclude a diagnosis of envenoming and to determine its extent. It is also important to obtain a description of the organism if possible. Multiple bites or stings are more likely to cause major envenoming. Ask for specific symptoms and search for specific signs that may indicate the type and extent of envenoming (p. 207).

Specific tests for venom are currently only commercially available for Australian snakebite but are likely to be developed for snakebite in other regions. They are not available for other types of envenoming, where venom concentrations are low. For snakebite, a screen for envenoming includes full blood count, coagulation screen, urea and electrolytes, creatinine, CK and ECG. Lung function tests, peripheral oximetry or arterial blood gases may be indicated in cases with potential or established respiratory failure. In areas without access to routine laboratory tests, the whole-blood clotting time (using a glass test tube) is a valuable test for coagulopathy. A derivative of this, the 20-minute whole-blood clotting test is useful (a few millilitres of venous blood are placed in a glass vessel and checked for clotting at 20 minutes).

If patients state that they have been bitten by a particular species, ensure this is accurate. Private keepers of venomous animals may not have accurate

9.22 Important venomous animals in the Americas and Australia

Scientific name[1]	Common name	Clinical effects	Antivenom/antidote/treatment
North America			
Crotalus spp. (Vc)	Rattlesnakes	Procoagulant coagulopathy, local necrosis/blistering (flaccid paralysis[2] rare)	CroFab AV® or Bioclon Antivipmyn AV®
Sistrurus spp. (Vc)	Massasaugas	Procoagulant coagulopathy, local necrosis/blistering, shock	CroFab AV® or Bioclon Antivipmyn AV®
Agkistrodon spp. (Vc)	Copperheads and moccasins	Procoagulant coagulopathy, local necrosis/blistering, shock	CroFab AV® or Bioclon Antivipmyn AV®
Micrurus spp. (E)	Coral snakes	Flaccid paralysis[3]	Bioclon Coralmyn AV®
Latrodectus mactans	Widow spider	Neuroexcitation	MSD Widow spider AV®
Centruroides sculpturatus	Arizona bark scorpion	Neuroexcitation	Bioclon Anascorp AV®
Central and South America			
Crotalus spp. (Vc)	Rattlesnakes	Flaccid paralysis[2], myolysis, procoagulant coagulopathy, shock, renal failure	Specific AV from country
Bothrops spp. (Vc)	Lancehead vipers	Procoagulant coagulopathy, local necrosis/blistering, shock, renal failure	Specific AV from country
Bothriechis spp. (Vc)	Eyelash pit vipers	Shock, pain and swelling	Specific AV from country
Lachesis spp. (Vc)	Bushmasters	Procoagulant coagulopathy, shock, renal failure, local necrosis/blistering	Specific AV from country
Micrurus spp. (E)	Coral snakes	Flaccid paralysis[2,3], myolysis, renal failure	Specific AV from country
Tityus serrulatus	Brazilian scorpion	Neuroexcitation, shock	Instituto Butantan scorpion AV®
Loxosceles spp.	Recluse spiders	Local necrosis	Instituto Butantan spider AV®
Phoneutria nigriventer	Banana spider	Neuroexcitation, shock	Instituto Butantan spider AV®
Potamotrygon, Dasyatis spp.	Freshwater stingrays	Necrosis of bite area, shock, severe pain and oedema	No available AV; good wound care
Australia			
Pseudonaja spp. (E)	Brown snakes	Procoagulant coagulopathy, renal failure, flaccid paralysis[2] (rare)	CSL brown snake AV® or PVAV
Notechis spp. (E)	Tiger snakes	Procoagulant coagulopathy, myolysis, flaccid paralysis[2,3], renal failure	CSL tiger snake AV® or PVAV
Oxyuranus spp. (E)	Taipans	Procoagulant coagulopathy, flaccid paralysis[2,3], myolysis, renal failure	CSL taipan AV® or PVAV
Acanthophis spp. (E)	Death adders	Flaccid paralysis[3]	CSL death adder AV® or PVAV
Pseudechis spp.	Black and mulga snakes	Anticoagulant coagulopathy, myolysis, renal failure	CSL black snake AV® or PVAV
Enhydrina schistosa	Sea snakes (all species globally)	Flaccid paralysis and/or myolysis	CSL sea snake AV®
Atrax, Hadronyche spp.	Funnel web spiders	Neuroexcitation, shock	CSL funnel web spider AV®
Latrodectus hasseltii	Red back spider	Neuroexcitation, pain and sweating	CSL red back spider AV®
Chironex fleckeri	Box jellyfish	Neuroexcitation, cardiotoxicity, local necrosis	CSL box jellyfish AV®
Synanceia spp.	Stonefish	Severe local pain	CSL stonefish AV®

[1]For family name, see Box 9.21. [2]Pre-synaptic. [3]Post-synaptic. (CSL = CSL Ltd, Melbourne, producer of Australian antivenoms)

knowledge of what they are keeping, and misidentification of a snake, scorpion or spider can have dire consequences if the wrong antivenom is used.

Treatment

Envenoming is managed on two levels, which must be delivered in tandem:

- supportive management of the organ systems affected and of the whole patient
- treating the effects with specific treatments/antidotes (usually antivenom).

For a snakebite by a potentially lethal species such as Russell's viper, the patient might have local effects with oedema, blistering, necrosis, and resultant fluid shifts causing shock, and at the same time have systemic effects such as intractable vomiting, coagulopathy, paralysis and secondary renal failure. Specific treatment with antivenom will be required to reverse

9.23 Important venomous animals in Africa and Europe

Scientific name[1]	Common name	Clinical effects	Antivenom/antidote/treatment
Africa			
Naja spp. (E)	Cobras		
	Non-spitters	Flaccid paralysis[3] ± local necrosis/blistering	South African PV or Sanofi Pasteur FavAfrica AV®
	Spitters	Local necrosis/blistering (flaccid paralysis[3] uncommon)	South African PV or Sanofi Pasteur FavAfrica AV®
Dendroaspis spp. (E)	Mambas	Mamba neurotoxin flaccid paralysis and muscle fasciculation, shock, necrosis (uncommon)	South African PV or Sanofi Pasteur FavAfrica AV®
Hemachatus haemachatus (E)	Rinkhals	Flaccid paralysis[3], local necrosis, shock	South African PV
Atheris spp. (Vv)	Bush vipers	Procoagulant coagulopathy, shock, pain and swelling	No available AV (can try South African AV)
Bitis spp. (Vv)	Puff adders etc.	Procoagulant coagulopathy, shock, cardiotoxicity, local necrosis/blistering	South African PV or Sanofi Pasteur FavAfrica AV®
Causus spp. (Vv)	Night adders	Pain and swelling	No available AV
Echis spp. (Vv)	Carpet vipers	Procoagulant coagulopathy, shock, renal failure, local necrosis/blistering	Specific anti-*Echis* AV for species/geographic region or Sanofi Pasteur FavAfrica AV®
Cerastes spp. (Vv)	Horned desert vipers	Procoagulant coagulopathy, local necrosis, shock	Specific or polyspecific AV covering *Cerastes* from country of origin
Dispholidus typus (C)	Boomslang	Procoagulant coagulopathy, shock	Boomslang AV
Androctonus spp.	North African scorpions	Neuroexcitation	Specific scorpion AV (Algeria, Tunisia, Sanofi Pasteur Scorpifav®)
Leiurus quinquestriatus	Yellow scorpion	Neuroexcitation, shock	Specific scorpion AV (Algeria, Tunisia, Sanofi Pasteur Scorpifav®)
Europe			
Vipera spp. (Vv)	Vipers and adders	Shock, local necrosis/blistering, procoagulant coagulopathy (flaccid paralysis[2] rare)	ViperaTab AV® or Zagreb AV® or SanofiPasteur Viperfav AV®

[1]For family name, see Box 9.21. [2]Pre-synaptic. [3]Post-synaptic.
More information is available from WHO Guidelines for the prevention and clinical management of snakebite in Africa and www.toxinology.com.

9.24 First aid for envenoming

Method	Situations where indicated
Immobilisation of bitten limb	All snakebites
Pressure bandage and immobilisation of bitten limb	Non-necrotic snakebites (Australian snakes, sea snakes, some cobras, king cobra, kraits, coral snakes, mambas, a few vipers, Australian funnel web spiders, blue-ringed octopus, cone shell)
Local heat (hot water immersion or shower, to 45°C)	Venomous fish stings, stingray injuries, jellyfish stings (except possibly box jellyfish)
Staunching local bleeding	Traumatic injury with significant bleeding (some stingray injuries)
Cardiorespiratory support	Cardiac or respiratory impairment and particularly if respiratory paralysis is developing (some snakes, paralysis ticks, blue-ringed octopus, cone shells)
No specific first aid	Widow and recluse spider bites

the coagulopathy, and may prevent worsening of the paralysis and reduce the vomiting, but will not greatly affect the local tissue damage or the renal failure or shock. The latter will require intravenous fluid therapy, possibly respiratory support, renal dialysis and local wound care, possibly including antibiotics.

Each animal will cause a particular pattern of envenoming, requiring a tailored response. Listing all of these is beyond the scope of this chapter (see Further information below). Pulse, blood pressure, pulse oximetry and urine output should be monitored in all cases.

Antivenom

This is the most important tool in treating envenoming. It is made by hyperimmunising an animal, usually horses, to produce antibodies against venom. Once refined, these bind to venom toxins and render them inactive or allow their rapid clearance. Antivenom is only available for certain venomous animals and cannot reverse all types of envenoming. With a few exceptions, it should be given intravenously, with adrenaline (epinephrine) ready in case of anaphylaxis. It should only be used when clearly indicated, and indications will vary between animals. It is critical that the correct antivenom is used at the appropriate dose. Doses vary widely between antivenoms; those recommended for North American antivenoms are not applicable to those elsewhere. In some situations (such as the Indian subcontinent), pre-treatment with subcutaneous adrenaline may reduce the chance of anaphylaxis to antivenom.

Antivenom can sometimes reverse post-synaptic neurotoxic paralysis (α-bungarotoxin-like neurotoxins) but will not usually reverse established pre-synaptic paralysis (β-bungarotoxin-like neurotoxins), so should be given before major paralysis has occurred. Coagulopathy is best reversed by antivenom, but even after all venom is neutralised, there may be a delay of hours before normal coagulation is restored. More antivenom should not be given because coagulopathy has failed to normalise fully in the first 1–3 hours (except in very particular circumstances). Thrombocytopenia may persist for days, despite antivenom. The role of antivenom in reversing established myolysis and renal failure is uncertain. Antivenom may help limit local tissue effects/injury in the bitten limb, but this is quite variable and time-dependent. Neuroexcitatory envenoming can respond very well to antivenom (Australian funnel web spider bites; Mexican, South American, Indian scorpion stings), but there is controversy about the effectiveness of antivenom for some species (some North African and Middle Eastern scorpions). The role of antivenom in limiting local venom effects, including necrosis, is also controversial; it is most likely to be effective when given early.

All patients receiving antivenom are at risk of both early and late adverse reactions, including anaphylaxis (early; not always IgE-related) and serum sickness (late).

Other treatments

Anticholinesterases are used as an adjunctive treatment for post-synaptic paralysis.

Prazosin (an α-adrenoceptor antagonist) is used in the management of hypertension or pulmonary oedema in scorpion sting cardiotoxicity, particularly for Indian red scorpion stings, though antivenom is now the preferred treatment.

Antibiotics are not routinely required for most bites/stings, though a few animals regularly cause significant wound infection/abscess, such as some South American pit vipers and stingrays. Tetanus is a risk in some bites or stings, such as snakebite, but intramuscular toxoid should not be given until any coagulopathy is reversed.

Mechanical ventilation (p. 194) is vital for established respiratory paralysis that will not reverse with antivenom, and may be required for prolonged periods – up to several months in some cases.

Follow-up

Cases with significant envenoming and those receiving antivenom should be followed up to ensure that any complications have resolved and to identify any delayed envenoming.

Psychiatry and the law 257

Psychiatric disorders have traditionally been considered as 'mental' rather than as 'physical' illnesses. This is because they manifest with disordered functioning in the areas of emotion, perception, thinking and memory, and/or have had no clearly established biological basis. However, as research identifies abnormalities of the brain in an increasing number of psychiatric disorders and an important role for psychological and behavioural factors in many medical illnesses, a clear distinction between mental and physical illness has become increasingly questionable. We therefore refer to psychiatric disorders simply to mean those conditions traditionally regarded as the province of psychiatry.

CLASSIFICATION OF PSYCHIATRIC DISORDERS

There are two main classifications of psychiatric disorders in current use:

- the American Psychiatric Association's Diagnostic and Statistical Manual (4th edition), or DSM-IV
- the World Health Organization's International Classification of Disease (10th edition), known as ICD-10.

The two systems are similar; here we use the ICD-10 classification (Box 10.1).

EPIDEMIOLOGY OF PSYCHIATRIC DISORDERS

Psychiatric disorders are amongst the most common of all human illnesses. The relative frequency of each varies with the setting (Box 10.2). In the general population, depression, anxiety disorders and adjustment disorders are most common (10%) and psychosis is rare (1–2%); in acute medical wards of general hospitals, organic disorders such as delirium (20–30%) are prevalent; in specialist general psychiatric services, psychoses are the most common disorders.

AETIOLOGY OF PSYCHIATRIC DISORDERS

The aetiology of psychiatric disorders is multifactorial, with a combination of biological, psychological and social causes. Each of these factors may play a role in predisposing to, precipitating or perpetuating the disorder (Box 10.3).

Biological factors

Genetic

Genetic factors play a predisposing role in many psychiatric disorders, including schizophrenia and bipolar

10.1 Classification of psychiatric disorders

Stress-related disorders
- Acute stress disorder
- Adjustment disorder
- Post-traumatic stress disorder

Anxiety disorders
- Generalised anxiety
- Phobic anxiety
- Panic disorder
- Obsessive-compulsive disorder

Affective (mood) disorders
- Depressive disorder
- Mania and bipolar disorder

Schizophrenia and delusional disorders

Substance misuse disorders
- Alcohol
- Drugs

Organic disorders
- Acute, e.g. delirium
- Chronic, e.g. dementia

Disorders of adult personality and behaviour
- Personality disorder
- Factitious disorder

Eating disorders
- Anorexia nervosa
- Bulimia nervosa

Somatoform disorders
- Somatisation disorder
- Dissociative (conversion) disorder
- Pain disorder
- Hypochondriasis
- Body dysmorphic disorder
- Somatoform autonomic dysfunction

Neurasthenia

Puerperal mental disorders

10.2 Prevalence of psychiatric disorders by medical setting

	Medical/surgical			
	General practice	Outpatients	Inpatients	Psychiatric services
Adjustment disorders	++	++	+++	++
Depression/anxiety	++	++	+++	+++
Alcohol abuse	++	++	+++	+++
Personality disorders	++	++	++	+++
Somatoform disorders	+	+++	++	+
Delirium	–	–	+++	–
Psychosis	–	–	–	+++

(– rare; + uncommon; ++ common; +++ very common)

10.3 Classification of aetiological factors in psychiatric disorders

Predisposing
• Increase susceptibility to psychiatric disorder • Established in utero or in childhood • Operate throughout patient's lifetime (e.g. genetic factors, congenital defects, disturbed family background, chronic physical illness)
Precipitating
• Trigger an episode of illness • Determine its time of onset (e.g. stressful life events, acute physical illness)
Perpetuating
• Delay recovery from illness (e.g. lack of social support, chronic physical illness)

affective disorder. However, whilst some disorders such as Huntington's disease are due to mutations in a single gene, the genetic contribution to most psychiatric disorders is polygenic in nature and mediated by the combined effects of several genetic variants, each with modest effects and modulated by environmental factors.

Brain structure and function

Brain structure is grossly normal in most psychiatric disorders, although abnormalities may be observed in some conditions, such as generalised atrophy in Alzheimer's disease and enlarged ventricles with a slight decrease in brain size in schizophrenia. The functioning of the brain, however, is commonly altered with, for example, changes in neurotransmitters such as dopamine, noradrenaline (norepinephrine) and 5-hydroxytryptamine (5-HT, serotonin), and differences in activity of specific areas of the brain, as seen on functional brain scans.

Psychological and behavioural factors

Early environment

Early childhood adversity, such as emotional deprivation or abuse, predisposes to psychiatric disorders such as depression and eating disorders in adulthood.

Personality

The relationship between personality and psychiatric disorder can be difficult to assess because the development of psychiatric disorder can change a patient's personality. However, some personality types predispose the individual to develop psychiatric disorder; for example, a depressive personality increases the risk of depression. A disordered personality may also perpetuate a psychiatric disorder once it is established, leading to a poorer prognosis.

Behaviour

A person's behaviour may predispose to the development of a disorder (e.g. excess alcohol intake leading to dependence, and dieting to anorexia) or perpetuate it, as in persistent avoidance of the feared situation in phobias.

Social and environmental factors

Social isolation

The lack of a close, confiding relationship predisposes to some psychiatric disorders such as depression. The reduced social support resulting from having a psychiatric disorder may also act to perpetuate it.

Stressors

Social and environmental stressors often play an important role in precipitating psychiatric disorder in those who are predisposed. For example, trauma in post-traumatic stress disorder, losses (such as bereavement) in depression, and events perceived as threatening (such as potential loss of employment) in anxiety.

DIAGNOSING PSYCHIATRIC DISORDERS

Psychiatric assessment differs from a standard medical assessment in the following ways:

- There is greater emphasis on the history.
- It includes a systematic examination of the patient's thinking, emotion and behaviour (mental state).
- It commonly includes the routine interviewing of an informant (usually a relative or friend who knows the patient), especially when the illness affects the patient's ability to give an accurate history.

Because of its greater complexity, a full psychiatric history (Box 10.4) and detailed mental state examination (MSE) may take an hour or more. However, a brief mental state examination, usually taking no more than a few minutes (see below), should be part of the assessment of *all* patients, not merely those deemed to be 'psychiatric'.

Psychiatric interview

The aims of the interview are to:

- establish a therapeutic relationship with the patient
- elicit the symptoms, history and background information (see Box 10.4)
- examine the mental state
- provide information, reassurance and advice.

Whilst some aspects of the patient's mental state may be observed whilst the history is being taken, specific enquiries for important features should always be made.

Mental state examination

General appearance and behaviour

Any abnormalities of alertness or motor behaviour, such as restlessness or retardation, are noted. The level of consciousness should be determined, especially in the assessment of possible delirium.

Speech

Speed and fluency should be observed, including slow (retarded) speech and word-finding difficulty. 'Pressure of speech' describes rapid speech that is difficult to interrupt.

10.4 How to structure a psychiatric interview

Presenting problem

Reason for referral
- Why the patient has been referred and by whom

Presenting complaints
- The patient should be asked to describe the main problems for which help is requested and what he or she wants the doctor to do

History of present illness
- The patient should be asked to describe the course of the illness from when symptoms were first noticed
- The interviewer asks direct questions to determine the nature, duration and severity of symptoms, and any associated factors

Background

Family history
- Description of parents and siblings, and a record of any mental illness in relatives

Personal history
- Birth history, major events in childhood, education, occupational history, relationship(s), marriage, children, current social circumstances

Previous medical and psychiatric history
- Previous health, accidents and operations
- Use of alcohol, tobacco and other drugs
- Direct questions may be needed concerning previous psychiatric history since this may not be volunteered: 'Have you ever been treated for depression or nerves?' or 'Have you ever suffered a nervous breakdown?'

Previous personality
- The patterns of behaviour and thinking that characterise a person, including their relationships with other people and reactions to stress
- The most useful information may be obtained from an informant who has known the patient well for many years

Mood

This can be judged by facial expression, posture and movements. Patients should also be asked if they feel sad or depressed and if they lack ability to experience pleasure (anhedonia). Are they anxious, worried or tense? Is mood elevated with excess energy and a reduced need for sleep, as in mania?

Thoughts

The content of thought can be elicited by asking 'What are your main concerns?' Is thinking negative, guilty or hopeless, suggesting depression? Are there thoughts of self-harm? If so, enquiry should be made about plans. Is he or she excessively worried about many things, suggesting anxiety? Does the patient think that he or she is especially powerful, important or gifted (grandiose thoughts), suggesting mania?

The form of thinking may also be abnormal. In schizophrenia, patients may display loosened associations between ideas, making it difficult to follow their train of thought. There may also be abnormalities of thought possession, when patients experience the intrusion of alien thoughts into their mind or the broadcasting of their own thoughts to other people (p. 247).

Abnormal beliefs

A delusion is a false belief, out of keeping with a patient's cultural background, which is held with conviction despite evidence to the contrary (p. 236).

Abnormal perceptions

Illusions are abnormal perceptions of real stimuli. Hallucinations are sensory perceptions which occur in the absence of external stimuli: for example, hearing voices when no one is present (p. 237).

Cognitive function

The Mini-Mental State Examination (MMSE) is a useful screening questionnaire to detect cognitive impairment. A score of less than 24 out of 30 typically suggests cognitive impairment. The Addenbrooke's Cognitive Examination – Revised (ACE-R) provides a more comprehensive assessment. A brief clinical assessment is as follows:

- *Memory.* Registration of memories is tested by asking the patient to repeat simple new information, such as a name and address, immediately after hearing it. Short-term memory is assessed by asking him or her to repeat it after an interval of 1–2 minutes, during which time the patient's attention should be diverted elsewhere. Long-term memory is assessed by gauging the recall of previous events.
- *Concentration.* Serial 7s is a test in which the patient is asked to subtract 7 from 100 and then 7 from the answer, and so on.
- *Orientation.* This is assessed by asking the patient about place – his or her exact location; time – what day, date, month and year it is now; and person – details of personal identity, such as name, date of birth, marital status and address.
- *Intellectual ability.* This can be gauged from the history of the patient's educational background and attainments but can also be assessed during the interview from the patient's speech, vocabulary and grasp of the interviewer's questions.

Note that the degree of cognitive impairment in delirium typically fluctuates over time, and consequently may be missed by a single assessment.

Patients' own understanding of their symptoms ('insight')

Patients should be asked what they think their symptoms are due to, and whether they warrant treatment. Lack of insight refers to a failure to accept that one is ill and/or in need of treatment, and is characteristic of acute psychosis.

PRESENTING PROBLEMS IN PSYCHIATRIC ILLNESS

Anxiety symptoms

Anxiety may be transient, persistent, episodic or limited to specific situations. The symptoms of anxiety are both psychological and somatic (Box 10.5). The differential diagnosis of anxiety is shown in Box 10.6. Most anxiety is part of a transient adjustment to stressful events: adjustment disorders (p. 242). Other more persistent forms of anxiety are described in detail on page 242.

10.5 Symptoms of anxiety disorder

Psychological

- Apprehension
- Irritability
- Worry
- Fear of impending disaster
- Poor concentration
- Depersonalisation

Somatic

- Palpitations
- Fatigue
- Tremor
- Dizziness
- Sweating
- Diarrhoea
- Frequent desire to pass urine
- Chest pain
- Initial insomnia
- Breathlessness
- Headache

10.6 Differential diagnosis of anxiety

- Normal response to threat
- Adjustment disorder
- Generalised anxiety disorder
- Panic disorder
- Phobic disorder
- Organic (medical) cause
  - Hyperthyroidism
  - Paroxysmal arrhythmias
  - Phaeochromocytoma
  - Alcohol and benzodiazepine withdrawal
  - Hypoglycaemia
  - Temporal lobe epilepsy

Anxiety may occasionally be a manifestation of a medical condition such as thyrotoxicosis (see Box 10.6).

Depressed mood

Depressive disorder is common, with a prevalence of approximately 5% in the general population. Depression is at least twice as common in the medically ill. It is important to note that depression has physical as well as mental symptoms (Box 10.7). The diagnosis of depression in the medically ill, who may have physical symptoms of disease, relies on detection of the core psychological symptoms of low mood and anhedonia.

Differential diagnosis

Depressive disorder must be differentiated from an adjustment disorder with depressed mood (p. 242). Adjustment disorders are common, self-limiting reactions to adversity, including physical illness, which are transient and require only general support. Depressive disorders (p. 243) are characterised by a more severe and persistent disturbance of mood and require specific treatment. In some cases, depression may occur as a result of a direct effect of a medical condition or its treatment on the brain, when it is referred to as an 'organic mood disorder' (Box 10.8).

Suicide

Depression is the major risk factor for suicide. Other risk factors are shown in Box 10.9. When depression is suspected, tactful enquiry should always be made into suicidal thoughts and plans. Asking about suicide does not increase the risk of it occurring, whereas failure to enquire denies the opportunity to prevent it.

10.7 Symptoms of depressive disorders

Psychological

- Depressed mood
- Reduced self-esteem
- Pessimism
- Guilt
- Loss of interest
- Loss of enjoyment (anhedonia)
- Suicidal thinking

Somatic

- Reduced appetite
- Weight change
- Disturbed sleep
- Fatigue
- Loss of libido
- Bowel disturbance
- Motor retardation (slowing of activity)

10.8 Organic mood disorders*

Neurological

- Cerebrovascular disease
- Cerebral tumour
- Multiple sclerosis
- Parkinson's disease
- Huntington's disease
- Alzheimer's disease
- Epilepsy

Endocrine

- Hypothyroidism
- Hyperthyroidism
- Cushing's syndrome
- Addison's disease
- Hyperparathyroidism

Malignant disease

Infections

- Infectious mononucleosis
- Herpes simplex
- Brucellosis
- Typhoid
- Toxoplasmosis

Connective tissue disease

- Systemic lupus erythematosus

Drugs

- Phenothiazines
- Phenylbutazone
- Corticosteroids, oral contraceptives
- Interferon

*Diseases that may cause organic affective disorders by direct action on the brain.

10.9 Risk factors for suicide

- Psychiatric illness (depressive illness, schizophrenia)
- Older age
- Male sex
- Living alone
- Unemployment
- Recent bereavement, divorce or separation
- Chronic physical ill health
- Drug or alcohol misuse
- Suicide note written
- History of previous attempts (especially if a violent method was used)

Elated mood

Elation, or euphoria, is the converse of depression and is characteristic of mania. It may manifest as infectious joviality, over-activity, lack of sleep and appetite, undue optimism, over-talkativeness, irritability, and recklessness in spending and sexual behaviour. When elated mood is severe, psychotic symptoms are often evident, such as delusions of grandeur (e.g. believing erroneously that one is royalty). Elevated mood is much less

common than depressed mood, and in medical settings is often secondary to drug or alcohol misuse, an organic disorder or medical treatment. Where none of these applies, the patient may have a bipolar disorder (p. 244).

Medically unexplained somatic symptoms

Patients commonly present to doctors with physical symptoms. Whilst these symptoms may be an expression of a medical condition, they often are not. They may then be referred to as 'medically unexplained symptoms' (MUS). MUS are very common in patients attending general medical outpatient clinics. Almost any symptom can be medically unexplained, e.g.:

- pain (including back, chest, abdominal and headache)
- fatigue
- dizziness
- fits, 'funny turns' and feelings of weakness.

Patients with MUS may receive a medical diagnosis of a so-called functional somatic syndrome, such as irritable bowel syndrome (Box 10.10), and may also merit a psychiatric diagnosis on the basis of the same symptoms. The most frequent psychiatric diagnoses associated with MUS are anxiety or depressive disorders. When these are absent, a diagnosis of somatoform disorder may be appropriate (Box 10.11).

Differential diagnosis

The main medical differential diagnosis for MUS is from symptoms of a medical disease. Diagnostic difficulties are most likely with unusual presentations of common diseases and with rare diseases. MUS are commonly an expression of depression and anxiety. A medical and psychiatric assessment should be completed in all cases (Fig. 10.1).

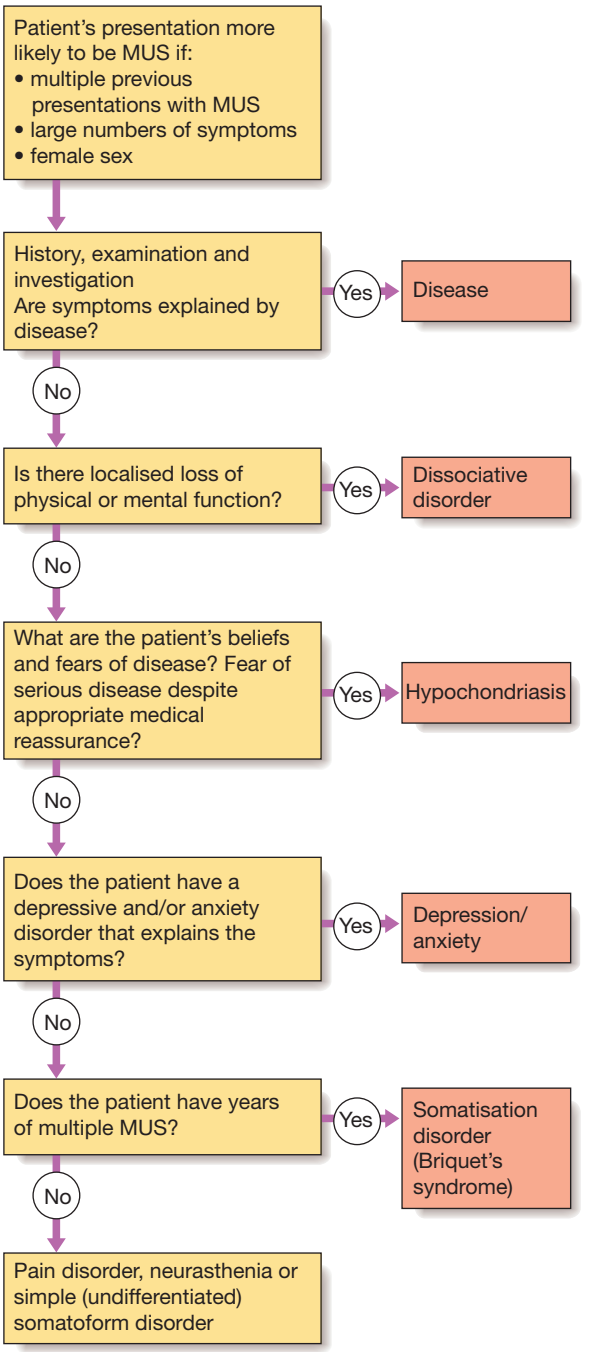

Fig. 10.1 Diagnosis of medically unexplained symptoms (MUS).

10.10 Functional somatic syndromes

- Gastroenterology: irritable bowel syndrome, functional dyspepsia
- Gynaecology: premenstrual syndrome, chronic pelvic pain
- Rheumatology: fibromyalgia
- Cardiology: atypical or non-cardiac chest pain
- Respiratory medicine: hyperventilation syndrome
- Infectious diseases: chronic (post-viral) fatigue syndrome
- Neurology: tension headache, non-epileptic attacks
- Dentistry: temporomandibular joint dysfunction, atypical facial pain
- Ear, nose and throat: globus syndrome
- Allergy: multiple chemical sensitivity

10.11 Psychiatric diagnoses for medically unexplained somatic symptoms

- Hypochondriasis: predominant concern about disease
- Somatisation: predominant concern about symptoms
- Somatic presentation of depression and anxiety
- Simple somatoform disorders: small number of symptoms
- Somatisation disorder (Briquet's syndrome): chronic multiple symptoms
- Conversion disorder: loss of function
- Body dysmorphic disorder: dislike of body parts

Delusions and hallucinations

Delusions

Various types of delusion are identified on the basis of their content. They may be:

- persecutory, such as a conviction that others are out to get me

- hypochondriacal, such as an unfounded conviction that one has cancer
- grandiose, such as a belief that one has special powers or status
- nihilistic, e.g. 'My head is missing', 'I have no body', 'I am dead'.

Delusions should be differentiated from over-valued ideas, which are strongly held but not fixed.

Hallucinations

These are perceptions without external stimuli. They can occur in any sensory modality, most commonly visual or auditory. Typical examples are hearing voices when no one else is present, or seeing 'visions'. Hallucinations have the quality of ordinary perceptions and are perceived as originating in the external world, not in the patient's own mind (when they are termed pseudo-hallucinations). Those occurring when falling asleep ('hypnagogic') and on waking ('hypnopompic') are not pathological. Hallucinations should be distinguished from illusions, which are misperceptions of real external stimuli (such as mistaking a shrub for a person in poor light).

Differential diagnosis

Agitation, terror or the fear of being thought 'mad' may make patients unable or unwilling to volunteer or describe their abnormal beliefs or experiences. Careful and tactful enquiry is therefore required. The nature of hallucinations can be important diagnostically; for example, 'running commentary' voices that discuss the patient are strongly associated with schizophrenia. In general, auditory hallucinations suggest schizophrenia, while hallucinations in other sensory modalities, especially vision but also taste and smell, suggest an 'organic psychosis' such as delirium or temporal lobe epilepsy.

Hallucinations and delusions often co-occur; if their content is consistent with coexisting emotional symptoms, they are described as 'mood-congruent'. Thus, patients with severely depressed mood may believe themselves responsible for all the evils in the world, and hear voices saying 'You're worthless. Go and kill yourself.' In this case, the diagnosis of depressive psychosis is made on the basis of the congruence of different phenomena (mood, delusion and hallucination). Incongruence between hallucinations, delusions and mood suggests schizophrenia.

Where hallucinations and delusions arise within disturbed consciousness and impaired cognition, the diagnosis is usually an organic disorder, most commonly delirium and/or dementia (p. 244). This differential diagnosis is made by assessing the nature, extent and time course of any cognitive disturbances, and by investigating for underlying causes.

Disturbed and aggressive behaviour

Disturbed and aggressive behaviour is common in general hospitals, especially in emergency departments. Most behavioural disturbance arises not from medical or psychiatric illness, but from alcohol intoxication, reaction to the situation and personality characteristics. The key principles of management are, first, to establish control of the situation rapidly and thereby ensure the safety of the patient and others, and, second, to assess the cause of the disturbance in order to remedy it. Establishing control requires the presence of an adequate number of trained staff, an appropriate physical environment and sometimes sedation (Fig. 10.2). Hospital security staff and sometimes the assistance of the police may be required. In all cases, the staff approach is important; a calm, non-threatening manner expressing understanding of the patient's concerns is often all that is required to defuse potential aggression (Box 10.12).

If sedating drugs are required, antipsychotic drugs, such as haloperidol, and benzodiazepines, such as diazepam, are commonly used. The choice of drug, dose, route and rate of administration will depend on the

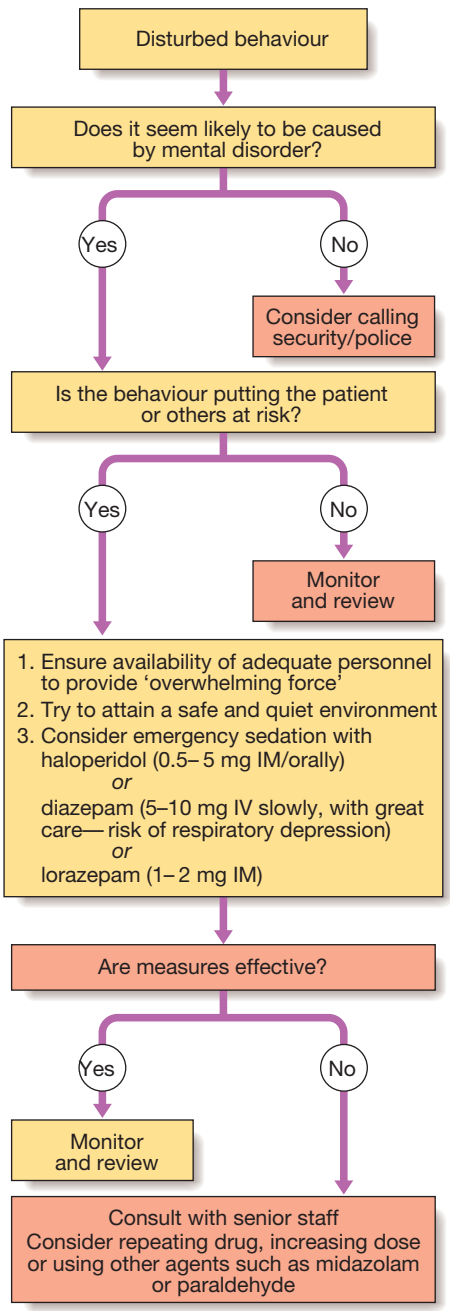

Fig. 10.2 Acute management of disturbed behaviour.

10.12 Psychiatric emergencies

- Intervene as necessary to reduce the risk of harm to the patient and to others
- Adopt a calm, non-threatening approach
- Arrange availability of other staff and parenteral medication
- Consider diagnostic possibilities of drug intoxication, acute psychosis and delirium
- Involve friends and relatives as appropriate

patient's age, sex and physical health, as well as the likely cause of the disturbed behaviour. The benefits of sedation must be balanced against the associated risks, however. Haloperidol can cause acute dystonias, including oculogyric crises, while the benzodiazepines can precipitate respiratory depression in patients with lung disease, and encephalopathy in those with liver disease. Thus, for a frail elderly woman with emphysema and delirium, sedation may be achieved with a low dose (0.5 mg) of oral haloperidol, while for a strong young man with an acute psychotic episode, at least 10 mg of intravenous diazepam and a similar dose of haloperidol may be needed. A parenterally administered anticholinergic agent, such as procyclidine, should be available to treat extrapyramidal effects arising from haloperidol, and flumazenil (p. 217) to reverse respiratory depression if large doses of benzodiazepines are used.

Differential diagnosis

Many factors may contribute to disturbed behaviour. When the patient is cooperative, these are best determined at interview. Other sources of information about the patient include medical and psychiatric records, and discussion with nursing staff, family members and other informants, including the patient's general practitioner. The following information should be sought:

- psychiatric, medical (especially neurological) and criminal history
- current psychiatric and medical treatment
- alcohol and drug misuse
- recent stressors
- the time course and accompaniments of the current episode in terms of mood, belief and behaviour.

Observation of the patient's behaviour may also yield useful clues. Do they appear to be responding to hallucinations? Are they alert or variably drowsy and confused? Are there physical features suggestive of drug or alcohol misuse or withdrawal? Are there new injuries or old scars, especially on the head? Do they smell of alcohol or solvents? Do they bear the marks of drug injection? Are they unwashed and unkempt, suggesting a gradual development of their condition?

If the person has an acute psychiatric disorder, then admission to a psychiatric facility may be indicated. If a medical cause is likely, psychiatric transfer is usually inappropriate and the patient should be managed in a medical setting, with whatever nursing and security support is required. Where it is clear that there is no medical or psychiatric illness, the person should be removed from the hospital, to police custody if necessary.

Measures such as restraint, sedation, the investigation and treatment of medical problems, and psychiatric transfer all raise legal as well as medical issues (p. 257). In most countries, including the UK, common law confers upon doctors the right, and indeed the duty, to intervene against a patient's wishes in cases of acute behavioural disturbance, if this is necessary to protect the patient or other people. Many countries, such as the UK, also have specific mental health legislation that may be used to detain patients.

10.13 Medical psychiatry in old age

- **Organic psychiatric disorders**: especially common, so cognitive function should always be assessed; if impaired, an associated medical condition or adverse drug effect should be suspected.
- **Disturbed behaviour**: delirium is the most common cause.
- **Depression**: common. Just because a person is old and frail does not mean that depression is 'to be expected' and that it should not be treated.
- **Self-harm**: associated with an increased risk of completed suicide.
- **Medically unexplained symptoms**: common and often associated with depressive disorder.
- **Loneliness, poverty and lack of social support**: must be taken into consideration in management decisions.

Confusion

This is a vague term used to describe a range of primarily cognitive problems, including disturbances in perception, belief and behaviour. 'Confusion' usually presents as a problem when it becomes clear that the patient cannot comply with medical care; they may repeatedly wander off the ward, pull out essential cannulae and catheters, and hit nurses. The methods of assessment of cognitive function range from simple screening questions to detailed psychometric testing. All doctors should be able to undertake a brief cognitive assessment, as outlined above (p. 233).

Differential diagnosis

A history from the patient and informants is essential to establish the time course, variability and functional consequences of any cognitive deficit. Mental state examination is necessary to seek evidence of associated mood disorder, hallucinations, delusions or behavioural abnormalities, and physical examination to identify any relevant medical conditions. The assessment should seek to distinguish between:

- organic disorders such as delirium, dementia, and focal deficits secondary to brain lesions
- psychiatric disorders such as depressive pseudodementia and dissociative disorder
- malingering (p. 247).

Further investigation will usually be needed to identify the specific causes of any cognitive impairment identified (see Box 10.32, p. 250, and p. 209).

Self-harm

Self-harm (SH) is a common reason for presentation to medical services. The term 'attempted suicide' is

potentially misleading, as most such patients are not unequivocally trying to kill themselves. Most cases of SH involve overdose, of either prescribed or non-prescribed drugs (Ch. 9). Less common methods include asphyxiation, drowning, hanging, jumping from a height or in front of a moving vehicle, and the use of firearms. Methods that carry a high chance of being fatal are more likely to be associated with serious psychiatric disorder. Self-cutting is common and often repetitive, but rarely leads to contact with medical services.

The incidence of SH varies over time and between countries. In the UK, the lifetime prevalence of suicidal ideation is 15% and that of acts of SH is 4%. SH is more common in women than men, and in young adults than the elderly. (In contrast, completed suicide is more common in men and the elderly (see Box 10.9).) There is a higher incidence of self-harm among lower socioeconomic groups, particularly those living in crowded, socially deprived urban areas. There is also an association with alcohol misuse, child abuse, unemployment and recently broken relationships.

Differential diagnosis

The main differential diagnosis is from accidental poisoning and so-called 'recreational' overdose in drug users. It must be remembered that SH is not a diagnosis but a presentation, and may be associated with any psychiatric diagnosis, the most common being adjustment disorder, substance and alcohol misuse, depressive disorder and personality disorder. In many cases, however, no psychiatric diagnosis can be made.

Initial management

A thorough psychiatric and social assessment should be attempted in all cases (Fig. 10.3), although some patients will discharge themselves before this can take place. The need for psychiatric assessment should not, however, delay urgent medical or surgical treatment, and may need to be deferred until the patient is well enough for interview. The purpose of the psychiatric assessment is to:

- establish the short-term risk of suicide
- identify potentially treatable problems, whether medical, psychiatric or social.

Topics to be covered when assessing a patient are listed in Box 10.14. The history should include events occurring immediately before and after the act, and especially any evidence of planning. The nature and severity of any current psychiatric symptoms must be assessed, along with the personal and social supports available to the patient outside hospital.

Most SH patients have depressive and anxiety symptoms on a background of chronic social and personal difficulties and alcohol misuse but no psychiatric disorder. They do not usually require psychotropic

10.14 Assessment of patients after self-harm

Current attempt

- Degree of intent at the time: preparations, plans, precautions against discovery, note
- Method used, particularly whether violent
- Degree of intent now
- Symptoms of psychiatric illness

Background

- Previous attempts and their outcome
- Family and personal history
- Social support
- Previous response to stress
- Extent of drug and alcohol misuse

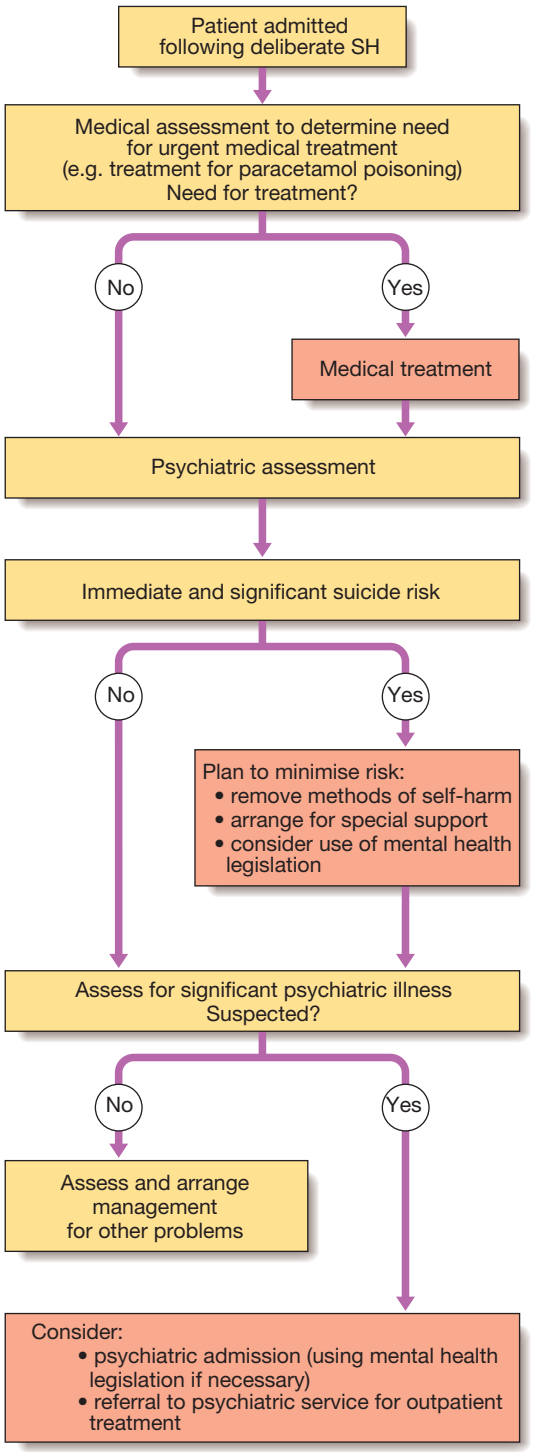

Fig. 10.3 Assessment of patients admitted following self-harm (SH).

medication or specialised psychiatric treatment but may benefit from personal support and practical advice from a GP, social worker or community psychiatric nurse. Admission to a psychiatric ward is necessary only for persons who:

- have an acute psychiatric disorder
- are at high risk of suicide
- need temporary respite from intolerable circumstances
- require further assessment of their mental state.

Approximately 20% of SH patients make a repeat attempt during the following year and 1–2% kill themselves. Factors associated with suicide after an episode of SH are listed in Box 10.9.

Alcohol misuse

Misuse of alcohol is a major problem worldwide. It presents in a multitude of ways, which are discussed further on page 252 and in Box 10.35 (p. 253). In many cases, the link to alcohol will be all too obvious; in others, it may not be. Denial and concealment of alcohol intake are common. In the assessment of alcohol intake, the patient should be asked to describe a typical week's drinking, quantified in terms of units of alcohol (1 unit contains approximately 8 g alcohol and is the equivalent of half a pint of beer, a single measure of spirits or a small glass of wine). Drinking becomes hazardous at levels above 21 units weekly for men and 14 units weekly for women. The history from the patient may need corroboration by the GP, earlier medical records and family members. The mean cell volume (MCV) and γ-glutamyl transferase (GGT) may be raised, but are abnormal in only half of problem drinkers; consequently, normal results on these tests do not exclude an alcohol problem. When abnormal, these measures may be helpful in challenging denial and monitoring treatment response. The prevention and management of alcohol-related problems are discussed on page 253.

Substance misuse

The misuse of drugs of all kinds is also widespread. As well as the general headings listed for alcohol problems in Box 10.35 (p. 253), there are two additional sets of problems associated with drug misuse:

- problems linked with the route of administration, such as intravenous injection
- problems arising from pressure applied to doctors to prescribe the misused substances (Box 10.15).

Assessment and management are described on page 254.

Psychological factors affecting medical conditions

Psychological factors may influence the presentation, management and outcome of medical conditions. Specific factors are shown in Box 10.16. The most common psychiatric diagnoses in the medically ill are anxiety and depressive disorders. Often these appear understandable as adjustments to illness and its treatment; however, if the anxiety and depression are severe and persistent, they may complicate the management of the medical condition and active management is required. Anxiety may present as an increase in somatic symptoms such as breathlessness, tremor or palpitations, or as the avoidance of medical treatment. It is most common in those facing difficult or painful treatments, deterioration of their illness or death. Depression may manifest as increased physical symptoms such as pain or fatigue and disability, as well as with depressed mood and loss of interest and pleasure. It is most common in patients who have suffered actual or anticipated losses, such as receiving a terminal diagnosis or undergoing disfiguring surgery.

Treatment is by psychological and/or pharmacological therapies, as described below. Care is required when prescribing psychotropic drugs to the medically ill in order to avoid exacerbation of the medical condition and harmful interactions with other prescribed drugs.

10.15 Substance misuse: additional presenting problems

Complications arising from the route of use

Intravenous
- Local: abscesses, cellulitis, thrombosis
- Systemic: bacterial (endocarditis), viral (hepatitis, human immunodeficiency virus (HIV))

Nasal ingestion
- Erosion of nasal septum, epistaxis

Smoking
- Oral, laryngeal and lung cancer

Inhalation
- Burns, chemical pneumonitis, rashes

Pressure to prescribe misused substance
- Manipulation, deceit and threats
- Factitious description of illness
- Malingering

10.16 Risk factors for psychological problems associated with medical conditions
- Previous history of depression or anxiety
- Lack of social support
- New diagnosis of a serious medical condition
- Deterioration of or failure of treatment for medical condition
- Unpleasant, disabling or disfiguring treatment
- Change in medical care, e.g. discharge from hospital
- Impending death

TREATING PSYCHIATRIC DISORDERS

The multifactorial origin of most psychiatric disorders means that there are multiple potential targets for treatment.

Biological treatments

These aim to relieve psychiatric disorder by modifying brain function. The main biological treatments are psychotropic drugs. These are widely used for various

10.17 Classification of commonly used psychotropic drugs

Action	Main groups	Clinical use
Antipsychotic	Phenothiazines Butyrophenones Second-generation antipsychotics	Schizophrenia Bipolar mania Acute confusion
Antidepressant	Tricyclics and related drugs	Depression/anxiety Obsessive-compulsive disorder
	Monoamine oxidase inhibitors	Depression/anxiety
	Serotonin and noradrenergic re-uptake inhibitors	Depression/anxiety Obsessive-compulsive disorder
Mood-stabilising	Lithium (Semi-)Sodium valproate	Treatment and prophylaxis of bipolar disorder
Anti-anxiety	Benzodiazepines	Anxiety/insomnia (short term) Alcohol withdrawal (short term)
	β-adrenoceptor antagonists	Anxiety (somatic symptoms)

purposes; a pragmatic classification is set out in Box 10.17. It should be noted that some drugs have applications to more than one condition; for example, antidepressants are also widely used in the treatment of anxiety *and* chronic pain. The specific subgroups of psychotropic drugs are discussed in the sections on the appropriate disorders.

Electroconvulsive therapy (ECT) entails producing a convulsion by the administration of high-voltage, brief, direct-current impulses to the head while the patient is anaesthetised and paralysed by muscle relaxant. If properly administered, it is remarkably safe, has few side-effects, and is of proven efficacy for severe depressive illness. There may be amnesia for events occurring a few hours before ECT (retrograde) and after it (anterograde). Pronounced amnesia can occur but is infrequent and difficult to distinguish from the effects of severe depression. Surgery to the brain (psychosurgery) has a very limited place and then only in the treatment of severe chronic psychiatric illness resistant to other measures.

Psychological treatments

These treatments are useful in many psychiatric disorders and also in non-psychiatric conditions. They are based on talking with patients, either individually or in groups. Sometimes discussion is supplemented by 'homework' or tasks to complete between treatment sessions. Psychological treatments take a number of forms based on the duration and frequency of contact, the specific techniques applied and their underlying theory.

General or supportive psychotherapy

This should be part of all medical treatment. It involves empathic listening to the patient's account of their symptoms and associated fears and concerns, followed by the sympathetic provision of accurate information that addresses these.

Cognitive therapy

This therapy is based on the observation that some psychiatric disorders are associated with systematic errors in the patient's conscious thinking: for example, a tendency to interpret events in a negative way or see them as unduly threatening. A triad of 'cognitive errors' has been described in depression (Box 10.18). Cognitive therapy aims to help patients to identify such cognitive errors and to learn how to challenge them. It is widely used for depression, anxiety and eating and somatoform disorders, and also increasingly in psychoses.

10.18 The negative cognitive triad associated with depression

- Negative view of self, e.g. 'I am no good'
- Negative view of current life experiences, e.g. 'The world is an awful place'
- Negative view of the future, e.g. 'The future is hopeless'

Behaviour therapy

This is a practically orientated form of treatment, in which patients are assisted in changing unhelpful behaviour: for example, helping patients to implement carefully graded exposure to the feared stimulus in phobias.

Cognitive behaviour therapy

Cognitive behaviour therapy (CBT) combines the methods of behaviour therapy and cognitive therapy. It is the most widely available and extensively researched psychological treatment.

Problem-solving therapy

This is a simplified brief form of CBT, which helps patients actively tackle problems in a structured way (Box 10.19). It is of benefit in mild to moderate depression, and can be delivered by non-psychiatric doctors and nurses after appropriate training.

Psychodynamic psychotherapy

This treatment, also known as 'interpretive psychotherapy', was pioneered by Freud, Jung and Klein, amongst others. It is based upon the theory that early life experience generates powerful but unconscious motivations. Psychotherapy aims to help the patient to

10.19 Stages of problem-solving therapy

- Define and list problems
- Choose one to work on
- List possible solutions
- Evaluate these and choose the best
- Try it out
- Evaluate the result
- Repeat until problems are resolved

become aware of these unconscious factors on the assumption that, once identified, their negative effects are reduced. The relationship between therapist and patient is used as a therapeutic tool to identify issues in patients' relationships with others, particularly parents, which may be replicated or transferred to their relationship with the therapist. Explicit discussion of this relationship (transference) is the basis for the treatment, which traditionally requires frequent sessions over a period of months or even years.

Interpersonal psychotherapy

Interpersonal psychotherapy (IPT) is a specific form of brief psychotherapy that focuses on patients' current interpersonal relationships and is an effective treatment for mild to moderate depression.

Social interventions

Some adverse social factors, such as unemployment, may not be readily amenable to intervention, but others, such as access to benefits and poor housing, may be. Patients can be helped to address these problems themselves by being taught problem-solving. Befrienders and day centres can reduce social isolation, benefits advisers can ensure appropriate financial assistance, and medical recommendations can be made to local housing departments to help patients obtain more appropriate accommodation.

PSYCHIATRIC DISORDERS

Stress-related disorders

Acute stress reaction

Following a stressful event such as a serious medical diagnosis or a major accident, some people develop a characteristic pattern of symptoms. These include a sense of bewilderment, anxiety, anger, depression, altered activity and withdrawal. The symptoms are transient and usually resolve completely within a few days.

Adjustment disorder

A more common psychological response to a major stressor is a less severe but more prolonged emotional reaction. The predominant symptom is usually depression and/or anxiety, which is insufficiently persistent or intense to merit a diagnosis of depressive or anxiety disorder. There may also be anger, aggressive behaviour and associated excessive alcohol use. Symptoms develop within a month of the onset of the stress, and their duration and severity reflect the course of the underlying stressor.

Grief reactions following bereavement are a particular type of adjustment disorder. They manifest as a brief period of emotional numbing, followed by a period of distress lasting several weeks, during which sorrow, tearfulness, sleep disturbance, loss of interest and a sense of futility are common. Perceptual distortions may occur, including misinterpreting sounds as the dead person's voice. 'Pathological grief' describes a grief reaction that is abnormally intense or persistent.

Management and prognosis

Ongoing contact with and support from a doctor or other who can listen, reassure, explain and advise are often all that is needed. Most patients do not require psychotropic medication, although benzodiazepines reduce arousal in acute stress reactions and can aid sleep in adjustment disorders. Psychotherapy may be helpful for patients with abnormal grief reactions. These conditions usually resolve with time but can develop into depressive or anxiety disorders and require treating as such.

Post-traumatic stress disorder

Post-traumatic stress disorder (PTSD) is a protracted response to a stressful event of an exceptionally threatening or catastrophic nature. Examples of such events include natural disasters, terrorist activity, serious accidents and witnessing violent deaths. PTSD may also sometimes occur after distressing medical treatments. There is usually a delay ranging from a few days to several months between the traumatic event and the onset of symptoms. Typical symptoms are recurrent intrusive memories (flashbacks) of the trauma, as well as sleep disturbance, especially nightmares (usually of the traumatic event) from which the patient awakes in a state of anxiety, symptoms of autonomic arousal, emotional blunting and avoidance of situations that evoke memories of the trauma. Anxiety and depression are often associated and excessive use of alcohol or drugs frequently complicates the clinical picture.

Management and prognosis

Immediate counselling for those who have survived a major trauma is only likely to benefit those who request it. The main aims are to provide support, direct advice and the opportunity for emotional catharsis. In established PTSD, structured psychological approaches (CBT, eye movement desensitisation and reprocessing (EMDR), and stress management) are effective. Antidepressant drugs are moderately effective. The condition runs a fluctuating course, with most patients recovering within 2 years. In a small proportion, the symptoms become chronic.

Anxiety disorders

These are characterised by the emotion of anxiety, worrisome thoughts, avoidance behaviour and the somatic symptoms of autonomic arousal. Anxiety disorders are divided into three main subtypes: phobic, paroxysmal (panic) and generalised (Box 10.20). The nature and prominence of the somatic symptoms often lead the

10.20 Classification of anxiety disorders

	Phobic anxiety disorder	Panic disorder	Generalised anxiety disorder
Occurrence	Situational	Paroxysmal	Persistent
Behaviour	Avoidance	Escape	Agitation
Cognitions	Fear of situation	Fear of symptoms	Worry
Symptoms	On exposure	Episodic	Persistent

patient to present initially to medical services. Anxiety may be stress-related and phobic anxiety may follow an unpleasant incident. Patients with anxiety often also have depression.

Phobic anxiety disorder

A phobia is an abnormal or excessive fear of an object or situation, which leads to avoidance of it (such as excessive fear of dying in an air crash leading to avoidance of flying). A generalised phobia of going out alone or being in crowded places is called agoraphobia. Phobic responses can develop to medical procedures such as venepuncture.

Panic disorder

Panic disorder describes repeated attacks of severe anxiety, which are not restricted to any particular situation or circumstances. Somatic symptoms such as chest pain, palpitations and paraesthesiae in lips and fingers are common. The symptoms are in part due to involuntary over-breathing (hyperventilation). Patients with panic attacks often fear that they are suffering from a serious illness such as a heart attack or stroke, and seek emergency medical attention. Panic disorder is often associated with agoraphobia.

Generalised anxiety disorder

This is a chronic anxiety state associated with uncontrollable worry. The associated somatic symptoms of muscle tension and bowel disturbance often lead to a medical presentation.

Management of anxiety disorders

Psychological treatment

Explanation and reassurance are essential, especially when patients fear they have a serious medical condition. Specific treatment may be needed. Treatments include relaxation, graded exposure (desensitisation) to feared situations for phobic disorders, and CBT.

Drug treatment

Antidepressants are the drugs of choice. Benzodiazepines are useful in the short term but long-term use can lead to dependence. A β-blocker such as propranolol can help when somatic symptoms are prominent.

Obsessive-compulsive disorder

Obsessive-compulsive disorder (OCD) is characterised by obsessive thoughts, which are recurrent, unwanted and usually anxiety-provoking, but recognised as one's own; and by compulsions, which are repeated acts performed to relieve the anxiety. An example is repeated hand-washing related to thoughts of contamination. The differential diagnosis is normal checking behaviour and delusional beliefs about thought possession. Unlike other anxiety disorders, which are more common in women, OCD is equally common in men and women.

Management and prognosis

OCD usually responds to some degree to antidepressant drugs (SSRIs; see Box 10.17) and to CBT, which helps patients expose themselves to the feared thought or situation without performing the anxiety-relieving compulsions. However, relapses are common and the condition often becomes chronic.

Mood disorders

Mood or affective disorders include:

- *unipolar depression*: one or more episodes of low mood and associated symptoms
- *bipolar disorder*: episodes of elevated mood interspersed with episodes of depression
- *dysthymia*: chronic low-grade depressed mood without sufficient other symptoms to count as 'clinically significant' or 'major' depression.

Depression

Major depressive disorder has a prevalence of 5% in the general population and approximately 10–20% in chronically ill medical outpatients. It is a major cause of disability and suicide. If comorbid with a medical condition, depression magnifies disability, diminishes adherence to medical treatment and rehabilitation, and may even shorten life expectancy.

Aetiology

There is a genetic predisposition to depression, especially when of early onset. The number and identity of the genes are largely unknown but the serotonin transporter gene is a candidate. Adversity and emotional deprivation early in life also predispose to depression. Depressive episodes are often, but not always, triggered by stressful life events (especially those that involve loss), including medical illnesses. Associated biological factors include hypofunction of monoamine neurotransmitter systems (5-HT and noradrenaline (norepinephrine)) and abnormal hypothalamo-pituitary-adrenal axis (HPA) regulation, which results in elevated cortisol levels that do not suppress with dexamethasone. Exclusion of Cushing's syndrome is described on page 773.

Diagnosis

The symptoms are listed in Box 10.7 (p. 235). Depression may be mild, moderate or severe. It may also be episodic, recurrent or chronic. It can be both a complication of a medical condition and a cause of MUS (see below), so physical examination is essential; an associated medical condition should always be considered (Box 10.21).

Management and prognosis

There is evidence that both drug and psychological treatments work in depression. In practice, the choice is

10.21 Pointers to an organic cause for psychiatric disorder

- Late age of onset of psychiatric illness
- No previous history of psychiatric illness
- No family history of psychiatric illness
- No apparent psychological precipitant

determined by patient preference and local availability. Severe depression complicated by psychosis, dehydration or suicide risk may require ECT.

Drug treatment

Antidepressant drugs are effective in patients whose depression is secondary to medical illness, as well as those in whom it is the primary problem (Box 10.22). These agents are all effective in moderate and severe depression. Commonly used antidepressants are shown in Box 10.23.

- *Tricyclic antidepressants (TCAs)*. These agents inhibit the *re-uptake* of the amines noradrenaline (norepinephrine) and 5-HT at synaptic clefts. The therapeutic effect is noticeable within a week or two. Side-effects, such as sedation, anticholinergic effects, postural hypotension, lowering of the seizure threshold and cardiotoxicity, can be troublesome during this period. TCAs may be dangerous in overdose and in people who have coexisting heart disease, glaucoma and prostatism.
- *Selective serotonin re-uptake inhibitors (SSRIs)*. These are less cardiotoxic and less sedative than TCAs, and have fewer anticholinergic effects. They are safer in overdose, but can still cause headache, nausea, anorexia and sexual dysfunction. They can also interact with other drugs increasing serotonin to produce 'serotonin syndrome'. This is a rare syndrome of neuromuscular hyperactivity, autonomic hyperactivity and agitation, and potentially seizures, hyperthermia, confusion and even death.
- *Newer antidepressants*. A variety is available, including venlafaxine, mirtazapine and duloxetine. They have slightly different modes of action and adverse effects but are generally no more effective than the agents listed above.
- *Monoamine oxidase inhibitors (MAOIs)*. These drugs increase the availability of neurotransmitters at synaptic clefts by inhibiting *metabolism* of noradrenaline (norepinephrine) and 5-HT. They are now rarely prescribed in the UK, since they can cause potentially dangerous interactions with drugs such as amphetamines, and foods rich in tyramine such as cheese and red wine. This is due to accumulation of amines in the systemic circulation, causing a potentially fatal hypertensive crisis.

These different classes of antidepressant have similar efficacy and about three-quarters of patients respond to treatment. Successful treatment requires the patient to take an appropriate dose of an effective drug for an adequate period. For patients who do not respond, a proportion will do so if changed to another antidepressant. The patient's progress must be monitored and, after recovery, treatment should be continued for at least 6–12 months to reduce the high risk of relapse. The dose should then be tapered off over several weeks to avoid discontinuation symptoms. SIGN (www.sign.ac.uk) and NICE (www.nice.org.uk) have published treatment guidelines.

EBM 10.22 Antidepressants in the medically ill

'Antidepressants are efficacious and safe in the treatment of depression occurring in the context of chronic physical health problems. The selective serotonin re-uptake inhibitors are probably the antidepressants of first choice, given their demonstrable effect on quality of life and their apparent safety in cardiovascular disease.'

- Taylor D, et al. B J Psych 2011; 198:179–188.

10.23 Antidepressant drugs

Group	Drug	Usual dose*
Tricyclics	Amitriptyline	75–150 mg daily
	Imipramine	75–150 mg daily
	Dosulepin	75–150 mg daily
	Clomipramine	75–150 mg daily
Selective serotonin re-uptake inhibitors (SSRIs)	Citalopram	20–40 mg daily
	Escitalopram	10–20 mg daily
	Fluoxetine	20–60 mg daily
	Fluvoxamine	100–300 mg daily
	Sertraline	50–100 mg daily
	Paroxetine	20–50 mg daily
Monoamine oxidase inhibitors (MAOIs)	Phenelzine	45–90 mg daily
	Tranylcypromine	20–40 mg daily
	Moclobemide	300–600 mg daily
Noradrenergic re-uptake inhibitors and SSRIs	Venlafaxine	75–375 mg daily
Noradrenergic and specific serotonergic inhibitor	Mirtazapine	15–45 mg daily

*Higher doses may be required: see guidelines.

Psychological treatments

Both CBT and interpersonal therapy are as effective as antidepressants for mild to moderate depression. Antidepressant drugs are, however, preferred for severe depression. Drug and psychological treatments can be used in combination.

Over 50% of people who have had one depressive episode and over 90% of people who have had three or more episodes will have another. The risk of suicide in an individual who has had a depressive disorder is ten times greater than in the general population.

Bipolar disorder

Bipolar disorder is an episodic disturbance with interspersed periods of depressed and elevated mood; the latter is known as hypomania when mild or short-lived, or mania when severe or chronic. The lifetime risk of developing bipolar disorder is approximately 1–2%. Onset is usually in the twenties, and men and women

are equally affected. In DSM-IV, bipolar disorder has been divided into two types:

- *Bipolar I disorder* has a clinical course characterised by one or more manic episodes or mixed episodes. Often individuals have also had one or more major depressive episodes.
- *Bipolar II disorder* features depressive episodes that are more frequent and more intense than manic episodes, but there is a history of at least one hypomanic episode.

Aetiology

Bipolar disorder is strongly heritable (approximately 70%). Relatives of patients have an increased incidence of both bipolar and unipolar affective disorder. Life events, such as physical illness, sleep deprivation and medication, may play a role in triggering episodes.

Diagnosis

The diagnosis is based on clear evidence of episodes of depression and mania. Isolated episodes of hypomania or mania do occur but they are usually preceded or followed by an episode of depression. Psychosis may occur in both the depressive and the manic phases, with delusions and hallucinations that are usually in keeping with the mood disturbance. This is described as an affective psychosis. Patients who present with symptoms of both bipolar disorder and schizophrenia may be given a diagnosis of schizoaffective disorder. A clinical picture of recurrent depression with one or more episodes of hypomania may be referred to as type 2 bipolar disorder.

Management and prognosis

Depression should be treated as described above. However, if antidepressants are prescribed, they should be combined with a mood-stabilising drug (see below) to avoid 'switching' the patients into (hypo)mania. Manic episodes and psychotic symptoms usually respond well to antipsychotic drugs (see Box 10.30, p. 249).

Prophylaxis to prevent recurrent episodes of depression and mania with mood-stabilising agents is important. The main drugs used are lithium and sodium valproate. Olanzapine, quetiapine and risperidone are increasingly used. Caution must be exercised when stopping these drugs, as a relapse may follow.

- *Lithium carbonate* is the drug of choice. It is also used for acute mania, and in combination with a tricyclic as an adjuvant treatment for resistant depression. It has a narrow therapeutic range, so regular blood monitoring is required to maintain a serum level of 0.5–1.0 mmol/L. Toxic effects include nausea, vomiting, tremor and convulsions. With long-term treatment, weight gain, hypothyroidism, increased calcium and parathormone, nephrogenic diabetes insipidus (p. 794) and renal failure can occur. Thyroid and renal function should be checked before treatment is started and regularly thereafter. Lithium may be teratogenic, and should not be prescribed during the first trimester of pregnancy.
- *Sodium valproate (an anticonvulsant) and olanzapine (an antipsychotic)* are both used as prophylaxis in bipolar disorder, usually as a second-line alternative to lithium. Valproate conveys a high risk of birth defects and should also not be used in women of child-bearing age. Olanzapine can cause significant weight gain. (For a list of the adverse effects of antipsychotic drugs, see Box 10.31.)

The relapse rate of bipolar disorder is high, although patients may be perfectly well between episodes. After one episode the annual average risk of relapse is about 10–15%, which doubles after more than three episodes. There is a substantially increased lifetime risk of suicide of 5–10%.

Somatoform disorders

The essential feature of these disorders is that the somatic symptoms are not explained by a medical condition (medically unexplained symptoms), nor better diagnosed as part of a depressive or anxiety disorder. Several syndromes are described within this category; there is considerable overlap between them in both aetiology and clinical presentation.

Aetiology

The cause of somatoform disorders is incompletely understood but contributory factors include depression and anxiety, the erroneous interpretation of somatic symptoms as evidence of disease, excessive concern with physical illness and a tendency to seek medical care. A family history or previous history of a particular condition may have shaped the patient's beliefs about illness. Doctors may exacerbate the problem, either by dismissing the complaints as non-existent or by overemphasising the possibility of disease.

Somatisation disorder

Somatisation disorder (Briquet's syndrome) is characterised by the occurrence of chronic multiple somatic symptoms for which there is no physical cause. Symptoms start in early adult life and may be referred to any part of the body. The disorder is much more common in women. Common complaints include pain, vomiting, nausea, headache, dizziness, menstrual irregularities and sexual dysfunction. Patients may undergo a multitude of negative investigations and unhelpful operations, particularly hysterectomy and cholecystectomy. There is no proven treatment but minimisation of iatrogenic harm from multiple investigations and attempts at medical treatment is important.

Hypochondriacal disorder

Patients with this condition, also known as health anxiety, have a strong fear or belief that they have a serious, often fatal, disease and that fear persists despite appropriate medical reassurance. They are typically highly anxious and seek many medical opinions and investigations in futile but repeated attempts to relieve their fears. Treatment with CBT may be helpful. The condition may become chronic.

In a small proportion of cases, the conviction that disease is present reaches delusional intensity. The best-known example is that of parasitic infestation ('delusional parasitosis'), which leads patients to consult dermatologists. Antipsychotic medication may be effective in such cases.

Body dysmorphic disorder

This describes a preoccupation with bodily shape or appearance, with the belief that one is disfigured in some way (previously known as dysmorphophobia). People with this condition may make inappropriate requests for cosmetic surgery. CBT or antidepressants may be helpful. The belief in disfigurement may sometimes be delusional, in which case antipsychotic drugs may help.

Somatoform autonomic dysfunction

This describes somatic symptoms referable to bodily organs that are largely under the control of the autonomic nervous system. The most common examples involve the cardiovascular system ('cardiac neurosis'), respiratory system (psychogenic hyperventilation) and gut (psychogenic vomiting and irritable bowel syndrome). Antidepressant drugs and CBT may be helpful.

Somatoform pain disorder

This describes severe, persistent pain that cannot be adequately explained by a medical condition. Antidepressant drugs (especially tricyclics and dual action drugs such as duloxetine and mirtazapine) are helpful, as are some of the anticonvulsant drugs, particularly carbamazepine, gabapentin and pregabalin. CBT and multidisciplinary pain management teams are also useful.

Chronic fatigue syndrome

Chronic fatigue syndrome (CFS) is also referred to as neurasthenia. It is characterised by excessive fatigue after minimal physical or mental exertion, poor concentration, dizziness, muscular aches and sleep disturbance. This pattern of symptoms may follow a viral infection such as infectious mononucleosis, influenza or hepatitis. Symptoms overlap with those of depression and anxiety. There is good evidence that many patients improve with carefully graded exercise and with CBT, as long as the benefits of such treatment are carefully explained.

Dissociative (conversion) disorder

Dissociative disorder refers to a loss or distortion of neurological functioning that is not fully explained by organic disease. Psychological functions commonly affected include conscious awareness and memory. Physical functions affected (conversion) include changes in sensory or motor function that may mimic lesions in the motor or sensory nervous system (Box 10.24). The aetiology of dissociation is unknown. There is an association with adverse childhood experiences, including physical and sexual abuse. Organic disease may both facilitate dissociative mechanisms and provide a model for symptoms; thus, for example, non-epileptic seizures often occur in those with epilepsy. CBT may be of benefit. Coexisting depression should be treated with CBT or antidepressant drugs.

10.24 Common presentations of dissociative (conversion) disorder

- Gait disturbance
- Loss of function in limbs
- Aphonia
- Non-epileptic seizures
- Sensory loss
- Blindness

General management for medically unexplained symptoms

The management of the various syndromes of medically unexplained complaints described above is based on general principles (Box 10.25).

Reassurance

Patients should be asked what they are most worried about. Clearly, it may be unwise to state categorically that the patient does not have any disease, as that is difficult to establish with certainty. However, it can be emphasised that the probability of having a disease is low. If patients repeatedly ask for reassurance about the same health concern despite reassurance, they may have hypochondriasis.

Explanation

Patients need a positive explanation for their symptoms. It is unhelpful to say that symptoms are psychological or 'all in the mind'. Rather, a term such as 'functional' (meaning that the symptoms represent a reversible disturbance of bodily function) may be more acceptable. When possible, it is useful to describe a plausible physiological mechanism that is linked to psychological factors such as stress and implies that the symptoms are reversible. For example, in irritable bowel syndrome, psychological stress results in increased activation of the autonomic nervous system, which leads to constriction of smooth muscle in the gut wall, which in turn causes pain and bowel disturbance.

Advice

This should focus on how to overcome factors perpetuating the symptoms: for example, by resolving stressful social problems or by practising relaxation. The doctor can offer to review progress, to prescribe (for example) an antidepressant drug and, if appropriate, to refer for physiotherapy or psychological treatments such as CBT. The attitudes of relatives may need to be addressed if they have adopted an over-protective role, unwittingly reinforcing the patient's disability.

Drug treatment

Antidepressant drugs are often helpful, even if the patient is not depressed (Box 10.26).

10.25 General management principles for medically unexplained symptoms

- Take a full sympathetic history
- Exclude disease but avoid unnecessary investigation or referral
- Seek specific treatable psychiatric syndromes
- Demonstrate to patients that you believe their complaints
- Establish a collaborative relationship
- Give a positive explanation for the symptoms, including but not over-emphasising psychological factors
- Encourage a return to normal functioning

EBM 10.26 Antidepressants for medically unexplained somatic symptoms

'There is evidence for the efficacy of antidepressant drugs for patients with medically unexplained symptoms.'

- Sumathipala A. Psychosom Med 2007; 69:889–900.

EBM 10.27 CBT for medically unexplained somatic symptoms

'CBT is consistently effective (11 of 13 trials) across a spectrum of somatoform disorders. Also, a psychiatric consultation letter to the primary care physician about strategies for managing the somatising patient seems to improve physical functioning and reduce costs.'

- Kroenke K. Psychosom Med 2007; 69:881–888.

Psychological treatment

There is evidence for the effectiveness of CBT (Box 10.27). Other psychological treatments such as IPT may also have a role.

Rehabilitation

Where there is chronic disability, particularly in dissociative (conversion) disorder, conventional physical rehabilitation may be the best approach.

Shared care with the GP

Ongoing planned care is required for patients with chronic intractable symptoms, especially those of somatisation disorder. Review by the same specialist, interspersed with visits to the same GP, is probably the best way to avoid unnecessary multiple re-referral for investigation, to ensure that treatable aspects of the patient's problems, such as depression, are actively managed, and to prevent the GP from becoming demoralised.

Factitious disorder and malingering

It is important to distinguish somatoform disorders from factitious disorder and malingering.

Factitious disorder

This describes the repeated and deliberate production of the signs or symptoms of disease to obtain medical care. It is uncommon. An example is the dipping of thermometers into hot drinks to fake a fever. The disorder feigned is usually medical but can be a psychiatric illness, with false reports of hallucinations or symptoms of depression.

Münchausen's syndrome

This refers to a severe chronic form of factitious disorder. Patients are usually older and male, with a solitary, peripatetic lifestyle in which they travel widely, sometimes visiting several hospitals in one day. Although the condition is rare, such patients are memorable because they present so dramatically. The history can be convincing enough to persuade doctors to undertake investigations or initiate treatment, including exploratory surgery. It may be possible to trace the patient's history and show that he has presented similarly elsewhere, often changing name several times. Some emergency departments hold lists of such patients.

Management is by gentle but firm confrontation with clear evidence of the fabrication of illness, together with an offer of psychological support. Treatment is usually declined but recognition of the condition may help to avoid further iatrogenic harm.

Malingering

Malingering is a description of behaviour, not a psychiatric diagnosis. It refers to the deliberate and conscious simulation of signs of disease and disability. Patients have motives that are clear to them but which they conceal from doctors. Examples include the avoidance of burdensome responsibilities (such as work or court appearances) or the pursuit of financial gain (fraudulent claims for benefits or compensation). Malingering can be hard to detect at clinical assessment, but is suggested by evasion or inconsistency in the history.

Schizophrenia

Schizophrenia is a psychosis characterised by delusions, hallucinations and lack of insight. Acute schizophrenia may present with disturbed behaviour, marked delusions, hallucinations and disordered thinking, or with insidious social withdrawal and other so-called negative symptoms and less obvious delusions and hallucinations. The prevalence is similar worldwide at about 1% and the disorder is more common in men. The children of one affected parent have approximately a 10% risk of developing the illness, but this rises to 50% if an identical twin is affected. The usual age of onset is the mid-twenties.

Aetiology

There is a strong genetic contribution, probably involving many susceptibility genes, each of small effect. The best candidates, such as *disrupted in schizophrenia-1* (*DISC1*) and *neuregulin-1* (*NRG1*), have supportive linkage, association, animal model and basic neurobiological evidence. Environmental risk factors include obstetric complications and urban birth. Brain imaging techniques have identified subtle structural abnormalities, including an enlargement of the lateral ventricles and an overall decrease in brain size (by about 3% on average), with relatively greater reduction in temporal lobe volume (5–10%). Episodes of acute schizophrenia may be precipitated by social stress and also by cannabis, which increase dopamine turnover and sensitivity. Consequently, schizophrenia is now viewed as a neurodevelopmental disorder, caused by abnormalities of brain development associated with genetic predisposition and early environmental influences, but precipitated by later triggers.

Diagnosis

Schizophrenia usually presents with an acute episode and progresses to a chronic state. Acute schizophrenia should be suspected in any individual with bizarre behaviour accompanied by delusions and hallucinations that are not due to organic brain disease or substance misuse. The diagnosis is made on clinical grounds, with

10.28 Symptoms of schizophrenia

First-rank symptoms of acute schizophrenia

- A = Auditory hallucinations – second- or third-person/écho de la pensée
- B = Broadcasting, insertion/withdrawal of thoughts
- C = Controlled feelings, impulses or acts ('passivity' experiences/phenomena)
- D = Delusional perception (a particular experience is bizarrely interpreted)

Symptoms of chronic schizophrenia (negative symptoms)

- Flattened (blunted) affect
- Apathy and loss of drive (avolition)
- Social isolation/withdrawal (autism)
- Poverty of speech (alogia)
- Poor self-care

10.29 Differential diagnosis of schizophrenia

Alternative diagnosis	Distinguishing features
Other functional psychoses	
Delusional disorders	Absence of specific features of schizophrenia
Psychotic depression	Prominent depressive symptoms
Manic episode	Prominent manic symptoms
Schizoaffective disorder	Mood and schizophrenia symptoms both prominent
Puerperal psychosis	Acute onset after childbirth
Organic disorders	
Drug-induced psychosis	Evidence of drug or alcohol misuse
Side-effects of prescribed drugs	Levodopa, methyldopa, corticosteroids, antimalarial drugs
Temporal lobe epilepsy	Other evidence of seizures
Delirium	Visual hallucinations; impaired consciousness
Dementia	Age; established cognitive impairment
Huntington's disease	Family history; choreiform movements; dementia

investigations used principally to rule out organic brain disease. The characteristic clinical features are listed in Box 10.28. Hallucinations are typically auditory, although they can occur in any sensory modality. They commonly involve voices from outside the head that talk to or about the person. Sometimes the voices repeat the person's thoughts. Patients may also describe 'passivity of thought', experienced as disturbances in the normal privacy of thinking – for example, the delusional belief that their thoughts are being 'withdrawn' from them, perhaps 'broadcast' to others, and/or alien thoughts being 'inserted' into their mind. Other characteristic symptoms are delusions of control: believing that one's emotions, impulses or acts are controlled by others. Another phenomenon is delusional perception, a delusion that arises suddenly alongside a normal perception (e.g. 'I saw the moon and I immediately knew he was evil'). Many other, less specific symptoms may occur, including thought disorder, as manifest by incomprehensible speech and abnormalities of movement, such as those in which the patient can become immobile or adopt awkward postures for prolonged periods (catatonia).

The main differential diagnosis of schizophrenia (Box 10.29) is:

- *Other functional psychoses*, particularly psychotic depression and mania, in which delusions and hallucinations are congruent with a marked mood disturbance (negative in depression and grandiose in mania). If features of schizophrenia and affective disorder coexist in equal measure, a diagnosis of schizoaffective disorder is made. Schizophrenia must also be differentiated from specific delusional disorders that are not associated with the other typical features of schizophrenia.
- *Organic psychoses*, including delirium, in which there is impairment of consciousness and loss of orientation (not found in schizophrenia), typically with visual hallucinations, and drug misuse, the latter particularly in young people. Schizophrenia must also be differentiated from other organic psychoses such as temporal lobe epilepsy, in which olfactory and gustatory hallucinations may occur.

Many of those who experience acute schizophrenia go on to develop a chronic state in which the acute, so-called positive symptoms resolve, or at least do not dominate the clinical picture, leaving so-called negative symptoms that include blunt affect, apathy, social isolation, poverty of speech and poor self-care. Patients with chronic schizophrenia may also manifest positive symptoms, particularly when under stress, and it can be difficult for those who do not know the patient to judge whether or not these are signs of an acute relapse.

Management

First-episode schizophrenia usually requires admission to hospital because patients lack the insight that they are ill and are unwilling to accept treatment. In some cases, they may be at risk of harming themselves or others. Subsequent acute relapses and chronic schizophrenia are now usually managed in the community.

Drug treatment

Antipsychotic agents are effective against the positive symptoms of schizophrenia in the majority of cases. They take 2–4 weeks to be maximally effective but have some beneficial effects shortly after administration. Treatment is then ideally continued to prevent relapse. In a patient with a first episode of schizophrenia, this will usually be for 1–2 years, but in patients with multiple episodes, treatment may be required for many years. The benefits of prolonged treatment must be weighed against the adverse effects, which include extrapyramidal side-effects (EPSE) like acute dystonic reactions (which may require treatment with parenteral anticholinergics), akathisia, Parkinsonism and tardive dyskinesia (abnormal movements, commonly of the face, over which the patient has no voluntary control). For long-term use, antipsychotic agents are often given in slow-release (depot) injected form to improve patient adherence.

10.30 Antipsychotic drugs

Group	Drug	Dose range
Phenothiazines	Chlorpromazine	100–1000 mg daily
Butyrophenones	Haloperidol	5–30 mg daily
Thioxanthenes	Flupentixol decanoate	20–200 mg fortnightly (depot injection)
Diphenylbutylpiperidines	Pimozide	4–30 mg daily
Substituted benzamides	Sulpiride	200–1800 mg daily
Dibenzodiazepines*	Clozapine	200–900 mg daily
Benzisoxazole*	Risperidone	2–16 mg daily
Thienobenzodiazepines*	Olanzapine	5–20 mg daily
Dibenzothiazepines	Quetiapine	25–800 mg daily

*Second-generation antipsychotics.

10.31 Side-effects of antipsychotic drugs

Weight gain due to increased appetite

Effects due to dopamine blockade*
- Acute dystonia
- Akathisia (motor restlessness)
- Parkinsonism
- Tardive dyskinesia
- Gynaecomastia
- Galactorrhoea

Effects due to cholinergic blockade
- Dry mouth
- Blurred vision
- Impotence
- Constipation
- Urinary retention

Hypersensitivity reactions
- Blood dyscrasias (neutropenia with clozapine)
- Cholestatic jaundice
- Photosensitive dermatitis

Ocular complications (long-term use)
- Corneal and lens opacities

*Less severe with clozapine, quetiapine and olanzapine, possibly because of strong 5-HT-blocking effect and relatively weak dopamine blockade.

A number of antipsychotic agents are available (Box 10.30). These may be divided into conventional (typical, first-generation) drugs such as chlorpromazine and haloperidol, and newer or atypical (also so-called novel or second-generation) drugs such as clozapine. All are believed to work by blocking D_2 dopamine receptors in the brain. Patients who have not responded to conventional drugs may respond to newer agents, which are also less likely to produce unwanted EPSE but do tend to cause greater weight gain and metabolic disturbances such as dyslipidaemia. Clozapine can also cause an agranulocytosis and consequently requires regular monitoring of the white blood cell count, initially on a weekly basis. Details of the side-effects of antipsychotic drugs are listed in Box 10.31.

Serious adverse effects of antipsychotic drugs include:

- *Neuroleptic malignant syndrome*, which is a rare but serious condition. It is characterised by fever, tremor and rigidity, autonomic instability and confusion. Characteristic laboratory findings are an elevated creatinine phosphokinase and leucocytosis. Antipsychotic medication must be stopped immediately and supportive therapy provided, often in an intensive care unit. Treatment includes ensuring hydration and reducing hyperthermia. Dantrolene sodium and bromocriptine may be helpful. Mortality is 20% untreated and 5% with treatment.
- *Prolongation of the QT_c interval*, which may be associated with ventricular tachycardia, torsades de pointes and sudden death. Treatment is by stopping the drug, monitoring the electrocardiogram (ECG) and treating serious arrhythmias (p. 562).

Psychological treatment

Psychological treatment, including general support for the patient and his or her family, is now seen as an essential component of management. CBT may help patients to cope with symptoms. There is evidence that personal and/or family education, when given as part of an integrated treatment package, reduces the rate of relapse.

Social treatment

After an acute episode of schizophrenia has been controlled by drug therapy, social rehabilitation may be required. Recurrent illness is likely to cause disruption to patients' relationships and their ability to manage their accommodation and occupation; consequently, they may need help to obtain housing and employment. A graded return to employment and sometimes a period of supported accommodation are required.

Patients with chronic schizophrenia have particular difficulties and may need long-term, supervised accommodation. This now tends to be in sheltered or hostel accommodation in the community. Patients may also benefit from sheltered employment if they are unable to participate effectively in the labour market. Ongoing contact with a health worker allows monitoring for signs of relapse, sometimes as part of a multidisciplinary team working to agreed plans (the 'care programme approach'). Partly because of a tendency to inactivity, smoking and a poor diet, patients with chronic schizophrenia are at increased risk of cardiovascular disease, diabetes and stroke, and require proactive medical as well as psychiatric care.

Prognosis

About one-quarter of those who develop an acute schizophrenic episode have a good outcome. One-third develop chronic, incapacitating schizophrenia, and the remainder largely recover after each episode but suffer relapses. Most will not work or live independently. Prophylactic treatment with antipsychotic drugs reduces the rate of relapse in the first 2 years after an episode of schizophrenia from 50% to 10%. Schizophrenia is associated with suicide, with up to 1 in 10 patients taking their own lives.

Delirium, dementia and other organic disorders

Delirium, dementia and other organic disorders could be considered to be medical conditions rather than psychiatric disorders, as they are a result of reduced brain function; they are, however, included in psychiatric classifications and are sometimes misdiagnosed because they often manifest with disturbed behaviour.

Delirium

Delirium is common in acute medical settings, especially in the elderly and patients in high-dependency and intensive care units. Aetiology, assessment and management are described in Chapters 7 and 26.

Dementia

Dementia is a clinical syndrome characterised by a loss of previously acquired intellectual function in the absence of impairment of arousal, and affects 5% of those over 65 and 20% of those over 85. It is defined as a global impairment of cognitive function, and is typically progressive and non-reversible. Although memory is most affected in the early stages, deficits in visuospatial function, language ability, concentration and attention gradually become apparent. There are many causes (Box 10.32) but Alzheimer's disease and diffuse vascular disease are the most common. Rarer causes of dementia should be actively sought in younger patients and those with short histories.

Aetiology

Dementia may be divided into 'cortical' and 'subcortical' types, depending on the clinical features. Many of the primary degenerative diseases that cause dementia have characteristic features that may allow a specific diagnosis during life. Creutzfeldt–Jakob disease, for example, is usually relatively rapidly progressive (over months), is associated with myoclonus, and demonstrates characteristic abnormalities on electroencephalogram (EEG). The more slowly progressive dementias are more difficult to distinguish during life, but fronto-temporal dementia typically presents with focal (temporal or frontal lobe) dysfunction, and Lewy body dementia may present with visual hallucinations. The course may also help to distinguish types of dementia, as it may be gradual (as in Alzheimer's disease) or step-wise (as in vascular dementia).

Clinical features

The usual presentation is with a disturbance of personality or memory dysfunction. A careful history is essential

10.32 Causes of dementia

Type	Common	Unusual	Rare
Vascular	Diffuse small-vessel disease	Amyloid angiopathy Multiple emboli	Cerebral vasculitis
Degenerative/ inherited	Alzheimer's disease	Fronto-temporal dementia (including Pick's disease) Leucodystrophies Huntington's disease Wilson's disease Dystrophia myotonica Cortical Lewy body disease Progressive supranuclear palsy Others (e.g. cortico-basal degeneration)	Mitochondrial encephalopathies
Neoplastic (p. 1193)	Secondary deposits	Primary cerebral tumour	Paraneoplastic syndrome (limbic encephalitis)
Inflammatory	–	Multiple sclerosis	Sarcoidosis
Traumatic	Chronic subdural haematoma Post-head injury	Punch-drunk syndrome	–
Hydrocephalus (p. 1216)		Communicating/non-communicating 'normal pressure' hydrocephalus	–
Toxic/nutritional	Alcohol	Thiamin deficiency B_{12} deficiency	Anoxia/carbon monoxide poisoning Heavy metal poisoning
Infective	–	Syphilis HIV	Post-encephalitic Whipple's disease Subacute sclerosing panencephalitis
Prion diseases (p. 1211)	–	Sporadic Creutzfeldt–Jakob disease (CJD)	Variant CJD Kuru Gerstmann–Sträussler–Scheinker disease

and it is important to interview both the patient and a close family member. Simple bedside tests such as the MMSE (p. 234), are useful in assessing the nature and severity of the cognitive deficit, although a more intensive neuropsychological assessment may sometimes be required, especially if there is diagnostic uncertainty. It is important to exclude a focal brain lesion. This is done by determining that there is cognitive disturbance in more than one area. Mental state assessment is important to seek evidence of depression, which may coexist with or occasionally cause apparent cognitive impairment.

Investigations

The aim is to seek treatable causes and to estimate prognosis. This is done using a standard set of investigations (Box 10.33). Imaging of the brain can exclude potentially treatable structural lesions, such as hydrocephalus, cerebral tumour or chronic subdural haematoma, though the only abnormality usually seen is that of generalised atrophy. If the initial tests are negative, more invasive investigations, such as lumbar puncture or, rarely, brain biopsy, may be indicated.

Management

This is directed at addressing treatable causes, and providing support for patient and carers if no specific treatment exists. If the diagnosis is Alzheimer-type dementia, anticholinesterase inhibitors and memantine may arrest progression for a time. Treating vascular risk factors may slow deterioration in vascular dementia. Psychotropic drugs may help where there is associated disturbance of sleep, perception or mood, but should be used with care because of an increased mortality in patients who have been treated long-term with these agents. Sedation is not a substitute for good care for patients and carers or, in the later stages, attentive residential nursing care. In the UK, incapacity and mental health legislation may be required to manage patients' financial and domestic affairs, as well as to determine their safe placement.

10.33 Initial investigation of dementia

In most patients

- Imaging of head (computed tomography (CT) and/or magnetic resonance imaging (MRI))
- Blood tests
  - Full blood count, erythrocyte sedimentation rate
  - Urea and electrolytes, glucose
  - Calcium, liver function tests
  - Thyroid function tests
  - Vitamin B_{12}
  - Venereal Diseases Research Laboratory (VDRL) test
  - ANA, anti-dsDNA
- Chest X-ray
- EEG

In selected patients

- Lumbar puncture
- HIV serology
- Brain biopsy

Alzheimer's disease

Alzheimer's disease is the most common cause of dementia, but is rare under the age of 45 years.

Aetiology

Genetic factors play an important role and about 15% of cases are familial. Familial cases fall into two main groups: early-onset disease with autosomal dominant inheritance and a later-onset group whose inheritance is polygenic. Mutations in several genes have been described. The inheritance of one of the alleles of apolipoprotein ε (apo ε4) is associated with an increased risk of developing the disease (2–4 times higher in heterozygotes and 6–8 times in homozygotes). Its presence is, however, neither necessary nor sufficient for the development of the disease, so screening for its presence is not clinically useful. The brain in Alzheimer's disease is macroscopically atrophic, particularly the cerebral cortex and hippocampus. Histologically, the disease is characterised by the presence of senile plaques and neurofibrillary tangles in the cerebral cortex. Histochemical staining demonstrates significant quantities of amyloid in the plaques (Fig. 10.4), which typically stain positive for the protein ubiquitin, involved in targeting unwanted or damaged proteins for degradation. This has led to the suggestion that the disease may be due to defects in the ability of neuronal cells to degrade unwanted proteins. Many different neurotransmitter abnormalities have also been described. In particular, there is impairment of cholinergic transmission, although

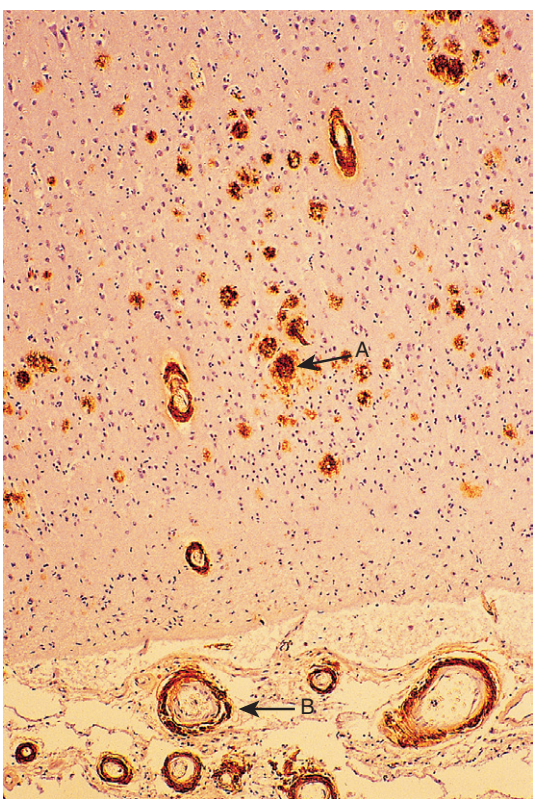

Fig. 10.4 Alzheimer's disease. Section of neocortex stained with polyclonal antibody against βA4 peptide showing amyloid deposits in plaques in brain substance (arrow A) and in blood vessel walls (arrow B).

abnormalities of noradrenaline, 5-HT, glutamate and substance P have also been described.

Clinical features

The key clinical feature is impairment of the ability to remember new information. Hence, patients present with gradual impairment of memory, usually in association with disorders of other cortical functions. Short-term and long-term memory are both affected, but defects in the former are usually more obvious. Later in the course of the disease, typical features include apraxia, visuo-spatial impairment and aphasia. In the early stages of the disease, patients may notice these problems, but as the disease progresses it is common for patients to deny that there is anything wrong (anosognosia). In this situation, patients are often brought to medical attention by their carers. Depression is commonly present. Occasionally, patients become aggressive, and the clinical features can be made acutely worse by intercurrent physical disease.

Investigations and management

Investigation is aimed at excluding treatable causes of dementia (see Box 10.32), as histological confirmation of the diagnosis usually occurs only after death. There is no known treatment, though anticholinesterases such as donepezil, rivastigmine and galantamine, and the NMDA receptor antagonist, memantine, have been shown to be of some benefit. Management consists largely of providing a familiar environment for the patient and support for the carers. Many patients are depressed, and treatment with antidepressant medication may be helpful.

Fronto-temporal dementia

This term encompasses a number of different syndromes, including Pick's diseases and primary progressive aphasia. Patients may present with personality change due to frontal lobe involvement or with language disturbance due to temporal lobe involvement. These diseases are much rarer than Alzheimer's disease. Histological examination of the brain reveals argyrophilic cytoplasmic inclusion bodies of tau (τ) protein rather than the ubiquitin as in Alzheimer's disease (Fig. 10.5). Memory is relatively preserved in the early stages. There is no specific treatment.

Lewy body dementia

This is a neurodegenerative disorder clinically characterised by dementia and signs of Parkinson's disease. The cognitive state often fluctuates and there is a high incidence of visual hallucinations. Affected individuals are particularly sensitive to the side-effects of anti-Parkinsonian medication and also to antipsychotic drugs. The condition is associated with accumulation of abnormal protein aggregates in neurons that contain the protein α-synuclein in association with other proteins including ubiquitin (see Fig. 26.29, p. 1195). The condition is often inherited and mutations in the α-synuclein and β-synuclein genes have been identified in affected patients. There is no specific treatment but anticholinesterase agents may well be helpful.

Alcohol misuse and dependence

Alcohol consumption associated with social, psychological and physical problems constitutes misuse. The criteria for alcohol dependence, a more restricted term, are shown in Box 10.34. Approximately one-quarter of male patients in general hospital medical wards in the UK have a current or previous alcohol problem.

Aetiology

Availability of alcohol and social patterns of use appear to be the most important factors. Genetic factors predispose to dependence. The majority of alcoholics do not have an associated psychiatric disorder, but a few drink heavily in an attempt to relieve anxiety or depression.

10.34 Criteria for alcohol dependence

- Narrowing of the drinking repertoire
- Priority of drinking over other activities (salience)
- Tolerance of effects of alcohol
- Repeated withdrawal symptoms
- Relief of withdrawal symptoms by further drinking
- Subjective compulsion to drink
- Reinstatement of drinking behaviour after abstinence

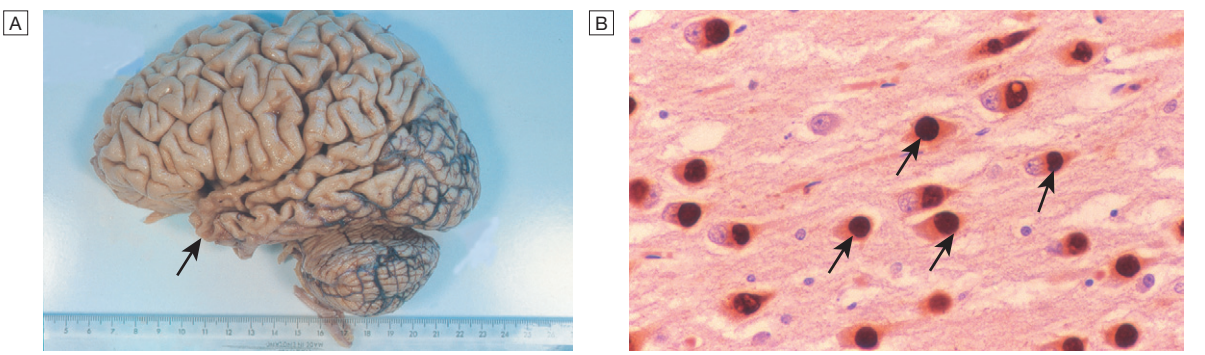

Fig. 10.5 Fronto-temporal dementia. A Lateral view of formalin-fixed brain from a patient who died of Pick's disease, showing gyral atrophy of frontal and parietal lobes and a more severe degree of atrophy affecting the anterior half of the temporal lobe (arrow). B High power (× 200) of hippocampal pyramidal layer, prepared with monoclonal anti-tau antibody. Many neuronal cell bodies contain sharply circumscribed, spherical cytoplasmic inclusion bodies (Pick bodies).

Diagnosis

Alcohol misuse may emerge during the patient's history, although patients may minimise their intake. It may also present via its effects on one or more aspects of the patient's life, listed below. Alcohol dependence commonly presents with withdrawal in those admitted to hospital, as they can no longer maintain their high alcohol intake in this setting.

Complications of chronic alcohol misuse

- *Social problems* include absenteeism from work, unemployment, marital tensions, child abuse, financial difficulties and problems with the law, such as violence and traffic offences.
- *Depression* is common. Alcohol has a direct depressant effect and heavy drinking creates numerous social problems. Attempted and completed suicide are associated with alcohol misuse.
- *Anxiety* is relieved by alcohol in the short term. People who are socially anxious may consequently use alcohol in this way and may develop dependence. Conversely, alcohol withdrawal increases anxiety.
- *Alcoholic hallucinosis* is a rare condition in which alcoholic individuals experience auditory hallucination in clear consciousness.
- *Alcohol withdrawal* is described in Box 10.35. Symptoms usually become maximal about 2–3 days after the last drink and can include seizures ('rum fits').
- *Delirium tremens* is a form of delirium associated with severe alcohol withdrawal. It has a significant mortality and morbidity (see Box 10.35).

Effects on the brain

The familiar features of drunkenness are ataxia, slurred speech, emotional incontinence and aggression. Very heavy drinkers may experience periods of amnesia for events that occurred during bouts of intoxication, termed 'alcoholic blackouts'. Established alcoholism may lead to alcoholic dementia, a global cognitive impairment resembling Alzheimer's disease, but which does not progress and may even improve if the patient becomes abstinent. Indirect effects on behaviour can result from head injury, hypoglycaemia and encephalopathy (p. 941).

A rare but important effect of chronic alcohol misuse is the Wernicke–Korsakoff syndrome. This organic brain disorder results from damage to the mamillary bodies, dorsomedial nuclei of the thalamus and adjacent areas of periventricular grey matter caused by a deficiency of thiamin (vitamin B_1), which most commonly results from long-standing heavy drinking and an inadequate diet. It can also arise from malabsorption or even protracted vomiting. Without prompt treatment (see below), the acute presentation of Wernicke's encephalopathy (nystagmus, ophthalmoplegia, ataxia and confusion) can progress to the irreversible deficits of Korsakoff's syndrome (severe short-term memory deficits and confabulation, and also reduced red blood cell transketolase). In those who die in the acute stage, microscopic examination of the brain shows hyperaemia, petechial haemorrhages and astrocytic proliferation.

10.35 Consequences of chronic alcohol misuse

Acute intoxication

- Emotional and behavioural disturbance
- Medical problems: hypoglycaemia, aspiration of vomit, respiratory depression
- Complication of other medical problems
- Accidents, injuries sustained in fights

Withdrawal phenomena

- Psychological symptoms: restlessness, anxiety, panic attacks
- Autonomic symptoms: tachycardia, sweating, pupil dilatation, nausea, vomiting
- Delirium tremens: agitation, hallucinations, illusions, delusions
- Seizures

Harmful use

Medical consequences

- Neurological: peripheral neuropathy, cerebellar degeneration, cerebral haemorrhage, dementia
- Hepatic: fatty change and cirrhosis, liver cancer
- Gastrointestinal: oesophagitis, gastritis, pancreatitis, oesophageal cancer, Mallory–Weiss syndrome, malabsorption, oesophageal varices
- Respiratory: pulmonary tuberculosis, pneumonia
- Skin: spider naevi, palmar erythema, Dupuytren's contractures, telangiectasias
- Cardiac: cardiomyopathy, hypertension
- Musculoskeletal: myopathy, fractures
- Endocrine and metabolic: pseudo-Cushing's syndrome, hypoglycaemia, gout
- Reproductive: hypogonadism, fetal alcohol syndrome, infertility

Psychiatric and cerebral consequences

- Depression
- Alcoholic hallucinosis
- Alcoholic 'blackouts'
- Wernicke's encephalopathy: nystagmus, ophthalmoplegia, ataxia, confusion
- Korsakoff's syndrome: short-term memory deficits, confabulation

Effects on other organs

These are protean and virtually any organ can be involved (see Box 10.35). These effects are discussed in detail in the relevant chapters.

Management and prognosis

For the person misusing alcohol, provision of clear information from a doctor about the harmful effects of alcohol and the safe levels of consumption is often all that is needed. In more serious cases, patients may have to be advised to alter leisure activities or change jobs to help them to reduce their consumption. Psychological treatment is used for patients who have recurrent relapses and is usually available at specialised centres. Support to stop drinking is also provided by voluntary organisations, such as Alcoholics Anonymous (AA) in the UK.

Alcohol withdrawal syndromes can be prevented, or treated once established, with benzodiazepines. Large doses may be required (e.g. diazepam 20 mg 4 times daily), tailed off over a period of 5–7 days as

symptoms subside. Prevention of the Wernicke–Korsakoff syndrome requires the immediate use of high doses of thiamine, which is initially given parenterally in the form of Pabrinex (two vials 3 times daily for 48 hours) and then orally (100 mg 3 times daily). There is no treatment for Korsakoff's syndrome once it has arisen. The risk of side-effects, such as respiratory depression with benzodiazepines and anaphylaxis with Pabrinex, is small when weighed against the risks of no treatment.

Acamprosate (666 mg 3 times daily) may help to maintain abstinence by reducing the craving for alcohol. Disulfiram (200–400 mg daily) can be given as a deterrent to patients who have difficulty resisting the impulse to drink after becoming abstinent. It blocks the metabolism of alcohol, causing acetaldehyde to accumulate. When alcohol is consumed, an unpleasant reaction follows, with headache, flushing and nausea. Disulfiram is always an adjunct to other treatments, especially supportive psychotherapy. Treatment with antidepressants may be required if depression is severe or does not resolve with abstinence. Antipsychotics (e.g. chlorpromazine 100 mg 3 times daily) are needed for alcoholic hallucinosis. Although such treatment may be successful, there is a high relapse rate.

Chronic alcohol misuse greatly increases the risk of death from accidents, disease and suicide (p. 100).

Substance misuse disorder

Dependence on and misuse of both illegal and prescribed drugs is a major problem worldwide. Drugs of misuse are described in detail in Chapter 9. They can be grouped as follows.

Sedatives

These commonly give rise to physical dependence, the manifestations of which are tolerance and a withdrawal syndrome. Drugs include benzodiazepines, opiates (including morphine, heroin, methadone and dihydrocodeine) and barbiturates (now rarely prescribed). Overdosage with opiates and benzodiazepines can be fatal, primarily as a result of respiratory depression (Ch. 9). Withdrawal from opiates is notoriously unpleasant, and withdrawal from benzodiazepines (Box 10.36) and barbiturates may cause seizures.

Intravenous opiate users are prone to bacterial infections, hepatitis B (p. 950), hepatitis C (p. 954) and HIV infection (Ch. 14) through needle contamination. Accidental overdose is common, mainly because of the varied and uncertain potency of illicit supplies of the drug. The withdrawal syndrome, which can start within 12 hours of last use, presents with intense craving, rhinorrhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting, diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

10.36 Benzodiazepine withdrawal symptoms

- Anxiety
- Heightened sensory perception
- Hallucinations
- Epileptic seizures
- Ataxia
- Paranoid delusions

Stimulants

Stimulant drugs include amphetamines and cocaine. They are less dangerous than the sedatives in overdose, although they can cause cardiac and cerebrovascular problems through their pressor effects. Physical dependence syndromes do not arise, but withdrawal causes a rebound lowering in mood and can give rise to an intense craving for further use, especially in any form of drug with a rapid onset and offset of effect, such as crack cocaine. Chronic ingestion can cause a paranoid psychosis similar to schizophrenia. A 'toxic psychosis' (delirium) can occur with high levels of consumption, and tactile hallucinations (formication) may be prominent.

Hallucinogens

The hallucinogens are a disparate group of drugs that cause prominent sensory disturbances. They include cannabis, ecstasy, lysergic acid diethylamide (LSD) and *Psilocybin* (magic mushrooms). A toxic confusional state can occur after heavy cannabis consumption. Acute psychotic episodes are well recognised, especially in those with a family or personal history of psychosis, and there is evidence that prolonged heavy use increases the risk of developing schizophrenia. Paranoid psychoses have been reported in association with ecstasy. A chronic psychosis has also been reported after regular LSD use.

Organic solvents

Solvent inhalation (glue sniffing) is popular in some adolescent groups. Solvents produce acute intoxication characterised by euphoria, excitement, dizziness and a floating sensation. Further inhalation leads to loss of consciousness; death can occur from the direct toxic effect of the solvent, or from asphyxiation if the substance is inhaled from a plastic bag.

Aetiology

Many of the aetiological factors for alcohol misuse also apply to drug dependence. The main factors are cultural pressures, particularly within a peer group, and availability of a drug. In the case of some drugs, medical over-prescribing (for example, of synthetic opiates) has increased their availability, but there has also been a relative decline in the price of illegal drugs. Most drug users take a range of drugs – so-called polydrug misuse.

Diagnosis

As with alcohol, the diagnosis either may be apparent from the history, or may only be made once the patient presents with a complication. Drug screening of samples of urine or blood can be valuable in confirming the diagnosis, especially if the patient persists in denial.

Management and prognosis

The first step is to determine whether patients wish to stop using the drug. If they do not, they can still benefit from advice about how to minimise harm from their habit: for example, how to obtain and use clean needles for those who inject. For those who are physically dependent on sedative drugs, substitute prescribing (using methadone, for example, in opiate dependence) may help stabilise their lives sufficiently to allow a

gradual reduction in dosage until they reach abstinence. Some specialist units offer inpatient detoxification. For details of the medical management of overdose, see Chapter 9.

The drug lofexidine, a centrally acting α-agonist, can be useful in treating the autonomic symptoms of opiate withdrawal, as can clonidine, although this carries a risk of hypotension and is best used by specialists. Long-acting opiate antagonists, such as naltrexone, may also have a place, again in specialist hands, in blocking the euphoriant effects of the opiate, thereby reducing addiction.

In some cases, complete opiate withdrawal is not successful and the patient functions better if maintained on regular doses of oral methadone as an outpatient. This decision to prescribe long-term methadone should only be taken by a specialist, and carried out under long-term supervision at a specialist drug treatment centre.

Substitute prescribing is neither necessary nor possible for the hallucinogens and stimulants, but the principles of management are the same as those that should accompany prescribing for the sedatives. These include identifying problems associated with the drug misuse that may serve to maintain it, and intervening where possible. Intervention may be directed at physical illness, psychiatric comorbidity, social problems or family disharmony.

Relapsing patients and those with complications should be referred to specialist drug misuse services. Support can also be provided by self-help groups and voluntary bodies, such as Narcotics Anonymous in the UK.

Personality disorders

Personality refers to the set of characteristics and behavioural traits that best describes an individual's patterns of interaction with the world. The intensity of particular traits varies from person to person, although many, such as shyness or irritability, are displayed to some degree by most people.

A personality disorder (PD) is diagnosed when an individual's personality causes persistent and severe problems for the person or for others. For example, anxiety may be so pronounced that the individual rarely ventures into any situation where he or she fears scrutiny. Antisocial traits, such as disregard for the well-being of others and a lack of guilt concerning the adverse effects of one's actions on others, if pronounced, may lead to damage to others and to criminal acts.

PD is classified into several subtypes (such as emotionally unstable, antisocial or schizotypal), depending on the particular behavioural traits in question. A patient who meets diagnostic criteria for one subtype commonly meets criteria for two or three others. As allocation to one particular subtype gives little guidance to management or prognosis, classification is of limited value. PD commonly accompanies other psychiatric conditions, making treatment of the latter more difficult and therefore affecting their prognosis.

Aetiology

Some personality disorders appear to have an inherited aspect (especially paranoid and schizotypal types) but most are more clearly related to an unsatisfactory upbringing and adverse childhood experiences.

Management and prognosis

Personality disorders usually persist throughout life and are not readily treated. However, they often become less extreme with age. Treatment options are limited but there is some evidence that emotionally unstable PD may also respond to dialectical behavioural therapy (an intensive type of CBT). Anxious (avoidant) and obsessional (anankastic) PD may benefit from prescription of anxiolytic drugs, while paranoid/schizotypal PD may benefit from treatment with low doses of antipsychotic agents.

Eating disorders

There are two well-defined eating disorders, anorexia nervosa (AN) and bulimia nervosa (BN); they share some overlapping features. Ninety per cent of cases are female. There is a much higher prevalence of abnormal eating behaviour in the population that does not meet diagnostic criteria for AN or BN. In developed societies, obesity is arguably a much greater problem but is usually considered to be more a disorder of lifestyle or physiology than a psychiatric disorder.

Anorexia nervosa

There is marked weight loss, arising from food avoidance, often in combination with bingeing, purging, excessive exercise, or the use of diuretics and laxatives. Body image is profoundly disturbed so that, despite emaciation, patients still feel overweight and are terrified of weight gain. These preoccupations are intense and pervasive, and the false beliefs may be held with a conviction approaching the delusional. Anxiety and depressive symptoms are common accompaniments. Downy hair (lanugo) may develop on the back, forearms and cheeks. Extreme starvation is associated with a wide range of physiological and pathological bodily changes. All organ systems may be affected, although the most serious problems are cardiac and skeletal (Box 10.37).

Aetiology

This is unknown but probably includes genetic and environmental factors, including, in many societies, the social pressure on women to be thin.

Diagnosis

The condition usually emerges in adolescence, with a marked female preponderance. Diagnostic criteria are shown in Box 10.38. Differential diagnosis is from other causes of weight loss, including psychiatric disorders such as depression, and medical conditions such as inflammatory bowel disease, malabsorption, hypopituitarism and cancer. The diagnosis is based on a pronounced fear of fatness despite being thin, and on the absence of alternative causes of weight loss.

Management and prognosis

The aims of management are to ensure patient's physical well-being, whilst helping them to gain weight by addressing the beliefs and behaviours that maintain the

10.37 Medical consequences of eating disorders

Cardiac
- ECG abnormalities: T wave inversion, ST depression and prolonged QT_c interval
- Arrhythmias, including profound sinus bradycardia and ventricular tachycardia

Haematological
- Anaemia, thrombocytopenia and leucopenia

Endocrine
- Pubertal delay or arrest
- Growth retardation and short stature
- Amenorrhoea
- Sick euthyroid state

Metabolic
- Uraemia
- Renal calculi
- Osteoporosis

Gastrointestinal
- Constipation
- Abnormal liver function tests

10.38 Diagnostic criteria for eating disorders

Anorexia nervosa
- Weight loss of at least 15% of total body weight (or body mass index ≤ 17.5)
- Avoidance of high-calorie foods
- Distortion of body image so that patients regard themselves as fat even when grossly underweight
- Amenorrhoea for at least 3 months

Bulimia nervosa
- Recurrent bouts of binge eating
- Lack of self-control over eating during binges
- Self-induced vomiting, purgation or dieting after binges
- Weight maintained within normal limits

low weight. Treatment is usually given on an outpatient basis, inpatient treatment being indicated only if weight loss is intractable and severe (for example, less than 65% of normal), or if there is a risk of death from medical complications or from suicide. There is a limited evidence base for treatment, although CBT and family therapy are commonly used. Psychotropic drugs are of little benefit except in those with clear-cut comorbid depressive disorder.

Weight gain is best achieved in a collaborative fashion. Compulsory admission and refeeding (including tube feeding) are very occasionally resorted to when patients are at risk of death and other measures have failed. Whilst this may produce a short-term improvement in weight, it probably does not change long-term prognosis. About 20% of patients with AN have a good outcome, a further 20% develop a chronic intractable disorder and the rest have an intermediate outcome. There is a long-term mortality rate of 10–20%, either due to the complications of starvation or from suicide.

Bulimia nervosa

In BN, patients are usually at or near normal weight (unlike in AN), but display a morbid fear of fatness associated with disordered eating behaviour. They recurrently embark on eating binges, often followed by corrective measures such as self-induced vomiting. The prevalence is similar to or slightly greater than that of AN, but only a small proportion of sufferers reach treatment services.

Diagnosis

BN usually begins later in adolescence than AN, and is even more predominantly a female malady. Diagnostic criteria are shown in Box 10.38. Physical signs of repeated self-induced vomiting include pitted teeth (from gastric acid), calluses on knuckles ('Russell's sign') and parotid gland enlargement. There are many associated physical complications, including the dental and oesophageal consequences of repeated vomiting, as well as electrolyte abnormalities, cardiac arrhythmias and renal problems (see Box 10.37).

Management and prognosis

CBT achieves both short-term and long-term improvements. Guided self-help and interpersonal psychotherapy may also be of value. There is also evidence for benefit from the SSRI, fluoxetine, although high doses (60 mg daily) and long courses (1 year) may be required; this appears to be independent of the antidepressant effect.

Bulimia does not carry the mortality associated with AN, and few sufferers develop anorexia. At 10-year follow-up, approximately 10% are still unwell, 20% have a subclinical degree of BN, and the remainder have recovered.

Puerperal disorders

There are three common psychiatric disorders that occur after childbirth. When managing these conditions, it is important always to consider both the mother and the baby, and their relationship (Box 10.39).

Post-partum blues

These are characterised by irritability, labile mood and tearfulness. Most women are affected to some degree. Symptoms begin soon after childbirth, peak on about the fourth day and then resolve. They may be related to hormonal or psychological changes associated with childbirth. No treatment is required, other than to reassure the mother.

10.39 Psychiatric illness and pregnancy
- Always consider the effects of psychiatric disorder and treatment on mother, fetus and neonate
- Lithium, carbamazepine and valproate are significant teratogens, so minimise their use
- Most cases of post-partum low mood ('blues') are transient
- However, persistent low mood may indicate depressive illness
- Puerperal psychosis usually requires psychiatric admission

Post-partum depression

This occurs in 10–15% of women and within a month of delivery. Women with a previous history of depression are at risk. Explanation and reassurance are important. The usual psychological and drug treatments for depression should be considered, as well as practical help with childcare. If hospital admission is required, it should ideally be to a mother and baby unit. Further episodes of depression, both after childbirth and in response to other stressors, are likely.

Puerperal psychosis

This has its onset in the first 2 weeks after childbirth. It is a rare but serious complication affecting about 1 in 500 women and usually takes the form of a manic or depressive psychosis. There is an association with a personal or familial history of bipolar disorder. Delirium is rare with modern obstetric management but should still be considered in the differential diagnosis. Admission to a psychiatric mother and baby unit may be required. Management depends on the type of psychosis that presents. In addition, it is important to consider the welfare of the baby, especially if the mother has ideas of harming it. If so, the risk to the baby must be assessed and, if necessary, the baby temporarily removed. Most women recover but are at an increased (25%) risk of puerperal psychosis with the next pregnancy, and a 50% lifetime risk.

PSYCHIATRY AND THE LAW

Medicine takes place in a legal framework, made up of legislation (statute law) drafted by parliament or other governing bodies, and common law (case law) built up from court judgements over time. Psychiatry is similar to other branches of medicine in the applicability of common law but differs in that patients with psychiatric disorders can also be subject to legislative requirements to remain in hospital or to undergo treatments they refuse, such as the administration of antipsychotic drugs to a patient with acute schizophrenia who lacks insight, and whose symptoms and/or behaviour pose a risk to himself/herself or to others.

The UK has three different Mental Health Acts, covering England and Wales, Scotland, and Northern Ireland, and all of these have recently been revised. Other countries may have very different provisions. It is important for practitioners to be familiar with the relevant provisions that apply in their jurisdictions and are likely to arise in the clinical settings in which they work.

All the countries that make up the UK have also introduced Incapacity Acts in recent years, with detailed provisions covering medical treatments for patients incapable of consenting, whether this incapacity arises from physical or mental illness. In general, the guiding principle in British law is that people should be free to make their own decisions about medical treatment, except where their ability to decide is impaired by mental illness or physical incapacity, and where there are clear risks to the health and safety of themselves or others. Any restrictions or compulsions applied should be the minimum necessary, and they should only be applied for as long as is necessary; there should also be provisions for appeals and oversight.

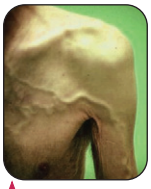
CLINICAL EXAMINATION OF THE CANCER PATIENT

1 Hands
Clubbing
Signs of smoking
Pallor
Tylosis of palms

Finger clubbing in lung cancer

Cushing's syndrome in a patient with ectopic adrenocorticotrophic hormone (ACTH) production

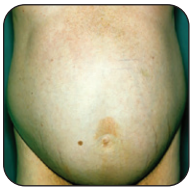
2 Breast



Skin tethering above the nipple

3 Lymph nodes
Neck
Supraclavicular
Axillary
Antecubital
Inguinal
Para-aortic

4 Face
Conjunctival pallor
Icterus, jaundice
Horner's syndrome
Cushingoid features



5 Cardiovascular
Superior vena cava (SVC) obstruction
Atrial fibrillation
Pericardial effusion
Hypo-/hypertension

SVC obstruction in a patient with a mediastinal mass

6 Respiratory
Stridor
Consolidation
Pleural effusion

7 Abdomen
Surgical scars
Umbilical nodule
Mass in epigastrium
Visible peristalsis
Abdominal distension
Ascites
Hepatomegaly
Splenomegaly
Renal mass
Pelvic or adnexal mass

Ascites (ovarian carcinoma)

8 Neurological
Focal neurological signs
Sensory deficit
Spinal cord compression
Memory deficit
Personality change

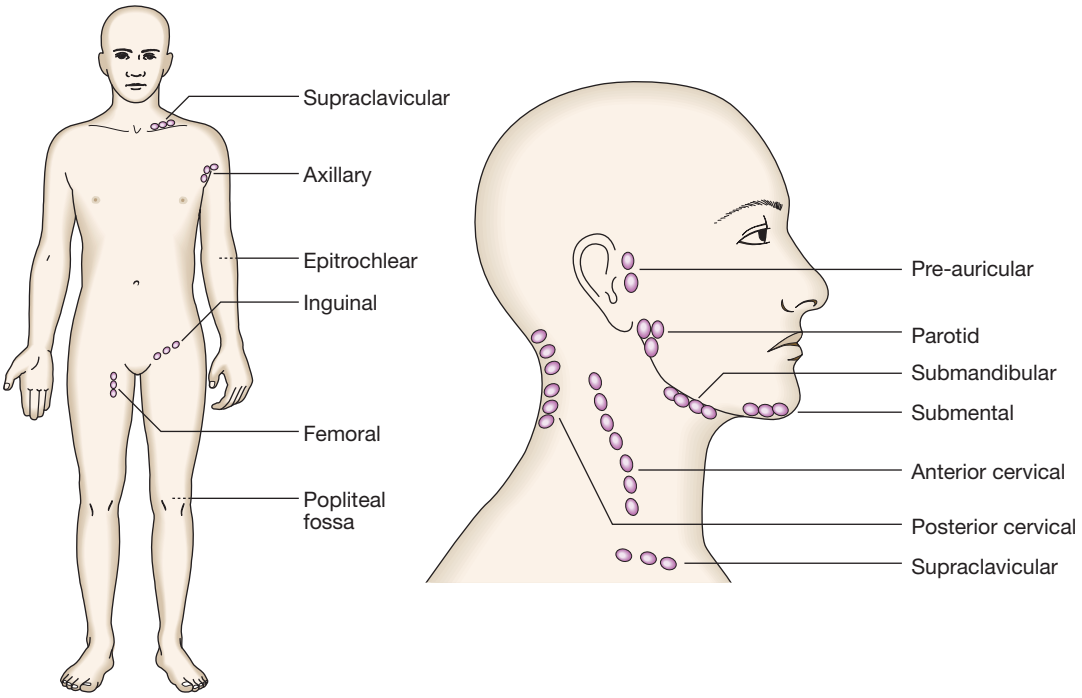
9 Skeletal survey
Focal bone tenderness (pelvis, spine, long bones)
Wrist tenderness (hypertrophic pulmonary osteoarthropathy)

10 Periphery
Calf tenderness, venous thrombosis
Clubbing (if present in hands)

Observation

- Skin changes
- Ascites
- Cushingoid appearance
- Cachexia
- Dehydration

Examination of the skin



Important features of skin lesions that should alert suspicion include:

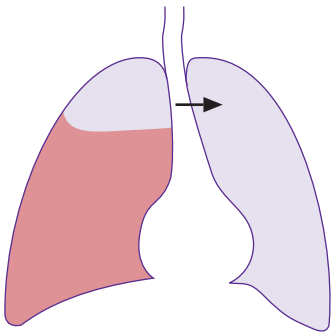
- Asymmetry: irregular shape
- Bleeding
- Border: not a smooth edge
- Colour: uneven, variegated or changing colour
- Diameter: > 6 mm in diameter or growing
- Itching or pain in a pre-existing mole

7 Abdominal examination

- Are there scars from previous surgery?
- Is the umbilicus everted, suggesting ascites?
- Is there a firm nodule at the umbilicus due to ovarian or gastric cancer metastasis, causing a Sister Mary Joseph's nodule?
- Is there smooth hepatomegaly – possibly primary liver cancer or heart failure?
- Is the liver firm or knobbly, suggesting metastasis?
- Is the ascites too tense to demonstrate hepatomegaly?
- Are other masses palpable in the abdomen?
- Are there signs of obstruction or paralytic ileus with absence of bowel sounds?
- Palpate for inguinal nodes (occasionally involved in ovarian cancer)
- Percuss for flank dullness and shifting dullness
- Perform vaginal and rectal examinations to detect adnexal or rectal masses

3 Examination of the lymph nodes

5 Superior vena cava obstruction



- Venous distension of neck
- Elevated but non-pulsatile jugular venous pulse
- Venous distension of chest wall
- Facial oedema
- Cyanosis
- Plethora of face
- Oedema of arms

5 Pericardial effusion

- Tachycardia
- Falling blood pressure
- Rising jugular venous pressure
- Muffled heart sounds
- Kussmaul's sign

6 Malignant pleural effusions

Large right pleural effusion

Inspection
Tachypnoea
Palpation
↓Expansion on R
Trachea and apex may be moved to L
Percussion
Stony dull
R mid- and lower zones
Auscultation
Absent breath sounds and diminished or absent vocal resonance R base
Crackles above effusion

Cancer is a significant global health-care problem, with an estimated worldwide incidence of 10 million new cases per year, 46% of which are in developed countries. Mortality is high, with more than 7 million deaths per year. The global costs and socioeconomic impact are considerable. The most common solid organ malignancies arise in the lung, breast and gastrointestinal tract (Fig. 11.1), but the most common form worldwide is skin cancer. Tobacco is a major factor in the aetiology of 30% of cancers, including those of the lung, nasopharynx, bladder and kidney, and these could be prevented by smoking cessation. Diet and alcohol contribute to a further 30% of cancers, including those of the stomach, colon, oesophagus, breast and liver. Lifestyle modification could reduce these if steps were taken to avoid animal fat and red meat, reduce alcohol, increase fibre, fresh fruit and vegetable intake, and avoid obesity. Infections account for a further 15% of cancers, including those of the cervix, stomach, liver, nasopharynx and bladder, and some of these could be prevented by infection control and vaccination.

THE TEN HALLMARKS OF CANCER

The formation and growth of cancer constitute a multistep process, during which sequentially occurring gene mutations result in the formation of a cancerous cell. For cells to initiate carcinogenesis successfully, they require key characteristics, collectively referred to as the hallmarks of cancer.

1. Genome instability and mutation

Random genetic mutations occur continuously throughout all cells of the body and very rarely confer a selective advantage on single cells, allowing overgrowth and dominance in local tissue environments. Multistep carcinogenesis results from successive clonal expansions of pre-malignant cells, each expansion being triggered by acquisition of a random enabling genetic mutation. Under normal circumstances, cellular DNA repair mechanisms are so effective that almost all spontaneous mutations are corrected without producing phenotypic changes, keeping the overall mutation rates very low. In cancer cells, the accumulation of mutations can be accelerated by compromising the surveillance systems that normally monitor genomic integrity and force genetically damaged cells into either senescence or apoptosis. Therefore, they can become more sensitive to mutagenic actions or develop DNA repair mechanism failure.

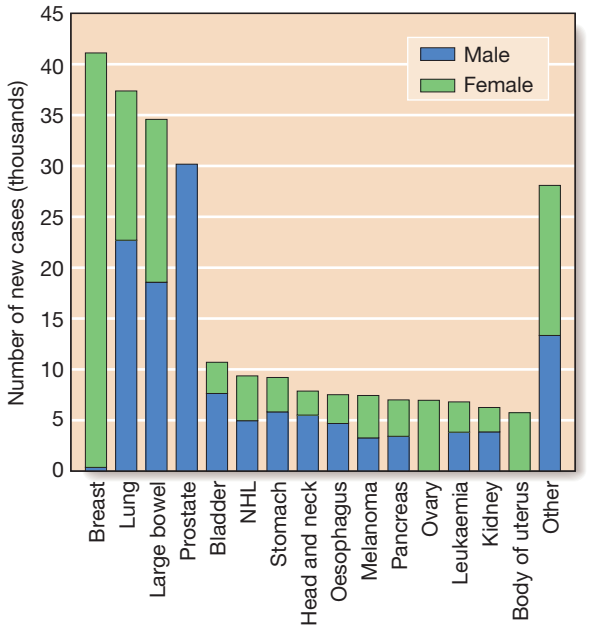


Fig. 11.1 The most commonly diagnosed cancers in the UK. (NHL = non-Hodgkin lymphoma) Statistics from Cancer Research UK website (http://info.cancerresearchuk.org).

2. Resisting cell death

There are three principal mechanisms through which cell death occurs in healthy tissues:

- *Apoptosis* is programmed cell death and is frequently found at markedly reduced rates in cancers, particularly those of high grade or those resistant to treatment. The cellular apoptotic system has regulatory elements which sense intrinsic and extrinsic pro-apoptotic signals and initiate a cascade of proteolysis and cell disassembly with nuclear fragmentation, chromosomal condensation, and shrinking of the cell with loss of intercellular contact, followed by cellular fragmentation and the formation of apoptotic bodies that are phagocytosed by neighbouring cells. The most important regulator of apoptosis is the *TP53* tumour suppressor gene, often described as the 'guardian of the genome', as it is able to induce apoptosis in response to sufficient levels of genomic damage. The largest initiator of apoptosis via *TP53* is cellular injury, particularly due to DNA damage from chemotherapy, oxidative damage and ultraviolet (UV) radiation.
- *Autophagy* is a catabolic process during which cellular constituents are degraded by lysosomal machinery within the cell. It is an important physiological mechanism, which usually occurs at low levels in cells but can be induced in response to environmental stresses, particularly radiotherapy and cytotoxic chemotherapy, which induce elevated levels of autophagy that are cytoprotective for malignant cells, thus impeding rather than perpetuating the killing actions of these stress situations. Severely stressed cancer cells have been shown to shrink via autophagy to a state of reversible dormancy.
- *Necrosis* is the premature death of cells and is characterised by the release of cellular contents into the local tissue microenvironment, in marked contrast to apoptosis, where cells are disassembled in a step-by-step fashion and the resulting cellular fragments phagocytosed. Necrotic cell death results in the recruitment of inflammatory immune cells, promotion of angiogenesis, cellular proliferation and tissue invasion. Necrotic cells also release stimulatory factors, which promote proliferation of neighbouring cells and can promote rather than inhibit carcinogenesis.

3. Sustaining proliferative signalling

Cancer cells can sustain proliferation beyond what would be expected for normal cells; this is typically due to growth factors, which are able to bind to cell surface-bound receptors that activate an intracellular tyrosine kinase-mediated signalling cascade, ultimately leading to changes in gene expression and promoting cellular proliferation and growth. Sustained proliferative capacity can result from over-production of growth factor ligands or receptors and production of structurally altered receptors, which can signal in the absence of ligand binding and activation of intracellular signalling pathway components so that signalling is no longer ligand-dependent.

The cell cycle

The cell cycle is comprised of four ordered, strictly regulated phases referred to as G_1 (gap 1), S (DNA synthesis), G_2 (gap 2) and M (mitosis) (Fig. 11.2). Normal cells grown in culture will stop proliferating and enter a quiescent state called G_0 once they become confluent or are deprived of serum or growth factors. The first gap phase (G_1) prior to the initiation of DNA synthesis represents the period of commitment that separates M and S phases as cells prepare for DNA duplication. Cells in G_0 and G_1 are receptive to growth signals, but once they have passed a restriction point, they are committed to enter DNA synthesis (S phase). Cells demonstrate arrest at different points in G_1 in response to different inhibitory growth signals. Mitogenic signals promote progression through G_1 to S phase, utilising phosphorylation of the retinoblastoma gene product (pRb). Following DNA synthesis, there is a second gap phase (G_2) prior to mitosis (M), allowing cells to repair errors that have occurred during DNA replication and thus preventing propagation of these errors to daughter cells. Although the duration of individual phases may vary, depending on cell and tissue type, most adult cells are in a G_0 state at any one time.

Cell cycle regulation

The cell cycle is orchestrated by a number of molecular mechanisms, most importantly by cyclins and cyclin-dependent kinases (CDKs). Cyclins bind to CDKs, and are regulated by both activating and inactivating phosphorylation, with two main checkpoints at G_1/S and G_2/M transition. The genes that inhibit progression play an important part in tumour prevention and are referred to as tumour suppressor genes (e.g. *TP53*, *TP21*, *TP16* genes). The products of these genes deactivate the cyclin–CDK complexes and are thus able to halt the cell cycle. The complexity of cell cycle control is susceptible to dysregulation, which may produce a malignant phenotype.

Stimulation of the cell cycle

Many cancer cells produce growth factors, which drive their own proliferation by a positive feedback known as autocrine stimulation. Examples include transforming growth factor-alpha (TGF-α) and platelet-derived growth factor (PDGF). Other cancer cells express growth factor receptors at increased levels due to gene amplification or express abnormal receptors that are permanently activated. This results in abnormal cell growth in response to physiological growth factor stimulation or even in the absence of growth factor stimulation (ligand-independent signalling). The epidermal growth factor receptor (EGFR) is often over-expressed in lung and gastrointestinal tumours and the HER2/neu receptor is frequently over-expressed in breast cancer. Both receptors activate the Ras–Raf–MAP kinase pathway, causing cell proliferation.

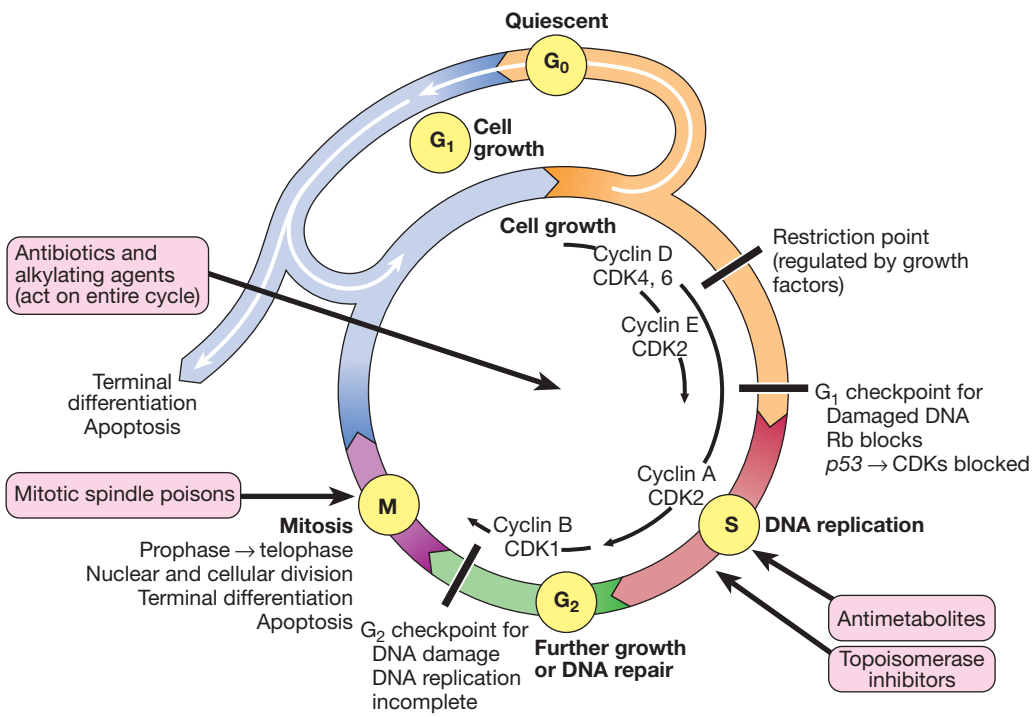

Fig. 11.2 The cell cycle and sites of action of chemotherapeutic agents. (Rb = retinoblastoma gene; CDK = cyclin-dependent kinase)

4. Evading growth suppressors

In healthy tissues, cell-to-cell contact in dense cell populations acts as an inhibitory factor on proliferation. This contact inhibition is typically absent in many cancer cell populations. Growth-inhibitory factors can modulate the cell cycle regulators and produce activation of the CDK inhibitors, causing inhibition of the CDKs. Mutations within inhibitory proteins are common in cancer. Loss of restriction by disruption of pRb regulation can be found in human tumours, which produces a loss of restraint on transition from G_1 to S phase of the cell cycle. Disruption of *p53* function will have downstream effects on *p21* that alter the coordination of DNA repair with cycle arrest and that result in the affected cell accumulating genomic defects. Down-regulation of *p21* and *p27*, which can be found in tumours with normal *p53* function, correlates notably with high tumour grade and poor prognosis.

5. Enabling replicative immortality

For cancer cells to evolve into macroscopic tumours, they need to acquire the ability for unlimited proliferation. Telomeric DNA sequences, which protect and stabilise chromosomal ends, play a central role in conferring this limitless replicative potential. During replication of normal cells, telomeres shorten progressively as small fragments of telomeric DNA are lost with successive cycles of replication. This shortening process is thought to represent a mitotic clock and eventually prevents the cell from dividing further. Telomerase, a specialised polymerase enzyme, adds nucleotides to telomeres, allowing continued cell division and thus preventing premature arrest of cellular replication. The telomerase enzyme is almost absent in normal cells but is expressed at significant levels in many human cancers.

6. Inducing angiogenesis

All cancers require a functional vascular network to ensure continued growth and will be unable to grow beyond 1 mm^3 without stimulating the development of a vascular supply. Tumours require sustenance in the form of nutrients and oxygen, as well as an ability to evacuate metabolic waste products and carbon dioxide. This entails the development of new blood vessels, which is termed angiogenesis (Figs 11.3 and 11.4).

Angiogenesis is dependent on the production of angiogenic growth factors, of which vascular endothelial growth factor (VEGF) and platelet-derived endothelial growth factor (PDGF) are the best characterised. During tumour progression, an angiogenic switch is activated and remains on, causing normally quiescent vasculature to sprout new vessels continually that help sustain expanding tumour growth. Angiogenesis is governed by a balance of pro-angiogenic stimuli and angiogenesis inhibitors, such as thrombospondin (TSP)-1, which binds to transmembrane receptors on endothelial cells and evokes suppressive signals.

A number of cells can contribute to the maintenance of a functional tumour vasculature and therefore sustain angiogenesis. These include pericytes and a variety of bone marrow-derived cells such as macrophages, neutrophils, mast cells and myeloid progenitors.

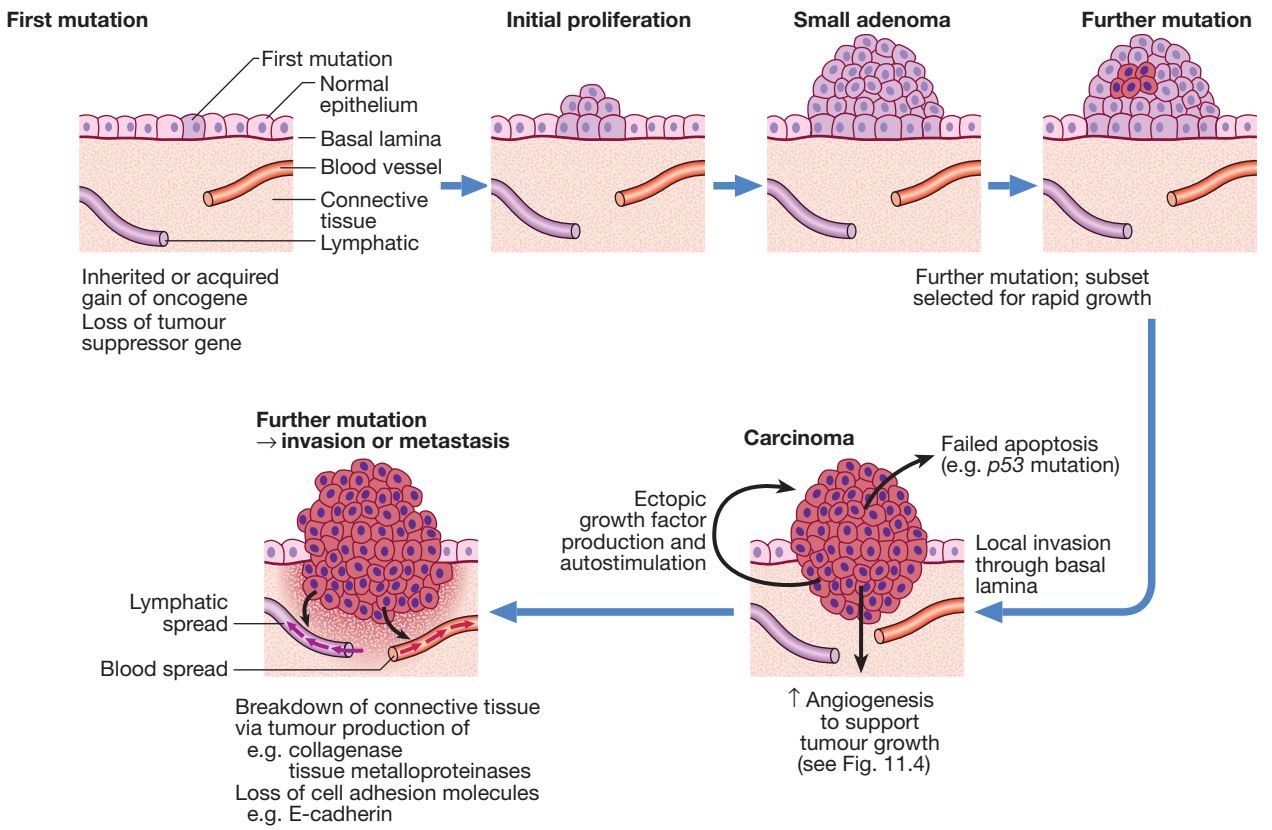

Fig. 11.3 Oncogenesis. The multistep origin of cancer, showing events implicated in cancer initiation, progression, invasion and metastasis.

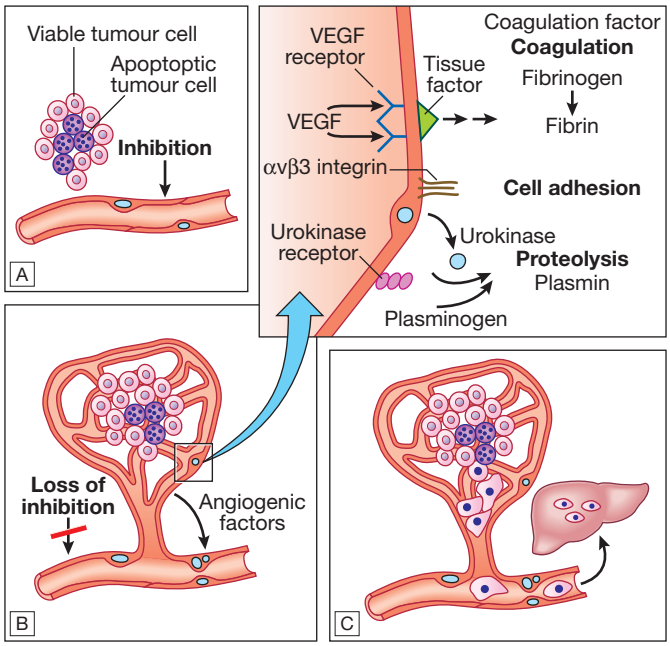

Fig. 11.4 Angiogenesis, invasion and metastasis. A For any cancer to grow beyond 1 mm^3 it must evoke a blood supply. B New vessel formation results from the release of angiogenic factors by the tumour cells and loss of inhibition of the endothelial cells. C The loss of cellular adhesion and disruption of the extracellular matrix allow cells to extravasate into the blood stream and metastasise to distant sites.

7. Activating invasion and metastasis

Invasion and metastasis are complex processes involving multiple discrete steps; it begins with local tissue invasion, followed by infiltration of nearby blood and lymphatic vessels by cancer cells. Malignant cells are eventually transported through haematogenous and lymphatic spread to distant sites within the body, where they form micrometastases that will eventually grow into macroscopic metastatic lesions (see Fig. 11.3).

Cadherin-1 (CDH1) is a calcium-dependent cell–cell adhesion glycoprotein that facilitates assembly of organised cell sheets in tissues, and increased expression is recognised as an antagonist of invasion and metastasis. In situ tumours usually retain cadherin-1 production, whereas loss of cadherin-1 production due to down-regulation or occasional mutational inactivation of CDH1 has been observed in human cancers, supporting the theory that CDH1 plays a key role in suppression of invasion and metastasis.

Cross-talk between cancer cells and cells of the surrounding stromal tissue is involved in the acquired capability for invasive growth and metastasis. Mesenchymal stem cells in tumour stroma have been found to secrete CCL5, a protein chemokine that helps recruit leucocytes into inflammatory sites. With the help of particular T-cell-derived cytokines (interleukin (IL)-2 and interferon (IFN)-γ), CCL5 induces proliferation and activation of natural killer cells and then acts reciprocally on cancer cells to stimulate invasive behaviour. Macrophages at the tumour periphery can foster local invasion by supplying matrix-degrading enzymes such as metalloproteinases and cysteine cathepsin proteases.

8. Reprogramming energy metabolism

Under aerobic conditions, oxidative phosphorylation functions as the main metabolic pathway for energy production; cells process glucose, first to pyruvate via glycolysis and thereafter to carbon dioxide in the mitochondria. Whilst under anaerobic conditions, glycolysis is favoured to produce adenosine triphosphate (ATP). Cancer cells can reprogramme their glucose metabolism to limit energy production to glycolysis, even in the presence of oxygen. This has been termed 'aerobic glycolysis'. Up-regulation of glucose transporters, such as GLUT1, is the main mechanism through which aerobic glycolysis is achieved.

This reprogramming of energy metabolism appears paradoxical, as overall energy production from glycolysis is significantly lower (18-fold) than that from oxidative phosphorylation. One explanation may be that the increased production of glycolytic intermediates can be fed into various biosynthetic pathways, including those that generate the nucleosides and amino acids, necessary for the production of new cells.

9. Tumour-promoting inflammation

Almost all tumours show infiltration with immune cells on pathological investigation and historically this finding was thought to represent an attempt of the immune system to eradicate the cancer. It is now clear that tumour-associated inflammatory responses promote tumour formation and cancer progression.

Cytokines are able to alter blood vessels to permit migration of leucocytes (mainly neutrophils), in order to permeate from the blood vessels into the tissue, a process known as extravasation. Migration across the endothelium occurs via the process of diapedesis, where chemokine gradients stimulate adhered leucocytes to move between endothelial cells and pass through the basement membrane into the surrounding tissues. Once within the tissue interstitium, leucocytes bind to extracellular matrix proteins via integrins and CD44 to prevent their loss from the site.

As well as cell-derived mediators, several acellular biochemical cascade systems consisting of pre-formed plasma proteins act in parallel to initiate and propagate the inflammatory response. These include the

complement system activated by bacteria, and the coagulation and fibrinolytic systems activated by necrosis, and also in burns and trauma, as well as cancer. Other bioactive molecules, such as growth factors and pro-angiogenic factors, may be released by inflammatory immune cells into the surrounding tumour microenvironment. In particular, the release of reactive oxygen species, which are actively mutagenic, will accelerate the genetic evolution of surrounding cancer cells, enhancing growth and contributing to cancer progression.

10. Evading immune destruction

The immune system operates as a significant barrier to tumour formation and progression, and the ability to escape from immunity is a hallmark of cancer development. Cancer cells continuously shed surface antigens into the circulatory system, prompting an immune response that includes cytotoxic T cell, natural killer cell and macrophage production. The immune system is thought to provide continuous surveillance, with resultant elimination of cells that undergo malignant transformation.

However, deficiencies in the development or function of CD8+ cytotoxic T lymphocytes, CD4+ Th1 helper T cells, or natural killer cells can each lead to a demonstrable increase in cancer incidence. Also, highly immunogenic cancer cells may evade immune destruction by disabling components of the immune system. This is done through recruitment of inflammatory cells, including regulatory T cells and myeloid-derived suppressor cells, both actively immunosuppressive against the actions of cytotoxic lymphocytes (see Fig. 4.6, p. 80).

Cancers develop and progress when there is loss of recognition by the immune system, lack of susceptibility due to escape from immune cell action and induction of immune dysfunction, often via inflammatory mediators.

ENVIRONMENTAL AND GENETIC DETERMINANTS OF CANCER

The majority of cancers do not have a single cause but rather are the result of a complex interaction between genetic factors and exposure to environmental carcinogens. These are often tumour type-specific but some general principles do apply.

Environmental factors

Environmental triggers for cancer have mainly been identified through epidemiological studies that examine patterns of distribution of cancers in patients in whom age, sex, presence of other illnesses, social class, geography and so on differ. Sometimes, these give strong

11.1 Environmental factors that predispose to cancer

Environmental aetiology	Processes	Diseases
Occupational exposure (see also ultraviolet and radiation)	Dye and rubber manufacturing (aromatic amines)	Bladder cancer
	Asbestos mining, construction work, shipbuilding (asbestos)	Lung cancer and mesothelioma
	Vinyl chloride (PVC) manufacturing	Liver angiosarcoma
	Petroleum industry (benzene)	Acute leukaemia
Chemicals	Chemotherapy (e.g. melphalan, cyclophosphamide)	Acute myeloid leukaemia
Cigarette smoking	Exposure to carcinogens from inhaled smoke	Lung and bladder cancer
Viral infection	Epstein–Barr virus	Burkitt's lymphoma and nasopharyngeal cancer
	Human papillomavirus	Cervical cancer
	Hepatitis B and C viruses	Hepatocellular carcinoma
Bacterial infection	*Helicobacter pylori*	Gastric mucosa-associated lymphoid tissue (MALT) lymphomas, gastric cancer
Parasitic infection	Liver fluke *(Opisthorchis sinensis)*	Cholangiocarcinoma
	Schistosoma haematobium	Squamous cell bladder cancer
Dietary factors	Low-roughage/high-fat content diet	Colonic cancer
	High nitrosamine intake	Gastric cancer
	Aflatoxin from contamination of *Aspergillus flavus*	Hepatocellular cancer
Radiation	Ultraviolet (UV) exposure	Basal cell carcinoma
		Melanoma
		Non-melanocytic skin cancer
	Nuclear fallout following explosion (e.g. Hiroshima)	Leukaemia
		Solid tumours, e.g. thyroid
	Diagnostic exposure (e.g. computed tomography (CT))	Cholangiocarcinoma following thorotrast usage
	Occupational exposure (e.g. beryllium and strontium mining)	Lung cancer
	Therapeutic radiotherapy	Medullary thyroid cancer
		Sarcoma
Inflammatory diseases	Ulcerative colitis	Colon cancer
Hormonal	Use of diethylstilbestrol	Vaginal cancer
	Oestrogens	Endometrial cancer
		Breast cancer

pointers to the molecular or cellular causes of the disease, such as the association between aflatoxin production within contaminated food supplies and hepatocellular carcinomas. However, for many solid cancers, such as breast and colorectal, there is evidence of a multifactorial pathogenesis, even when there is a principal environmental cause (Box 11.1).

Smoking is now established beyond all doubt as a major cause of lung cancer, but there are obviously additional predisposing factors since not all smokers develop cancer. Similarly, most carcinomas of the cervix are related to infection with human papillomavirus (HPV subtypes 16 and 18). For carcinomas of the bowel and breast, there is strong evidence of an environmental component. For example, the risk of breast cancer in women of Far Eastern origin remains relatively low when they first migrate to a country with a Western lifestyle, but rises in subsequent generations to approach that of the resident population of the host country. The precise environmental factor that causes this change is unclear, but may include diet (higher intake of saturated fat and/or dairy products), reproductive patterns (later onset of first pregnancy) and lifestyle (increased use of artificial light and shift in diurnal rhythm).

Genetic factors

A number of inherited cancer syndromes are recognised that account for 5–10% of all cancers (Box 11.2). Their molecular basis is discussed in Chapter 3, but in general they result from inherited mutations in genes that regulate cell growth, cell death and apoptosis. Examples include the *BRCA1*, *BRCA2* and *AT* (ataxia telangiectasia) genes that cause breast and some other cancers, the *FAP* gene that causes bowel cancer, and the *Rb* gene that causes retinoblastoma. Although carriers of these gene mutations have a greatly elevated risk of cancer, none has 100% penetrance and additional modulating factors, both genetic and environmental, are likely to be operative. Exploration of a possible genetic contribution is a key part of cancer management, especially with regard to ascertaining the risk for an affected patient's offspring.

11.2 Inherited cancer predisposition syndromes

Syndrome	Malignancies	Inheritance	Gene
Ataxia telangiectasia	Leukaemia, lymphoma, ovarian, gastric, brain, colon	AR	*AT*
Breast/ovarian	Breast, ovarian, colonic, prostatic, pancreatic	AD	*BRCA1, BRCA2*
Bloom's syndrome	Leukaemia, tongue, oesophageal, colonic, Wilms' tumour	AR	*BLM*
Cowden's syndrome	Breast, thyroid, gastrointestinal tract, pancreatic	AD	*PTEN*
Familial adenomatous polyposis	Colonic, upper gastrointestinal tract	AD	*APC, MUTYH*
Fanconi anaemia	Leukaemia, oesophageal, skin, hepatoma	AR	*FACA, FACC, FACD*
Gorlin's syndrome	Basal cell skin, brain	AD	*PTCH*
Hereditary non-polyposis colon cancer (HNPCC)	Colonic, endometrial, ovarian, pancreatic, gastric	AD	*MSH2, MLH1, MSH6, PMS1, PMS2*
Li–Fraumeni syndrome	Sarcoma, breast, osteosarcoma, leukaemia, glioma, adrenocortical	AD	*TP53*
Melanoma	Melanoma	AD	*CDK2 (TP16)*
Multiple endocrine neoplasia (MEN)-1	Pancreatic islet cell, pituitary adenoma, parathyroid adenoma and hyperplasia	AD	*MEN1*
MEN-2	Medullary thyroid, phaeochromocytoma, parathyroid hyperplasia	AD	*RET*
Neurofibromatosis 1	Neurofibrosarcoma, phaeochromocytoma, optic glioma	AD	*NF1*
Neurofibromatosis 2	Vestibular schwannoma	AD	*NF2*
Papillary renal cell cancer syndrome	Renal cell cancer	AD	*MET*
Peutz–Jeghers syndrome	Colonic, ileal, breast, ovarian	AD	*STK11*
Prostate cancer	Prostate	AD	*HPC1*
Retinoblastoma	Retinoblastoma, osteosarcoma	AD	*RB1*
von Hippel–Lindau syndrome	Haemangioblastoma of retina and CNS, renal cell, phaeochromocytoma	AD	*VHL*
Wilms' tumour	Nephroblastoma, neuroblastoma, hepatoblastoma, rhabdomyosarcoma	AD	*WT1*
Xeroderma pigmentosum	Skin, leukaemia, melanoma	AR	*XPA, XPC, XPD (ERCC2), XPF*

(AD = autosomal dominant; AR = autosomal recessive)

INVESTIGATIONS

When a patient is suspected of having cancer, a full history should be taken; specific questions should be included as to potential risk factors such as smoking and occupational exposures. A thorough clinical examination is also essential to identify sites of metastases, and to discover any other conditions that may have a bearing on the management plan. In order to make a diagnosis and to plan the most appropriate management, information is needed on:

- the type of tumour
- the extent of disease, as assessed by staging investigations
- the patient's general condition and any comorbidity.

The overall fitness of a patient is often assessed by the Eastern Cooperative Oncology Group (ECOG) performance scale (Box 11.3). The outcome for patients with a performance status of 3 or 4 is worse in almost all malignancies than for those with a status of 0–2, and this has a strong influence on the approach to treatment in the individual patient.

The process of staging determines the extent of the tumour; it entails clinical examination, imaging and in some cases surgery, to establish the extent of disease involvement. The outcome is recorded using a standard staging classification that allows comparisons to be made between different groups of patients. Therapeutic decisions and prognostic predictions can then be made using the evidence base for the disease. One of the most commonly used systems is the T (tumour), N (regional lymph nodes), M (metastatic sites) approach of the International Union against Cancer (UICC, Box 11.4). For some tumours, such as colon cancer, the Dukes system (p. 914) is used rather than the UICC classification.

11.3 Eastern Cooperative Oncology Group (ECOG) performance status scale

0	Fully active, able to carry on all usual activities without restriction and without the aid of analgesics
1	Restricted in strenuous activity but ambulatory and able to carry out light work or pursue a sedentary occupation. This group also contains patients who are fully active, as in grade 0, but only with the aid of analgesics
2	Ambulatory and capable of all self-care but unable to work. Up and about more than 50% of waking hours
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
4	Completely disabled, unable to carry out any self-care and confined totally to bed or chair

11.4 TNM classification

Extent of primary tumour*	
TX	Not assessed
T0	No tumour
T1, T2, T3, T4	Increases in primary tumour size or depth of invasion
Increased involvement of nodes*	
NX	Not assessed
N0	No nodal involvement
N1, N2/3	Increases in involvement
Presence of metastases	
MX	Not assessed
M0	Not present
M1	Present

*Exact criteria for size and region of nodal involvement have been defined for each anatomical site.

Histology

Histological analysis of a biopsy or resected specimen is pivotal in clinching the diagnosis and in deciding on the best form of management. The results of histological analysis are most informative when combined with knowledge of the clinical picture; therefore biopsy results should be reviewed and discussed within the context of a multidisciplinary team meeting.

Light microscopy

Examination of tumour samples by light microscopy remains the core method of cancer diagnosis and, in cases where the primary site is unclear, may also give clues to the origin of the tumour:

- Signet-ring cells favour a gastric primary.
- Presence of melanin favours melanoma.
- Mucin is common in gut/lung/breast/endometrial cancers, but particularly common in ovarian cancer and rare in renal cell or thyroid cancers.
- Psammoma bodies are a feature of ovarian cancer (mucin +) and thyroid cancer (mucin –).

Immunohistochemistry

Immunohistochemical (IHC) staining for tumour markers can provide useful diagnostic information and can help with treatment decisions. Commonly used examples of IHC in clinical practice include:

- *Oestrogen (ER) and progesterone (PR) receptors.* Positive results indicate that the tumour may be sensitive to hormonal manipulation.
- *Alpha-fetoprotein (AFP)* and *human chorionic gonadotrophin (hCG) ± placental alkaline phosphatase (PLAP).* These favour germ-cell tumours.
- *Prostate-specific antigen (PSA)* and *prostatic acid phosphatase (PAP).* These favour prostate cancer.
- *Carcinoembryonic antigen (CEA), cytokeratin* and *epithelial membrane antigen (EMA).* These favour carcinomas.
- *HER2 receptor.* Breast cancers that have high levels of expression of HER2 indicate that the tumour may respond to trastuzumab (herceptin), an antibody directed against the HER2 receptor.

The pattern of immunoglobulin, T-cell receptor and cluster designation (CD) antigen expression on the surface is also helpful in the diagnosis and classification of lymphomas. This can be achieved by IHC staining of biopsy samples or flow cytometry.

Electron microscopy

Electron microscopy (EM) can sometimes be of diagnostic value. Examples include the visualisation of melanosomes in amelanotic melanoma and dense core granules in neuro-endocrine tumours. EM may also help to distinguish adenocarcinoma from mesothelioma, as the ultrastructural properties of these two diseases are different (mesothelioma appears to have long, narrow, branching microvilli while adenocarcinomas appear to have short, stubby microvilli). EM is also useful for differentiating spindle-cell tumours (sarcomas, melanomas, squamous cell cancers) from small round-cell tumours, again due to their ultra-structural differences.

Cytogenetic analysis

Some tumours demonstrate typical chromosomal changes that help in diagnosis. The utilisation of fluorescent in situ hybridisation (FISH) techniques can be useful in Ewing's sarcoma and peripheral neuroectodermal tumours where there is a translocation between chromosome 11 and 22–t(11; 22)(q24; q12). In some cases, gene amplification can also be detected via FISH (e.g. determining over-expression of HER2/neu).

Imaging

Imaging plays a critical role in oncology, not only in locating the primary tumour, but also in staging the disease. The imaging modality employed depends primarily on the site of the disease and likely patterns of spread, but usually more than one modality is required.

Radiography

Plain radiographs remain part of the initial workup, but have a limited role in defining disease extent and have been superseded by more sophisticated techniques.

Ultrasound

Ultrasound is useful in characterising lesions within the liver, kidney, pancreas and reproductive organs. It can be used for guiding biopsies of tumours in breast and liver. Endoscopic ultrasound is helpful in staging upper gastrointestinal and pancreatic cancers; it involves a special endoscope with an ultrasound probe attached.

Computerised tomography

Computerised tomography (CT) is a key investigation in cancer patients and is particularly useful in imaging the thorax and abdomen. With some modern scanners it is possible to visualise the bowel, and sometimes detection of colorectal adenomas and cancer is feasible.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) has a high resolution and because of this is the preferred technique for brain imaging. It is also used to image structures within the pelvis and is widely employed for staging of rectal, cervical and prostate cancers.

Positron emission tomography

Positron emission tomography (PET) visualises metabolic activity of tumour cells and is widely used, often in combination with CT (PET-CT), to evaluate patients with various cancers, including lung cancer and lymphoma (Fig. 11.5). It can accurately assess the severity and spread of cancer by detecting tumour metabolic activity following injection of small amounts of radioactive tracers such as fluorodeoxyglucose (FDG). In addition to having a role in diagnosis, PET can also be used in some patients to assess treatment response.

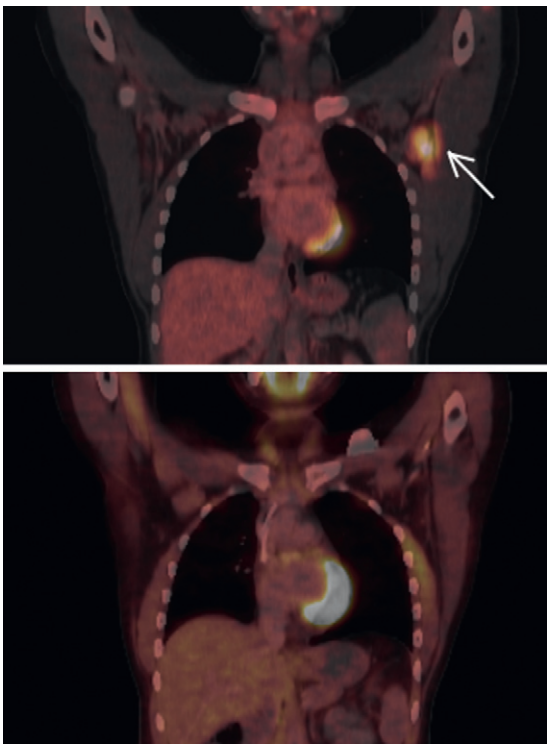

Fig. 11.5 PET-CT images. A There is a neoplastic lesion in the left axilla, evidenced by the increased uptake of FDG traces. B Imaging after chemotherapy, demonstrating that the abnormal uptake has disappeared and Indicating a response to treatment.

Biochemical markers

Many tumours produce substances called tumour markers, which can be used in diagnosis and surveillance. Some are useful in population screening, diagnosis, prognostication, treatment monitoring, detection of relapse and imaging of metastasis. Unfortunately, most tumour markers are not sufficiently sensitive or specific to be used in isolation and need to be interpreted in the context of the other clinical features. However, some can be used for antibody-directed therapy or imaging, where they have a greater role in diagnosis. Tumour markers in routine use are outlined in Box 11.5.

PRESENTING PROBLEMS IN ONCOLOGY

In the early stages of cancer development, the number of malignant cells is small and the patient is usually asymptomatic. With tumour progression, localised signs or symptoms develop due to mass effects and/or invasion of local tissues. With further progression, symptoms may occur at distant sites as a result of metastatic disease or from non-metastatic manifestations due to

11.5 Commonly used serum tumour markers

Name	Natural occurrence	Tumours
Alpha-fetoprotein (AFP)	Glycoprotein found in yolk sac and fetal liver tissue. Transient elevation in liver diseases. Has a role in screening during pregnancy for the detection of neural tube defects and Down's syndrome	Ovarian non-seminomatous germ cell tumours (80%), testicular teratoma (80%), hepatocellular cancer (50%)
Calcitonin	32 amino acid peptide from C cells of thyroid. Used to screen for MEN-2	Medullary cell carcinoma of thyroid
Cancer antigen 125 (CA-125)	Differentiation antigen of coelomic epithelium (Muller's duct). Raised in any cause of ascites, pleural effusion or heart failure. Can be raised in inflammatory conditions	Ovarian epithelial cancer (75%), gastrointestinal cancer (10%), lung cancer (5%) and breast cancer (5%)
CA-19.9	A mucin found in epithelium of fetal stomach, intestine and pancreas. It is eliminated exclusively via bile and so any degree of cholestasis can cause levels to rise	Pancreatic cancer (80%), mucinous tumour of the ovary (65%), gastric cancer (30%), colon cancer (30%)
Carcinoembryonic antigen (CEA)	Glycoprotein found in intestinal mucosa during embryonic and fetal life. Elevated in smokers, cirrhosis, chronic hepatitis, ulcerative colitis, pneumonia	Colorectal cancer, particularly with liver metastasis, gastric cancer, breast cancer, lung cancer, mucinous cancer of the ovary
Human chorionic gonadotrophin (hCG)	Glycoprotein hormone, 14KD α subunit and 24KD β subunit from placental syncytiotrophoblasts. Used for disease monitoring in hydatidiform mole and as the basis of a pregnancy test	Choriocarcinoma (100%), hydatidiform moles (97%), ovarian non-seminomatous germ cell tumours (50–80%), seminoma (15%)
Placental alkaline phosphatase (PLAP)	Isoenzyme of alkaline phosphatase	Seminoma (40%), ovarian dysgerminoma (50%)
Prostate-specific antigen (PSA)	Glycoprotein member of human kallikrein gene family. PSA is a serine protease that liquefies semen in excretory ducts of prostate. Can be elevated in benign prostatic hypertrophy and prostatitis	Prostate cancer (95%)
Thyroglobulin	Matrix protein for thyroid hormone synthesis in normal thyroid follicles	Papillary and follicular thyroid cancer
β-2-microglobulin	A human leucocyte antigen (HLA) common fragment present on surface of lymphocytes, macrophages and some epithelial cells. Can be elevated in autoimmune disease and renal glomerular disease	Non-Hodgkin's lymphoma, myeloma

11.6 Local features of malignant disease

Symptom	Typical site or possible tumour
Haemorrhage	Stomach, colon, bronchus, endometrium, bladder, kidney
Lump	Breast, lymph node (any site), testicle
Bone pain or fracture	Bone (primary sarcoma, secondary metastasis from breast, prostate, bronchus, thyroid, kidney)
Skin abnormality	Melanoma, basal cell carcinoma (rodent ulcer)
Ulcer	Oesophagus, stomach, anus, skin
Dysphagia	Oesophagus, bronchus, gastric
Increasing constipation, abdominal discomfort or pain	Colon, rectum, ovary
Airway obstruction, stridor, cough, recurrent infection	Bronchus, thyroid
Odynophagia, early satiety, vomiting	Bronchus, stomach, oesophagus, colon, rectum
Abdominal swelling (ascites)	Ovary, stomach, pancreas

production of biologically active hormones by the tumour or as the result of an immune response to the tumour. The possible presentations are summarised in Boxes 11.6 and 11.7, and common presenting features discussed below. Although the incidence of cancer increases with patient age, the approach to investigation and management is similar at all ages (Box 11.8).

Palpable mass

A palpable mass detected by the patient or physician may be the first sign of cancer. Primary tumours of the thyroid, breast, testis and skin are often detected in this way, whereas palpable lymph nodes in the neck, groin

11.7 Non-metastatic manifestations of malignant disease

Feature	Common cancer site associations
Weight loss and anorexia	Lung, gastrointestinal tract
Fatigue	Any
Hypercalcaemia	Myeloma, breast, kidney
Prothrombotic tendency	Ovary, pancreas, gastrointestinal tract
SIADH **Ectopic ACTH**	Small cell lung cancer
Lambert–Eaton myasthenia-like syndrome	Small cell lung cancer
Subacute cerebellar degeneration	Small cell lung cancer, ovarian cancer
Acanthosis nigricans	Stomach, oesophagus
Dermatomyositis/ polymyositis	Stomach, lung

(ACTH = adrenocorticotrophic hormone; SIADH = syndrome of inappropriate antidiuretic hormone secretion)

11.8 Cancer in old age

- **Incidence**: around 50% of cancers occur in the 15% of the population aged over 65 years.
- **Screening**: women aged over 65 in the UK are not invited to breast cancer screening but can request it. Uptake is low despite increasing incidence with age.
- **Presentation**: may be later for some cancers. When symptoms are non-specific, patients (and their doctors) may initially attribute them to age alone.
- **Life expectancy**: an 80-year-old woman can expect to live 8 years, so cancer may still shorten life and an active approach remains appropriate.
- **Prognosis**: histology, stage at presentation and observation for a brief period are better guides to outcome than age.
- **Rate of progression**: malignancy may have a more indolent course. This is poorly understood but may be due to reduced effectiveness of angiogenesis with age, inhibiting the development of metastases.
- **Response to treatment**: equivalent to that in younger people – well documented for a range of cancers and for surgery, radiotherapy, chemotherapy and hormonal therapy.
- **Treatment selection**: chronological age is of minor importance compared to comorbid illness and patient choice. Although older patients can be treated effectively and safely, aggressive intervention is not appropriate for all. Symptom control may be all that is possible or desired by the patient.

or axilla may indicate secondary spread of tumour. Hepatomegaly may be the first sign of primary liver cancer or tumour metastasis, whereas skin cancer may present as an enlarging or changing pigmented lesion.

Weight loss and fever

Unintentional weight loss is a characteristic feature of advanced cancer, but can be due to other causes such as thyrotoxicosis, chronic inflammatory disease and chronic infective disorders. Fever can occur in any cancer secondary to infection, but may be a primary feature in Hodgkin's disease, lymphoma, leukaemia, renal cancer and liver cancer. The presence of unexplained weight loss or fever warrants investigation to exclude the presence of occult malignancy.

Finger clubbing

Finger clubbing is a characteristic feature of lung cancer, and especially non-small cell lung cancer, although benign causes are recognised. It is often part of the wider process of hypertrophic osteoarthropathy in which there is periosteal new bone formation and arthritis due to increased levels of prostaglandin E. The diagnosis is primarily clinical, but X-rays show periosteal reaction and an isotope bone scan shows increased tracer update in the affected digits.

Ectopic hormone production

In some cases, the first presentation of cancer is with a metabolic abnormality due to ectopic production of hormones by tumour cells, including insulin, ACTH, ADH, fibroblast growth factor (FGF) 23, erythropoietin and parathyroid hormone-related protein (PTHrP). This can result in a wide variety of presentations, as summarised in Box 11.9. Further details on presentation and management of ACTH- and ADH-producing tumours are given on page 776, and of FGF23-producing tumours on page 1128. The management of hypercalcaemia associated with malignancy is discussed on page 273.

11.9 Ectopic hormone production by tumours

Hormone	Consequence	Tumours
ADH	Hyponatraemia	SCLC
ACTH	Cushing's syndrome	SCLC
FGF-23	Hypophosphataemic osteomalacia	Mesenchymal tumours
Insulin	Hypoglycaemia	Insulinoma
Erythropoietin	Polycythaemia	Kidney, hepatoma, cerebellar haemangioblastoma, uterine fibroids
PTHrP	Hypercalcaemia	NSCLC (squamous cell), breast, kidney

(ACTH = adrenocorticotrophic hormone; ADH = antidiuretic hormone; FGF = fibroblast growth factor; NSCLC = non-small cell lung cancer; PTHrP = parathyroid hormone-related protein; SCLC = small cell lung cancer)

Neurological paraneoplastic syndromes

These form a group of conditions associated with cancer thought to be due to an immunological response to the tumour that results in damage to the nervous system or muscle. The cancers most commonly implicated are

those of the lung (small cell and non-small cell), pancreas, breast, prostate, ovary and lymphoma.

- *Peripheral neuropathy* results from axonal degeneration or demyelination.
- *Encephalomyelitis* can present with diverse symptoms, depending on which region of the brain is involved. Lumbar puncture shows raised protein in the cerebrospinal fluid (CSF) and a pleocytosis, predominantly that of lymphocytes. In some centres, flow cytometry of the CSF is also used to detect carcinomatous cells. MRI shows meningeal enhancement, particularly at the level of the brain stem, and anti-Hu antibodies may be detectable in serum. Encephalomyelitis is due to perivascular inflammation and selective neuronal degeneration. Most cases are caused by small cell lung cancer (75%).
- *Cerebellar degeneration* may be the presenting feature of an underlying malignancy and presents with rapid onset of cerebellar ataxia. Diagnosis is by MRI or CT, which may show cerebellar atrophy. Patients with these neurological paraneoplastic syndromes may be found to have circulating anti-Yo, Tr and Hu antibodies, but these are not completely specific and negative results do not exclude the diagnosis.
- *Retinopathy* is a rare complication of cancer and presents with blurred vision, episodic visual loss and impaired colour vision. If left untreated, it may lead to blindness. The diagnosis should be suspected if the electroretinogram is abnormal and anti-retinal antibodies are detected.
- *Lambert–Eaton syndrome* (LEMS) is due to underlying cancer in about 60% of cases. It presents with proximal muscle weakness that improves on exercise and is caused by the development of antibodies to pre-synaptic calcium channels (p. 1227). The diagnosis is made by electromyelogram (EMG), which shows a low-amplitude compound muscle action potential that enhances to near normal following exercise.
- *Dermatomyositis* or *polymyositis* may be the first presentation of some cancers. Clinical features and management of these conditions are discussed on page 1114.

Cutaneous manifestations of cancer

Many cancers can present with skin manifestations that are not due to metastases:

- *Pruritus* may be a presenting feature of lymphoma, leukaemia and CNS tumours.
- *Acanthosis nigricans* may precede cancers by many years and is particularly associated with gastric cancer.
- *Vitiligo* may be associated with malignant melanoma, and is possibly due to an immune response to melanocytes.
- *Pemphigus* may occur in lymphoma, Kaposi's sarcoma and thymic tumours.
- *Dermatitis herpetiformis* associated with coeliac disease may precede tumour development by many years, and is associated with gastrointestinal lymphoma.

The clinical features and management of these skin conditions is discussed in Chapter 28.

EMERGENCY COMPLICATIONS OF CANCER

Spinal cord compression

Spinal cord compression complicates 5% of cancers and is most common in myeloma, prostate, breast and lung cancers that involve bone. Cord compression often results from posterior extension of a vertebral body mass but intrathecal spinal cord metastases can cause similar signs and symptoms.

Clinical features

The earliest sign is back pain, particularly on coughing and lying flat. Subsequently, sensory changes develop in dermatomes below the level of compression and motor weakness distal to the block occurs. Finally, sphincter disturbance, causing urinary retention and bowel incontinence, is observed. Involvement of the lumbar spine may cause conus medullaris or cauda equina compression (Box 11.10). Physical examination reveals findings consistent with an upper motor neuron lesion, but lower motor neuron findings may predominate early on or in cases of nerve root compression.

Management

Spinal cord compression is a medical emergency and should be treated with analgesia and high-dose steroid therapy (Box 11.11). Neurosurgical treatment produces superior outcome and survival compared to radiotherapy alone, and should be considered first for all patients. Radiotherapy is used for the remaining patients and selected tumour types when the cancer is likely to be radiosensitive. The prognosis varies considerably, depending on tumour type, but the degree of neurological dysfunction at presentation is the strongest predictor of outcome irrespective of the underlying diagnosis.

11.10 Comparison of features of neurological deficit

Clinical feature	Spinal cord	Conus medullaris	Cauda equina
Weakness	Symmetrical and profound	Symmetrical and variable	Asymmetrical, may be mild
Reflexes	Increased (or absent) knee and ankle reflexes with extensor plantar reflex	Increased knee reflex, decreased ankle reflex, extensor plantar reflex	Decreased knee and ankle reflexes with flexor plantar reflex
Sensory loss	Symmetrical, sensory level	Symmetrical, saddle distribution	Asymmetrical, radicular pattern
Sphincters	Late loss	Early loss	Often spared
Progression	Rapid	Variable	Variable

11.11 Management of suspected spinal cord compression

- Confirm diagnosis with urgent MRI scan
- Administer high-dose steroids
  - Dexamethasone 16 mg IV stat
  - Dexamethasone 8 mg twice daily orally
- Ensure adequate analgesia
- Refer for surgical decompression or urgent radiotherapy

Ambulation can be preserved in more than 80% of patients who are ambulatory at presentation, but neurological function is seldom regained in patients with established deficits such as paraplegia.

Superior vena cava obstruction

Superior vena cava obstruction (SVCO) is a common complication of cancer that can occur through extrinsic compression or intravascular blockage. The most common causes of extrinsic compression are lung cancer, lymphoma and metastatic tumours. Patients with cancer can also develop SVCO due to intravascular blockage in association with a central catheter or thrombophilia secondary to the tumour.

Clinical features

The typical presentation is with oedema of the arms and face, distended neck and arm veins and dusky skin coloration over the chest, arms and face. Collaterals may develop over a period of weeks and the flow of blood in the collaterals helps to confirm the diagnosis. Headache secondary to cerebral oedema arising from the backflow pressure may also occur and tends to be aggravated by bending forward, stooping or lying down. The severity of symptoms is related to the rate of obstruction and the development of a venous collateral circulation. Accordingly, symptoms may develop rapidly or gradually. Clinical features are summarised in Box 11.12.

Investigations and management

The investigation of choice is CT of the thorax since it can clinch the diagnosis and distinguish between extra- and intravascular causes. A biopsy should be obtained when the tumour type is unknown because tumour type has a major influence on treatment. CT of the brain may be indicated if cerebral oedema is suspected. Tumours that are exquisitely sensitive to chemotherapy, such as germ cell tumours and lymphoma, can be treated with chemotherapy alone, but for most other tumours mediastinal radiotherapy is required. This relieves symptoms within 2 weeks in 50–90% of patients. In most centres, stenting is now increasingly favoured over radiotherapy, as it produces rapid results and can be repeated with reasonable effectiveness. This technique is particularly useful when dealing with tumours that are relatively chemo- or radio-resistant, such as non-small cell lung cancer or carcinoma of unknown primary. Where possible, these measures should be followed by treatment of the primary tumour, as long-term outcome is strongly dependent on the prognosis of the underlying cancer.

11.12 Common symptoms and physical findings in superior vena cava obstruction*

Symptoms	
• Dyspnoea (63%)	• Arm swelling (18%)
• Facial swelling and head fullness (50%)	• Chest pain (15%)
• Cough (24%)	• Dysphagia (9%)
Physical findings	
• Venous distension of neck (66%)	• Facial oedema (46%)
• Venous distension of chest wall (54%)	• Cyanosis (20%)
	• Plethora of face (19%)
	• Oedema of arms (14%)

*Percentage of patients affected.

Hypercalcaemia

Hypercalcaemia is the most common metabolic disorder in patients with cancer and has a prevalence of 15–20 cases per 100 000 persons. The incidence is highest in myeloma and breast cancer (approximately 40%), intermediate in non-small cell lung cancer, and uncommon in colon, prostate and small cell lung carcinomas. It is most commonly due to over-production of PTHrP, which binds to the PTH receptor and elevates serum calcium by stimulating osteoclastic bone resorption and increasing renal tubular reabsorption of calcium.

Clinical features

The symptoms of hypercalcaemia are often non-specific and may mimic those of the underlying malignancy. They include drowsiness, confusion, nausea and vomiting, constipation, polyuria, polydipsia and dehydration.

Investigations and management

The diagnosis is made by measuring serum total calcium and adjusting for albumin. It is especially important to correct for albumin in cancer because hypoalbuminaemia is common and total calcium values underestimate the level of ionised calcium. The principles of management are outlined in Box 11.13.

Patients should initially be treated with intravenous 0.9% saline to improve renal function and increase urinary calcium excretion. This alone often results in clinical improvement. Concurrently, intravenous bisphosphonates should be given to inhibit bone resorption. Calcitonin acts rapidly to increase calcium excretion and to reduce bone resorption and can be combined with fluid and bisphosphonate therapy for the first 24–48 hours in patients with life-threatening hypercalcaemia. Bisphosphonates will usually reduce the serum calcium levels to normal within 5 days, but if not, treatment can be repeated. The duration of action is up to 4 weeks and repeated therapy can be given at 3–4-weekly intervals as an outpatient. Hypercalcaemia is frequently a sign of tumour progression and the patient requires further investigation to establish disease status and review of the anti-cancer therapy.

11.13 Medical management of severe hypercalcaemia

- IV 0.9% saline 2–4 L/day
- Zoledronic acid 4 mg IV *or* pamidronate 60–90 mg IV
- IM/SC calcitonin 100 U 3 times daily for first 24–48 hours in life-threatening hypercalcaemia

Neutropenic fever

Neutropenia is a common complication of malignancy. It is usually secondary to chemotherapy but may occur with radiotherapy if large amounts of bone marrow are irradiated; it may also be a component of pancytopenia due to malignant infiltration of the bone marrow. Neutropenic fever is defined as a pyrexia of 38°C for over 1 hour in a patient with a neutrophil count $< 1.0 \times 10^9$/L. The risk of sepsis is related to the severity and duration of neutropenia and the presence of other risk factors such as intravenous or bladder catheters. Neutropenic fever is an emergency in cancer patients as, if left untreated, it can result in septicaemia with a high mortality rate.

Clinical features

The typical presentation is with high fever and affected patients are often non-specifically unwell. Examination is usually unhelpful in defining a primary source of the infection. Hypotension is an adverse prognostic feature and may progress to systemic circulatory shutdown and organ failure.

Investigations and management

An infection screen should be performed to include blood cultures (both peripheral and from central lines), urine culture, chest X-ray, and swabs for culture (throat, central line, wound). High-dose intravenous antibiotics should then be commenced, pending the results of cultures. Typical first-line empirical therapy consists of an anti-pseudomonal β-lactam (ceftazidime, cefotaxime or meropenem), or a combination of an aminoglycoside and a broad-spectrum penicillin with anti-pseudomonal activity (gentamicin and piperacillin), but this may need adjusting on the basis of local hospital policy and antibiotic resistance patterns. Metronidazole should be added if anaerobic infection is suspected, and flucloxacillin or vancomycin or teicoplanin where Gram-positive infection is suspected (for example, in patients with central lines). If there is no response after 36–48 hours, treatment with amphotericin B or voriconazole should be considered to cover fungal infection. Antibiotics should be adjusted according to culture results, though these are often negative. Other supportive therapy, including intravenous fluids, inotrope therapy, ventilation or haemofiltration, may be required.

METASTATIC DISEASE

Metastatic disease is the major cause of death in cancer patients and the principal cause of morbidity. For the majority, the aim of treatment is palliative, but treatment of a solitary metastasis can occasionally be curative.

Brain metastases

Brain metastases occur in 10–30% of adults and 6–10% of children with cancer, and are an increasingly important cause of morbidity. Tumours that typically metastasise to the brain are shown in Box 11.14. Most involve the brain parenchyma but can also affect the cranial nerves, the blood vessels and other intracranial structures. In cases of solitary metastasis to the brain, the use of surgery and adjuvant radiotherapy has been shown to increase survival. However, practices vary for patients with more advanced brain metastases. In these cases, median survival without treatment is approximately 1 month. Steroids can increase survival to 2–3 months and whole-brain radiotherapy improves survival to 3–6 months, but the true efficacy of these interventions has not been proven adequately in a randomised trial setting. Patients with brain metastases as the only manifestation of an undetected primary tumour have a more favourable prognosis, with an overall median survival of 13.4 months. Tumour type also influences prognosis; breast cancer patients have a better prognosis than those with other types of tumour, and those with colorectal carcinoma tend to have a poorer prognosis.

11.14 Primary tumour sites that metastasise to brain

Primary tumour	Patients (%)
Lung	48
Breast	15
Melanoma	9
Colon	5
Other known primary	13
Unknown primary	11

Clinical features

Presentation is with headaches (40–50%), focal neurological dysfunction (20–40%), cognitive dysfunction (35%), seizures (10–20%) and papilloedema (< 10%).

Investigations and management

The diagnosis can be confirmed by CT or contrast-enhanced MRI. Treatment options include high-dose steroids (dexamethasone 4 mg 4 times daily) for tumour-associated oedema, anticonvulsants for seizures, whole-brain radiotherapy, and chemotherapy. Surgery may be considered for single sites of disease and can be curative; stereotactic radiotherapy may also be considered for solitary site involvement where surgery is not possible.

Lung metastases

These are common in breast cancer, colon cancer and tumours of the head and neck. The presentation is usually with a lesion on chest X-ray or CT. Solitary lesions require investigation, as single metastases can be difficult to distinguish from a primary lung tumour. Patients with two or more pulmonary nodules can be assumed to have metastases. The approach to treatment depends on the extent of disease in the lung and elsewhere. For solitary lesions, surgery should be considered with a generous wedge resection. Radiotherapy, chemotherapy or endocrine therapy can be used as systemic treatment and is dependent on the underlying primary cancer diagnosis.

Liver metastases

Metastatic cancer in the liver can represent the sole or life-limiting component of disease for many with colorectal cancer, ocular melanoma, neuro-endocrine tumours and, less commonly, other tumour types. The most common clinical presentations are with right upper quadrant pain due to stretching of the liver capsule,

jaundice, deranged liver function tests or an abnormality detected on imaging. In selected cases, resection of the metastasis can be contemplated. In colorectal cancer, successful resection of a metastasis improves 5-year survival from 3% to 30–40%. Other techniques, such as chemoembolisation or radiofrequency ablation, can also be used, provided the number and size of metastases remain small. If these are not feasible, symptoms may respond to systemic chemotherapy.

Bone metastases

Bone is the third most common organ involved by metastasis, after lung and liver. Bone metastases are a major clinical problem in patients with myeloma and breast or prostate cancers, but other tumours that commonly metastasise to bone include those of the kidney and thyroid. Bone metastases are an increasing management problem in other tumour types that do not classically target bone, due to the prolonged survival of patients generally. Accordingly, effective management of bony metastases has become a focus in the treatment of patients with many incurable cancers.

Clinical features

The main presentations are with pain, pathological fractures and spinal cord compression (p. 272). The pain tends to be progressive and worst at night, and may be partially relieved by activity, but subsequently becomes more constant in nature and is exacerbated by movement. Most pathological fractures occur in metastatic breast cancer (53%); other tumour types associated with fracture include the kidney (11%), lung (8%), thyroid (5%), lymphoma (5%) and prostate (3%).

Investigations and management

The most sensitive way of detecting bone metastases is by isotope bone scan. This can have false-positive results in healing bone, particularly as a flare response following treatment and false-negative results occur in multiple myeloma due to suppression of osteoblast activity. Therefore plain X-ray films are preferred for any sites of bone pain, as lytic lesions may not be detected by a bone scan. In patients with a single lesion, it is especially important to perform a biopsy to obtain a tissue diagnosis, since primary bone tumours may look very similar to metastases on X-ray.

The main goals of management are:

- pain relief
- preservation and restoration of function
- skeletal stabilisation
- local tumour control (e.g. relief of tumour impingement on normal structure).

Surgical intervention may be warranted where there is evidence of skeletal instability (e.g. anterior or posterior spinal column fracture) or an impending fracture (e.g. large lytic lesion on a weight-bearing bone with more than 50% cortical involvement). Intravenous bisphosphonates (pamidronate, zoledronic acid or ibandronate) are widely used for bone metastases and are effective at improving pain and in reducing further skeletal related events, such as fractures and hypercalcaemia (Box 11.15). In certain types of cancer, such as breast and prostate, hormonal therapy may be effective. Radiotherapy, in the form of external beam therapy or systemic radionucleotides (strontium treatment), can also be useful for these patients. In some settings (e.g. breast carcinoma), chemotherapy may also be used in the management of bony metastases.

EBM 11.15 Use of bisphosphonates in bony metastases

'The use of bisphosphonates in cancer patients with bony metastases results in decreased pain and a decrease in skeletal-related events.'

- Dror Michaelson M, Smith MR. J Clin Oncol 2005; 23(32): 8219–8224.

Malignant pleural effusion

This is a common complication of cancer and 40% of all pleural effusions are due to malignancy. The most common causes are lung and breast cancers, and the presence of an effusion indicates advanced and incurable disease. The presentation may be with dyspnoea, cough or chest discomfort, which can be dull or pleuritic in nature. Diagnosis and management of ascites is discussed on p. 938.

Investigations and management

Pleural aspirate is the key investigation and may show the presence of malignant cells. Malignant effusions are commonly blood-stained and are exudates with a raised fluid to serum lactate dehydrogenase (LDH) ratio (> 0.6) and a raised fluid to serum protein ratio (> 0.5). Treatment should focus on palliation of symptoms and be tailored to the patient's physical condition and prognosis. Aspiration alone may be an appropriate treatment in frail patients with a limited life expectancy (Box 11.16). Those who present with malignant pleural effusion as the initial manifestation of breast cancer, small cell lung cancer, germ cell tumours or lymphoma should

11.16 How to aspirate a malignant pleural effusion

- Ask the patient to sit up and lean forward slightly.
- Identify a suitable site for aspiration. Typically, this should be in the mid-scapular line, below the top of the fluid level and above the diaphragm.
- Confirm that the site is below the fluid level by reviewing the chest X-ray and percussing the chest.
- Infiltrate the skin and the intercostal space immediately above the rib below with 1% lidocaine.
- As you advance the needle, aspirate at each step prior to injecting the local anaesthetic.
- On reaching the pleural cavity, you should be able to aspirate pleural fluid; when you do, note the depth of the needle.
- Insert a thoracentesis needle into the pleural space by advancing it along the same track as was used for the local anaesthetic and connect it to a three-way tap and container to collect the fluid.
- Drain the pleural effusion, to a maximum of 1.5 L. If the effusion is larger than this, repeat the procedure on further occasions as necessary.
- Consider using ultrasound-guided placement of a drainage catheter if the effusion proves difficult to drain.
- Permanent drains can be useful for some patients with recurrent effusions where pleurodesis is not possible.

have the fluid aspirated and should be given systemic chemotherapy to try to treat disease in the pleural space. Treatment options for patients with recurrent pleural effusion include pleurodesis, pleurectomy and pleuroperitoneal shunt. Ideally, pleurodesis should be attempted once effusions recur after initial drainage.

THERAPEUTICS IN ONCOLOGY

Anti-cancer therapy may be either curative or palliative, and this distinction influences the approach to management of individual patients. The goal of treatment should be recorded in the medical notes.

- *Palliative chemotherapy* is the most common treatment and is primarily used to treat patients with metastasis. The goal is an improvement in symptoms with a focus on improving quality of life, and any survival increments are secondary. As a result, the treatment should be well tolerated and should aim to minimise adverse effects.
- *Adjuvant chemotherapy* is given after an initial intervention that is designed to cyto-reduce the tumour bulk and remove all macroscopic disease. Chemotherapy is then given with the intention of eradicating the micrometastatic disease that remains. The focus is on achieving an improvement in disease-free and overall survival.
- *Neoadjuvant chemotherapy* or primary medical therapy is where chemotherapy is administered first before a planned cyto-reductive procedure. This can result in a reduced requirement for surgery, increase the likelihood of successful debulking, reduce the duration of hospitalisation and improve the fitness of the patient prior to interval debulking. This approach has the same goals as adjuvant treatment but creates an opportunity for translational research to measure responses to treatment and correlate with subsequent specimens removed at the time of surgery.
- *Chemoprevention* is the use of pharmacological agents to prevent cancer developing in patients identified as being at particular risk. Therefore the agents used aim to modify risk and, as such, should not have significant adverse effects.

Surgical treatment

Surgery has a pivotal role in the management of cancer. There are three main situations in which it is necessary.

Biopsy

In the vast majority of cases, a histological or cytological diagnosis of cancer is necessary, and tissue will also provide important information such as tumour type and differentiation, to assist subsequent management. Cytology can be obtained with fine needle aspiration but a biopsy is usually preferred. This can be a core biopsy, an image-guided biopsy or an excision biopsy.

Excision

The main curative management of most solid cancers is surgical excision. In early, localised cases of colorectal, breast and lung cancer, cure rates are high with surgery. There is increasing evidence that outcome is related to surgical expertise, and most multidisciplinary teams include surgeons experienced in the management of a particular cancer. There are some cancers for which surgery is one of two or more options for primary management, and the role of the multidisciplinary team is to recommend appropriate treatment for a specific patient. Examples include prostate and transitional cell carcinoma of the bladder, in which radiotherapy and surgery may be equally effective.

Palliation

Surgical procedures are often the quickest and most effective way of palliating symptoms. Examples include the treatment of faecal incontinence with a defunctioning colostomy; fixation of pathological fractures and decompression of spinal cord compression; and the treatment of fungating skin lesions by 'toilet' surgery. A more specialist role for surgery is in resection of residual masses after chemotherapy and, in very selected cases, resection of metastases.

Systemic chemotherapy

Chemotherapeutic drugs are classified by their mode of action. They have the greatest activity in proliferating cells and this provides the rationale for their use in the treatment of cancer. Chemotherapeutic agents are not specific for cancer cells, however, and the side-effects of treatment are a result of their anti-proliferative actions in normal tissues such as the bone marrow, skin and gut.

Combination therapy

In order to overcome drug resistance and to limit the side-effects of different drugs, chemotherapy is most commonly given as a combination of agents. Combinations usually include drugs from different classes, with the aim of targeting several pathways and gaining maximum therapeutic effect. Drugs are conventionally given by intravenous injection every 3–4 weeks, allowing enough time for the patient to recover from short-term toxic effects before the next dose. Between four and eight such cycles of treatment are usually given in total. More recently, other strategies have been developed. For example, 5-fluorouracil (5-FU), which has a very short half-life, has increased efficacy when given by continuous intravenous infusion, using a semi-permanent in-dwelling intravenous catheter. However, the use of such catheters is not without risk and the potential of oral 5-FU is now being explored, using precursors such as capecitabine. Schedules of administration at weekly or 2-weekly intervals have also found their place in the management of both solid and haematological malignancies. Each tumour type has specific regimens that are used at various stages of the disease.

Mode of administration

Most drugs have to be given intravenously, and many are vesicant or locally irritant if there is an extravasation. Chemotherapy should be administered into a vein in which the infusion is free-flowing to minimise the risk of extravasation. A few patients require central venous

catheters due to the nature of their treatment or poor vascular access. Patients who receive chemotherapy through a peripheral line must be carefully observed, and the chemotherapy stopped at the first sign of any extravasation. Chemotherapy is potentially dangerous to the person giving the therapy, because cytotoxics are carcinogenic and teratogenic. In view of this, policies must be in place for the use of gloves and aprons and for the safe disposal of syringes containing cytotoxics. Other oral chemotherapeutic agents have been developed over the past 30 years, although not many have replaced their intravenous counterparts.

Adverse effects

Most cytotoxics have a narrow therapeutic window or index and can have significant adverse effects, as shown in Figure 11.6. Considerable supportive therapy is often required to enable patients to tolerate therapy and achieve benefit. Nausea and vomiting are common, but with modern antiemetics, regimens such as the combination of dexamethasone and highly selective 5-hydroxytryptamine (5-HT_3) receptor antagonists like ondansetron, most patients now receive chemotherapy without any significant problems. Myelosuppression is common to almost all cytotoxics. This not only limits the dose of drug, but also can cause life-threatening complications. The risk of neutropenia can be reduced with the use of specific growth factors that accelerate the re-population of myeloid precursor cells. The most commonly employed is granulocyte–colony-stimulating factor (G-CSF), which is widely used in conjunction with chemotherapy regimens that induce a high rate of neutropenia. More recently, it has also been used to 'accelerate' the administration of chemotherapy, enabling standard doses to be given at shorter intervals where the rate-limiting factor has been the time taken for the peripheral neutrophil count to recover. Accelerated chemotherapy regimens have now been demonstrated to offer therapeutic advantages in small cell lung cancer, lymphoma and possibly breast cancer.

Radiation therapy

Radiation therapy (radiotherapy) involves treating the cancer with ionising radiation; for certain localised cancers it may be curative. Ionising radiation can be delivered by radiation emitted from the decay of radioactive isotopes or by high-energy radiation beams, usually X-rays. Three methods are usually employed:

- *Teletherapy*: application from a distance by a linear accelerator.
- *Brachytherapy*: direct application of a radioactive source on to or into a tumour. This allows the delivery of a very high, localised dose of radiation and is integral to the management of localised

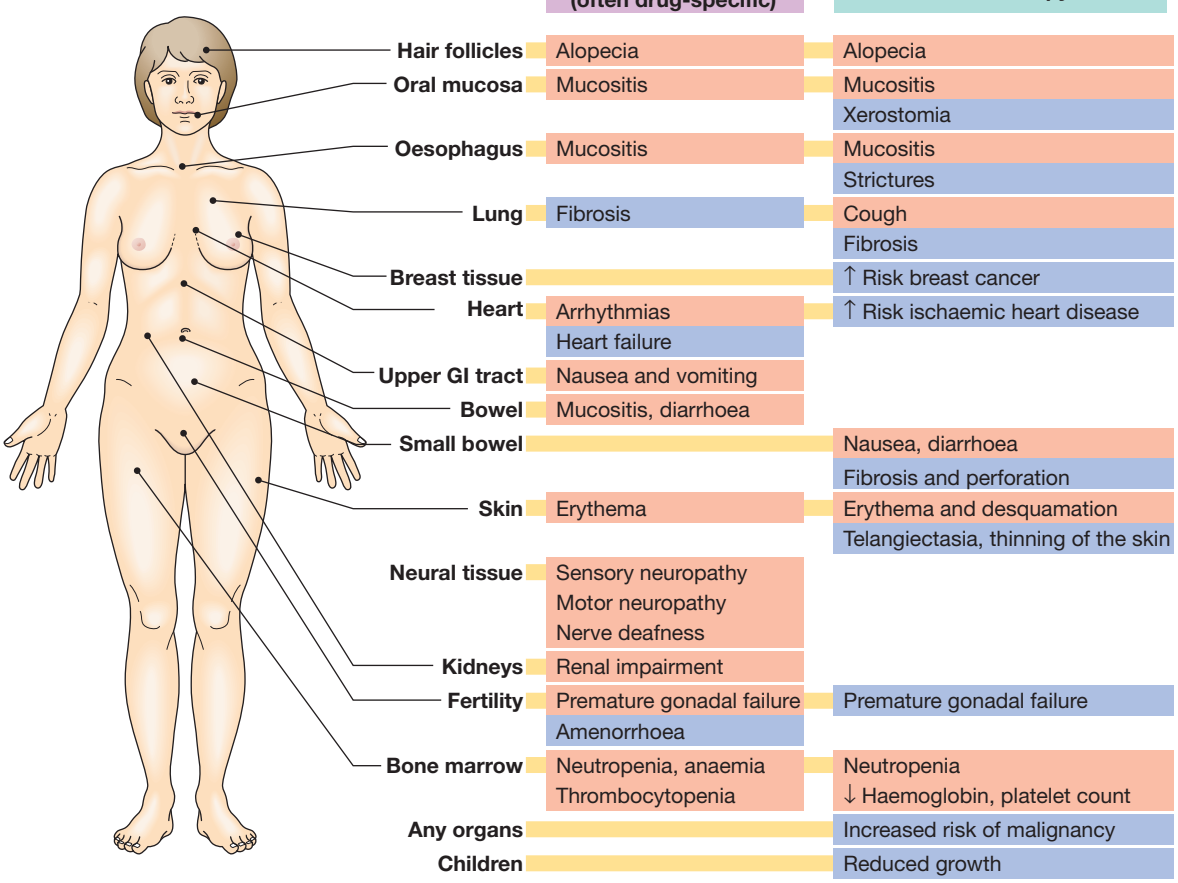

Fig. 11.6 Adverse effects of chemotherapy and radiotherapy. Acute effects are shown in pink and late effects in blue.

cancers of the head and neck and cancer of the cervix and endometrium.
- *Intravenous injection of a radioisotope*: such as ^{131}iodine for cancer of the thyroid and ^{89}strontium for the treatment of bone metastases from prostate cancer.

The majority of treatments are now delivered by linear accelerators; these produce electron or X-ray beams of high energy that are used to target tumour tissue. Whatever the method of delivery, the biological effect of ionising radiation is to cause lethal and sublethal damage to DNA. Since normal tissues are also radiosensitive, treatment has to be designed to maximise exposure of the tumour and minimise exposure of normal tissues. This is now possible with modern imaging techniques such as CT and MRI, which allow better visualisation of normal and tumour tissue. In addition, techniques such as conformal radiotherapy, where shaped rather than conventional square or rectangular beams are used, allow much more precise targeting of therapy to the tumour, and reduce the volume of normal tissue irradiated by up to 40% compared to non-conformal techniques.

Biological differences between normal and tumour tissues are also used to obtain therapeutic gain. Fundamental to this is fractionation, which entails delivering the radiation as a number of small doses on a daily basis. This allows normal cells to recover from irradiation damage but recovery occurs to a lesser degree in malignant cells. Fractionation regimens vary from centre to centre but radical treatments given with curative intent are often delivered in 20–30 fractions given daily, 5 days a week over 4–6 weeks. Radiotherapy can also be extremely useful for the alleviation of symptoms, and for palliative treatments such as this a smaller number of fractions (1–5) is usually adequate.

Both normal and malignant tissues vary widely in their sensitivity to radiotherapy. Germ cell tumours and lymphomas are extremely radiosensitive and relatively low doses are adequate for cure, but most cancers require doses close to or beyond that which can be tolerated by adjacent normal structures. Normal tissue also varies in its radiosensitivity, the central nervous system, small bowel and lung being amongst the most sensitive. The side-effects of radiotherapy (see Fig. 11.6) depend on the normal tissues treated, their radiosensitivity and the dose delivered.

Adverse effects

An acute inflammatory reaction commonly occurs towards the end of most radical treatments and is localised to the area treated. For example, skin reactions are common with breast or chest wall radiotherapy, and proctitis and cystitis with treatment to the bladder or prostate. These acute reactions settle over a period of a few weeks after treatment, assuming normal tissue tolerance has not been exceeded. Late effects of radiotherapy develop 6 weeks or more after treatment and occur in 5–10% of patients. Examples include brachial nerve damage and subcutaneous fibrosis after breast cancer treatment, and shrinkage and fibrosis of the bladder after treatment for bladder cancer. There is a risk of inducing cancer after radiotherapy, which varies depending on the site treated and whether the patient has had other treatment such as chemotherapy.

Hormone therapy

Hormone therapy is most commonly used in the treatment of breast cancer and prostate cancer. Breast tumours that are positive for expression of the oestrogen receptor (ER) respond well to anti-oestrogen therapy, and assessment of ER status is now standard in the diagnosis of breast cancer. Several drugs are now available that reduce oestrogen levels or block the effects of oestrogen on the receptor. When targeted appropriately, adjuvant hormone therapy reduces the risk of relapse and death at least as much as chemotherapy, and in advanced cases can induce stable disease and remissions that may last months to years, with acceptable toxicity. Hormonal manipulation may be effective in other cancers. In prostate cancer, hormonal therapy (e.g. luteinising hormone releasing hormone (LHRH) analogues such as goserelin and/or anti-androgens such as bicalutamide) aimed at reducing androgen levels can provide good long-term control of advanced disease, but there is no convincing evidence that it is an effective therapy following potentially curative surgery. Progestogens are active in the treatment of endometrial and breast cancer. In the metastatic setting, progestogen use (e.g. megestrol acetate) is associated with response rates of 20–40% in endometrial cancer. In breast cancer, progestogens are used in patients whose disease has progressed with conventional anti-oestrogen therapy. Their exact mechanism in this setting is not fully understood.

Immunotherapy

A profound stimulus to the patient's immune system can sometimes alter the natural history of a malignancy, and the discovery of interferons was the impetus for much research. Although solid tumours show little benefit, interferons are active in melanoma and lymphoma, and there is evidence that they are beneficial as adjuvants (after surgery and chemotherapy respectively) to delay recurrence. Whether interferon-induced stimulation of the immune system is capable of eradicating microscopic disease remains unproven. More powerful immune responses can be achieved with potent agents like interleukin-2 (IL-2), but the accompanying systemic toxicity is a problem still to be overcome. The most striking example of successful immunotherapy is that with rituximab, an antibody against the common B-cell antigen CD20. It increases complete response rates and improves survival in diffuse large cell non-Hodgkin's lymphoma when combined with chemotherapy, and is also effective in palliating advanced follicular non-Hodgkin's lymphoma (p. 1043).

Biological therapies

Advances in knowledge about the molecular basis of cancer have resulted in the development of a new generation of treatments to block the signalling pathways responsible for the growth of specific tumours. This has created the potential to target cancer cells more selectively, with reduced toxicity to normal tissues. Some

examples are discussed below, but in the years to come many more such agents will come into clinical use, with the potential to revolutionise our approach to some cancers.

Gefitinib/erlotinib

These agents inhibit the activity of the epidermal growth factor receptor, which is over-expressed in many solid tumours. However, the drugs' activity does not depend on the amount of receptor over-expression but on factors such as gene copy number and mutation status.

Imatinib

Imatinib was developed to inhibit the *BCR-ABL* gene product, tyrosine kinase, that is responsible for chronic myeloid leukaemia (p. 1039), and it does this extremely effectively. It is also active in gastrointestinal stromal tumour (GIST), a type of sarcoma that has over-expression of another cell surface tyrosine kinase, c-kit. This agent has good tolerability and is particularly useful in GIST, where conventional chemotherapy is less effective.

Bevacizumab

This is a humanised monoclonal antibody that inhibits vascular endothelial growth factor A (VEGF-A), a key stimulant of angiogenesis in tumours. This has activity in colorectal, lung, breast, renal and ovarian cancers, although the licence was subsequently revoked for breast cancer; while bevacizumab slows the rate of progression of metastatic breast cancer, it had little impact on survival or improved quality of life.

Trastuzumab

Trastuzumab (herceptin) targets the HER2 receptor, an oncogene that is over-expressed in around one-third of breast cancers and in a number of other solid tumours. It is effective as a single-agent therapy, but also improves survival in patients with advanced breast cancer when used in conjunction with chemotherapy. Unfortunately, trastuzumab can induce cardiac failure by an unknown biological mechanism, especially in combination with doxorubicin.

SPECIFIC CANCERS

The diagnosis and management of cancers are discussed in more detail elsewhere in the book (Box 11.17). Here we discuss the clinical features, pathogenesis and management of common tumours that are not covered elsewhere.

Breast cancer

Globally, the incidence of breast cancer is only second to that of lung cancer and the disease represents the leading cause of cancer-related deaths among women. Invasive ductal carcinoma with or without ductal carcinoma in situ (DCIS) is the most common histology, accounting for 70%, whilst invasive lobular carcinoma accounts for most of the remaining cases. DCIS constitutes 20% of breast cancers detected by mammography screening. It is multifocal in one-third of women and has a high risk of becoming invasive (10% at 5 years following excision only). Pure DCIS does not cause lymph node metastases, although these are found in 2% of cases where nodes are examined, owing to undetected invasive cancer. Lobular carcinoma in situ (LCIS) is a predisposing risk factor for developing cancer in either breast (7% at 10 years). The survival for breast cancer by stage is outlined in Box 11.18.

11.18 Five-year survival rates for breast cancer by stage

Tumour stage	Stage definition	5-year survival (%)
Stage I	Tumour < 2 cm, no lymph nodes	96
Stage II	Tumour 2–5 cm, and/or mobile axillary lymph nodes	81
Stage III	Chest wall or skin fixation, and/or fixed axillary lymph nodes	52
Stage IV	Metastasis	18

Pathogenesis

Both genetic and hormonal factors play a role; about 5–10% of breast cancers are hereditary and occur in patients with mutations of *BRCA1*, *BRCA2*, *AT* or *TP53* genes. Prolonged oestrogen exposure associated with early menarche, late menopause and use of hormone replacement therapy (HRT) has been associated with an increased risk. Other risk factors include obesity, alcohol intake, nulliparity and late first pregnancy. There is no definite evidence linking use of the contraceptive pill to breast cancer.

Clinical features

Breast cancer usually presents as a result of mammographic screening or as a palpable mass with nipple discharge in 10% and pain in 7% of patients. Less common presentations include inflammatory carcinoma with diffuse induration of the skin of the breast, and this confers an adverse prognosis. Around 40% of patients will have axillary nodal disease, with likelihood correlating with increasing size of the primary tumour. Distant metastases are infrequently present at diagnosis and the most common sites of spread are: bone (70%), lung (60%), liver (55%), pleura (40%), adrenals (35%), skin (30%) and brain (10–20%).

Investigations

Following clinical examination, patients should have imaging with mammography or ultrasound evaluation and a biopsy using fine needle aspiration for cytology or core biopsy for histology. Histological assessment should be carried out to assess tumour type and to determine oestrogen and progesterone receptor (ER/PR) status and HER2 status. If distant spread is suspected, CT of the thorax and abdomen and an isotope bone scan are required.

Management

Surgery is the mainstay of treatment for most patients, and this can range from a lumpectomy, where only the tumour is removed, to mastectomy, where the whole breast is removed. Lymph node sampling is performed at the time of surgery. Adjuvant radiotherapy is given to reduce the risk of local recurrence to 4–6%. Adjuvant hormonal therapy improves disease-free and overall survival in pre- and post-menopausal patients who have tumours that express ER. Patients at low risk, with tumours that are small and ER-positive, only require adjuvant hormonal therapy with tamoxifen. Patients with tumours that are ER-positive and who are pre-menopausal should receive an LHRH analogue. Aromatase inhibitors also have benefit in this setting and are still under investigation.

Adjuvant chemotherapy is considered for patients at higher risk of recurrence. Factors that increase the risk of recurrence include a tumour of greater than 1 cm, tumour that is ER-negative or the presence of involved axillary lymph nodes. Such patients should be offered adjuvant chemotherapy, which improves disease-free and overall survival (Box 11.19). The role of adjuvant treatment has been studied by meta-analyses and data support the use of adjuvant trastuzumab, a humanised monoclonal antibody to HER2, in addition to standard chemotherapy for women with early HER2-positive breast cancer.

Metastatic disease management includes radiotherapy to palliate painful bone metastases and second-line endocrine therapy with aromatase inhibitors, which inhibit peripheral oestrogen production in adrenal and adipose tissues. Advanced ER-negative disease may be treated with combination chemotherapy.

EBM 11.19 Use of adjuvant chemotherapy and endocrine therapy in early breast cancer

'The use of anthracycline-based chemotherapy reduces the annual breast cancer rate from 38% to 20%, while the adjuvant use of tamoxifen for 5 years in early breast cancer for patients with ER-positive disease reduces the annual breast cancer death rate by 31%.'

- Early Breast Cancer Trialists Collaborative Group (EBCTCG). Lancet 4 Feb 2012; 379(9814):432–444.

Ovarian cancer

Ovarian cancer is the most common gynaecological tumour in Western countries. Most ovarian cancers are epithelial in origin (90%), and up to 7% of women with ovarian cancer have a positive family history. Patients often present late in ovarian cancer with vague abdominal discomfort, low back pain, bloating, altered bowel habit and weight loss. Occasionally, peritoneal deposits are palpable as an omental 'cake' and nodules in the umbilicus (Sister Mary Joseph nodules).

Pathogenesis

Genetic and environmental factors play a role. The risk of ovarian cancer is increased in patients with *BRCA1* or *BRCA2* mutations, and Lynch type II families (a subtype of hereditary non-polyposis colon cancer (HNPCC)) have ovarian, endometrial, colorectal and gastric tumours due to mutations of mismatch repair enzymes. Advanced age, nulliparity, ovarian stimulation and Caucasian descent all increase the risk of ovarian cancer, whilst suppressed ovulation appears to protect, so pregnancy, prolonged breastfeeding and the contraceptive pill have all been shown to reduce the risk of ovarian cancer.

Investigations

Initial workup for patients with suspected ovarian malignancy includes imaging in the form of ultrasound and CT. Serum levels of the tumour marker CA-125 are often measured. Surgery plays a key role in the diagnosis, staging and treatment of ovarian cancer, and in early cases, palpation of viscera, intraoperative washing and biopsies are generally performed to define disease extent.

Management

In early disease, surgery followed by adjuvant chemotherapy with carboplatin, or carboplatin plus paclitaxel, is the treatment of choice. Surgery should include removal of the tumour along with total hysterectomy, bilateral salpingo-oophorectomy, and omentectomy. Even in advanced disease, surgery is undertaken to debulk the tumour and is followed by adjuvant chemotherapy, typically using carboplatin and paclitaxel. Bevacizumab is indicated for patients with high-grade tumours that are suboptimally debulked or those with a more aggressive biological pattern. Monitoring for relapse is achieved through a combination of serum CA-125 and clinical examination with CT imaging for those with suspected relapse. Second-line chemotherapy is aimed at improving symptoms and should not be used for CA-125 elevation only in the absence of symptoms. Treatments can include further platinum/

paclitaxel combination, liposomal doxorubicin or topotecan. These regimens are associated with a response rate of 10–40%. The best responses are observed in patients with a treatment-free interval of more than 12 months.

Endometrial cancer

Endometrial cancer accounts for 4% of all female malignancies, producing a 1 in 73 lifetime risk. The majority of patients are post-menopausal, with a peak incidence at 50–60 years of age. Mortality from endometrial cancer is currently falling. The most common presentation is with post-menopausal bleeding, which often results in detection of the disease before distant spread has occurred.

Pathogenesis

Oestrogen plays an important role in the pathogenesis of endometrial cancer, and factors that increase the duration of oestrogen exposure, such as nulliparity, early menarche, late menopause and unopposed HRT, increase the risk. Endometrial cancer is 10 times more common in obese women, and this is thought to be due to elevated levels of oestrogens.

Investigations

The diagnosis is confirmed by endometrial biopsy.

Management

Surgery is the treatment of choice and is also used for staging. A hysterectomy and bilateral salpingo-oophorectomy are performed with peritoneal cytology and, in some cases, lymph node dissection. Where the tumour extends beyond the inner 50% of the myometrium, involves the cervix and local lymph nodes, or there is lymphovascular space invasion, adjuvant pelvic radiotherapy is recommended. Chemotherapy and hormonal therapies have not demonstrated a sufficient survival advantage to be recommended for routine use in the adjuvant setting but have a role in recurrent disease.

Cervical cancer

This is the second most common gynaecological tumour worldwide. The incidence is decreasing in developed countries but continues to rise in developing nations. Cervical cancer is the leading cause of death from gynaecological cancer. The most common presentation is with an abnormal smear test, but with locally advanced disease the presentation is with vaginal bleeding, discomfort, discharge or symptoms attributable to involvement of adjacent structures, such as bladder, or rectal or pelvic wall. Occasionally, patients present with distant metastases to bone and lung.

Pathogenesis

There is a strong association between cervical cancer and sexual activity that includes sex at a young age and multiple sexual partners. Infection with HPV has an important causal role, and this has underpinned the introduction of programmes to immunise teenagers against HPV in an effort to prevent the later development of cervical cancer (p. 425).

Investigations

Diagnosis is made by smear or cone biopsy. Dilatation and curettage is also used diagnostically, with cystoscopy and flexible sigmoidoscopy if there are symptoms referable to the bladder, colon or rectum. In contrast to other gynaecological malignancies, cervical cancer is a clinically staged disease. MRI is often used to characterise the primary tumour. A routine chest X-ray should be obtained to help rule out pulmonary metastasis. CT of the abdomen and pelvis is performed to look for metastasis in the liver and lymph nodes and to exclude hydronephrosis and hydroureter.

Management

This depends on the stage of disease. Pre-malignant disease can be treated with laser ablation or diathermy, whereas in microinvasive disease a large loop excision of the transformation zone (LLETZ) or a simple hysterectomy is employed. Invasive but localised disease requires radical surgery, while chemotherapy and radiotherapy, including brachytherapy, may be given as primary treatment, especially in patients with adverse prognostic features such as bulky or locally advanced disease, or lymph node or parametrium invasion. In metastatic disease, cisplatin-based chemotherapy may be beneficial in improving symptoms but does not improve survival significantly.

Head and neck tumours

Head and neck cancers are typically squamous tumours that arise in the nasopharynx, hypopharynx and larynx. They are most common in elderly males, but now occur with increasing frequency in a younger cohort, as well as in women, especially where oropharyngeal cancers are concerned. The rising incidence of oropharyngeal cancers, especially in the developed world, is thought to be secondary to HPV infection. Presentation depends on the location of the primary tumour and the extent of disease. For example, early laryngeal cancers may present with hoarseness, while more extensive local disease may present with pain due to invasion of local structures or with a lump in the neck. Patients who present late often have pulmonary symptoms, as this is the most common site of distant metastases (Box 11.20).

Pathogenesis

The tumours are strongly associated with a history of smoking and excess alcohol intake, but other recognised risk factors include Epstein–Barr virus for nasopharyngeal cancer and HPV infection for oropharyngeal tumours.

Investigations

Careful inspection of the primary site is required as part of the staging process, and most patients will require endoscopic evaluation and examination under anaesthesia. Tissue biopsies should be taken from the most accessible site. CT of the primary site and the thorax is the

11.20 Common presenting features by location in head and neck cancer

Hypopharynx	
• Dysphagia • Odynophagia	• Referred otalgia • Enlarged lymph nodes

Salivary gland	
• Painless swelling	• Facial nerve palsy

investigation of choice for visualising the tumour, while MRI may be useful in certain cases.

Management

Generally speaking, the majority of patients with early or locally advanced disease are treated with curative intent. In localised disease where there is no involvement of the lymph nodes, long-term remission can be achieved in up to 90% of patients with surgery or radiotherapy. The choice of surgery versus radiotherapy often depends on patient preference, as surgical treatment can be mutilating with an adverse cosmetic outcome. Patients with lymph node involvement or metastasis are treated with a combination of surgery and radiotherapy (often with chemotherapy as a radiosensitising agent – proven agents include cisplatin or cetuximab), and this produces long-term remission in approximately 60–70% of patients. Recurrent or metastatic tumour may be palliated with further surgery or radiotherapy to aid local control, and systemic chemotherapy has a response rate of around 20–30%. Second malignancies are common (3% per year) following successful treatment for primary disease, and all patients should be encouraged to give up smoking and drinking alcohol to lower their risk.

Carcinoma of unknown origin

Some patients are found to have evidence of metastatic disease at their initial presentation prior to diagnosis of a primary site. In many cases, a subsequent biopsy reveals adenocarcinoma but the primary site is not always clear.

Investigations

In this situation, there is a temptation to investigate the patient endlessly in order to determine the original primary site. However, there is a compromise between exhaustive investigation and obtaining sufficient information to plan appropriate management. For all patients, histological examination of an accessible site of metastasis is required. The architecture of the tissue can assist the pathologist in determining the likely primary site, and therefore it is better to perform a biopsy rather than fine needle aspiration. The greater volume of tissue also permits the use of immunohistochemistry. Extensive imaging to search for the primary is rarely indicated; a careful history to identify symptoms and risk factors (including familial) will often permit a judicious choice of imaging.

Management

Management of the patient will depend on that person's circumstances, as well as on the site(s) involved and the likely primary sites. The overriding principle is to ensure that a curable diagnosis has not been overlooked. For example, lung metastases from a testicular teratoma do not preclude cure; nor do one or two liver metastases from a colorectal cancer. Early discussion with an oncologist within a multidisciplinary team is essential and avoids unnecessary investigation; for example, a single hCG-based pregnancy test in a young man with lung metastases might confirm the presence of a teratoma and allow rapid administration of potentially curative chemotherapy. Treatment should not necessarily wait for a definitive diagnosis; appropriate analgesia, radiotherapy and surgical palliation can all be helpful. Some patients remain free of cancer for some years after resection of a single metastasis of an adenocarcinoma of unknown primary, justifying this approach in selected patients.

In those with no obvious primary, systemic chemotherapy may achieve some reduction in tumour burden and alleviation of symptoms, but long-term survival is rare.

PRINCIPLES OF PALLIATIVE CARE

Palliative care is the active total care of patients with far advanced, rapidly progressive and ultimately fatal disease. Its focus is quality of life rather than cure, and it encompasses a distinct body of knowledge and skills that all good physicians must possess to allow them to care effectively for patients at the end of life. In palliative care, there is a fundamental change of emphasis in decision-making away from a focus on prolonging life towards decisions that balance comfort and the individual's wishes with treatments that might prolong life. There is a growing recognition that the principles of, and some specific interventions developed in the palliative care of patients with cancer are equally applicable to other conditions. The principles of palliative care may therefore be applied not only to cancer but also to any chronic disease state.

Palliative care is often seen as a means of managing distress and symptoms in patients with cancer, where metastatic disease has been diagnosed and death is seen as inevitable. In other illnesses, the challenge is recognising when patients have entered this phase of their illness, as there are fewer clear markers and the course of the illness is much more variable.

Different chronic disease states progress at different rates, allowing some general trajectories of illness or dying to be defined (Fig. 12.1). These trajectories are useful in helping decision-making in individual patients and also in planning services.

Traditionally, palliative care has been associated with cancer because the latter is typified by a progressive decline in function which was more predictable than in many other diseases. This 'rapid decline' trajectory is the best-recognised pattern need for palliative care and many traditional hospice services are designed to meet the needs of people on this trajectory: for example, motor neuron disease, or AIDS where antiretroviral therapy (ART) is not available. With the improvements in management of malignant disease, this is no longer so true for all patients with cancer, whose illness may follow an erratic or intermittent decline trajectory.

Many chronic diseases, such as advanced chronic obstructive pulmonary disease (COPD) and intractable congestive heart failure, carry as high a burden of symptoms as cancer, as well as psychological and family distress. The 'palliative phase' of these illnesses may be more difficult to identify because of periods of relative stability interspersed with acute episodes of severe illness. However, it is still possible to recognise those patients whose care may benefit from a palliative approach. The challenge is that symptom management needs to be delivered at the same time as treatment for acute exacerbations. This leads to difficult decisions as to the balance between symptom relief and aggressive management of the underlying disease. The starting point of need for palliative care in these conditions is the point at which consideration of comfort and individual values becomes important in decision-making, often alongside management of the underlying disease.

The third major trajectory is categorised by years of poor function and frailty before a relatively short terminal period; it is exemplified by dementia, but is also increasingly true for patients with many different chronic illnesses. As medical advances extend survival, this mode of dying is being experienced by increasing numbers of people. The main challenge lies in providing nursing care and ensuring that plans are agreed for the time when medical intervention is no longer beneficial.

In a situation where death is inevitable and foreseeable, palliative care balances the 'standard textbook' approach with the wishes and values of the patient and a realistic assessment of the benefits of medical interventions. This often results in a greater focus on comfort, symptom control and support for patient and family, and may enable withdrawal of interventions that are ineffective or burdensome. Commonly, the outcome is less certain. In many cases, there is a substantial risk that the patient will die but there may be a small chance of improvement with further treatment. In these circumstances, it is often (but not always) correct and helpful to share this information with the patient so that better decisions can be made about further care.

The principles of palliative care are being used increasingly in many different diseases so that death can be managed effectively and compassionately. Palliative management of the most common symptoms is discussed in the next section.

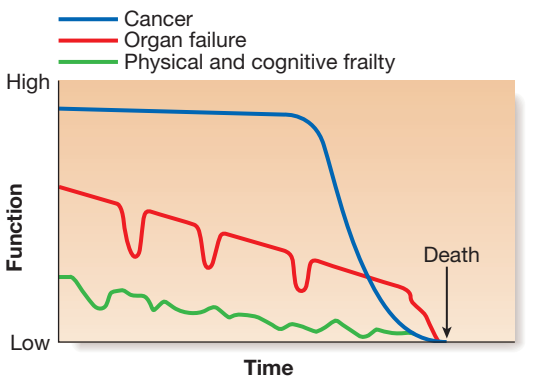

Fig. 12.1 Archetypal trajectories of dying. From Murray, et al. 2005 – see p. 292.

PRESENTING PROBLEMS IN PALLIATIVE CARE

Pain

The International Association for the Study of Pain (IASP) has defined pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage'. It follows that each patient's experience and expression of pain are different, and that severity of pain does not correlate with the degree of tissue damage. Effective pain treatment facilitates recovery from injury or surgery, aids rapid recovery of function, and may minimise chronic pain and disability. Unfortunately, the delivery of effective pain relief is often impeded by factors such as poor assessment and concerns about the use of opioid analgesia.

12.1 Features of neuropathic pain

- Burning, stabbing or pulsing pain
- Spontaneous pain, without ongoing tissue damage
- Pain in an area of sensory loss
- Presence of a major neurological deficit
- Pain in response to non-painful stimuli: 'allodynia'
- Increased pain in response to painful stimuli: 'hyperalgesia'
- Unpleasant abnormal sensations: 'dysaesthesias'
- Poor relief from opioids alone

Pain classification and mechanisms

Pain can be classified into two types:

- *Nociceptive*: due to direct stimulation of peripheral nerve endings by a noxious stimulus such as trauma, burns or ischaemia.
- *Neuropathic*: due to dysfunction of the pain perception system within the peripheral or central nervous system as a result of injury, disease or surgical damage, such as continuing pain experienced from a limb which has been amputated (phantom limb pain). This should be identified early (Box 12.1) because it is more difficult to treat once established.

The pain perception system (p. 1147) is not a simple hard-wired circuit of nerves connecting tissue pain receptors to the brain, but a dynamic system in which a continuing pain stimulus can cause central changes that lead to an increase in pain perception. This plasticity (changeability) applies to all the peripheral and central components of the pain pathway. Early and appropriate treatment of pain reduces the potential for chronic undesirable changes to develop.

Assessment and measurement of pain

Accurate assessment of the patient is the first step in providing good analgesia.

History and measurement of pain

A full pain history should be taken, to establish its causes and the underlying diagnoses. Patients may have more than one pain; for example, bone and neuropathic pain may both arise from skeletal metastases (Box 12.2).

A diagram of the body on which the patient can mark the pain site can be helpful. When asked to score pain, patients consistently rate it higher than health professionals and should, if able, always be asked to rate pain themselves. Methods include:

- *Verbal rating scale.* Different verbal descriptions are used to rate pain – 'no pain', 'mild pain', 'moderate pain' and 'severe pain'.
- *Visual analogue scale.* A question is used, such as 'Over the past 24 hours, how would you rate your pain, if 0 is no pain and 10 is the worst pain you could imagine?'
- *Behavioural rating scale.* It can be particularly difficult to decide whether a patient with cognitive impairment is suffering pain. A variety of measures are available which use observed behaviours, such as agitation and withdrawn posture, to assess levels of pain. Commonly used scales include Abbey and Dolorplus. Changes in behavioural rating pain scores can indicate whether drug measures have been successful.

Regular recording of formal pain assessment and patient-rated pain scores improves pain management and reduces the time taken to achieve pain control.

12.2 Types of pain

Type of pain	Features	Management options
Bone pain	Tender area over bone Possible pain on movement	Non-steroidal anti-inflammatory drugs (NSAIDs) Bisphosphonates Radiotherapy
Increased intracranial pressure	Headache, worse in the morning, associated with vomiting and occasionally confusion	Corticosteroids Radiotherapy Codeine
Abdominal colic	Intermittent, severe, spasmodic, associated with nausea or vomiting	Antispasmodics Hyoscine butylbromide
Liver capsule pain	Right upper quadrant abdominal pain, often associated with tender enlarged liver Responds poorly to opioids	Corticosteroids
Neuropathic pain	See Box 12.1	Anticonvulsants: Gabapentin Pregabalin Carbamazepine Antidepressants Amitriptyline Duloxetine Ketamine
Ischaemic pain	Diffuse severe aching pain associated with evidence of poor perfusion Responds poorly to opioids	NSAIDs Ketamine
Incident pain	Episodic pain usually related to movement or bowel spasm	Intermittent short-acting opioids Nerve block

Psychological aspects of chronic pain

Perception of pain is influenced by many factors other than the painful stimulus, and pain cannot therefore be easily classified as wholly physical or psychogenic in any individual (Fig. 12.2). Patients who suffer chronic pain will be affected emotionally and, conversely, emotional distress can exacerbate physical pain (p. 240). Full assessment for symptoms of anxiety and depression is essential to effective pain management.

Examination

This should include careful assessment of the painful area, looking for signs of neuropathic pain (see Box 12.1) or bony tenderness suggestive of bone metastases. In

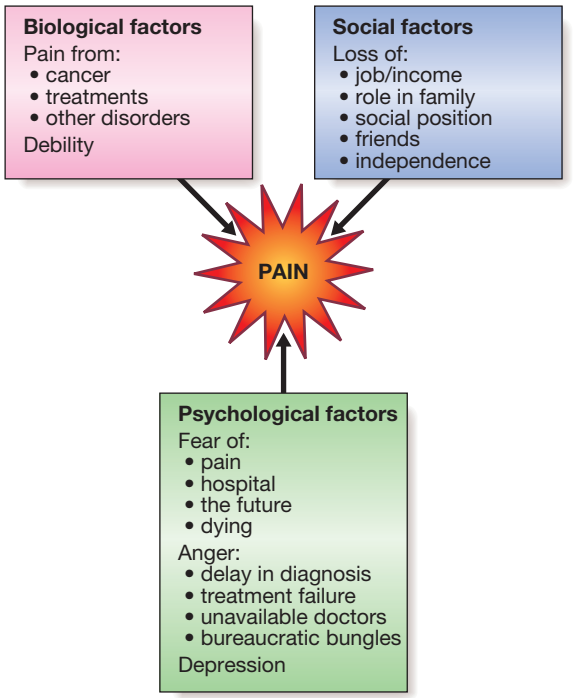

Fig. 12.2 Components of pain.

patients with cancer, it should not be assumed that all pains are due to the cancer or its metastases.

Appropriate investigations

Investigations should be directed towards diagnosis of an underlying cause, remembering that treatable conditions are possible even in patients with advanced disease. Imaging may be indicated, such as plain X-ray for fracture or magnetic resonance imaging (MRI) for spinal cord compression.

Management of pain

Many of the principles of pain management apply to any painful condition. There are, however, distinct differences between management of acute, chronic and palliative pain. Acute pain post-surgery or following trauma should be controlled with medication without causing unnecessary side-effects or risk to the patient. Chronic, non-malignant pain is more difficult and it may be impossible to relieve completely. In the management of chronic pain there is a greater emphasis on non-pharmacological treatments and on enabling the patient to live with pain. Strong opioids may help chronic pain but need to be used with caution after full assessment. They are used more readily in patients with a poorer prognosis.

Two-thirds of patients with cancer experience moderate or severe pain, and a quarter will have three or more different pains. Many of these are of mixed aetiology and 50% of pain from cancer has a neuropathic element. Careful evaluation to identify the likely pain mechanism facilitates appropriate treatment (see Box 12.2). It is vital that the patient's concerns about opioids are explored. Patients should be reassured that, when they are used for pain, psychological dependence and tolerance are extremely rare (Box 12.3).

12.3 Opioid myths

Myth	Fact
Pain is inevitable in cancer and many other diseases	**Pain can usually be controlled**
Opioids should be avoided because of dangerous side-effects	**Opioids can cause side-effects and sometimes the therapeutic window is narrow. However, side-effects are treatable and reversible**
The use of opioids commonly leads to addiction	**Addiction is very rare in patients who have pain and no previous history of addiction**
Taking opioids leads to more rapid decline and earlier death	**Opioids do not cause organ damage or other serious harm when used appropriately**

Nearly all types of pain respond to morphine to some degree. Some are completely opioid-responsive but others, such as neuropathic and ischaemic pain, are relatively unresponsive. Opioid-unresponsive or poorly responsive pain will only be relieved by opioids at a dose which causes significant side-effects. In these situations, effective pain relief may only be achieved with the use of adjuvant analgesics (see below).

Pharmacological treatments

Non-opioids

- *Paracetamol.* This is often effective for mild to moderate pain. For severe pain, it is inadequate alone, but is a useful and well-tolerated adjunct.
- *NSAIDs.* These are effective in the treatment of mild to moderate pain, and are also useful adjuncts in the treatment of severe pain. Adverse effects may be serious, especially in the elderly (p. 175).

Weak opioids

Codeine and dihydrocodeine are weak opioids. They have lower analgesic efficacy than strong opioids and a ceiling dose. They are effective for mild to moderate pain.

Strong opioids

Immediate-release (IR) oral morphine takes about 20 minutes to have an effect and usually provides pain relief for 4 hours. Most patients with continuous pain should be prescribed IR oral morphine every 4 hours initially, as this will provide continuous pain relief over the whole 24-hour period. Controlled-release (CR) morphine lasts for 12 or 24 hours but takes longer to provide analgesia.

The WHO analgesic ladder

The basic principle of the WHO ladder (Fig. 12.3) is that analgesia which is appropriate for the degree of pain should be prescribed. If pain is severe or remains poorly controlled, strong opioids should be prescribed and increased as indicated by the patient's need for additional analgesia (opioid titration).

A patient with mild pain is started on a non-opioid analgesic drug, such as paracetamol 1 g 4 times daily (step 1). If the maximum recommended dose is not

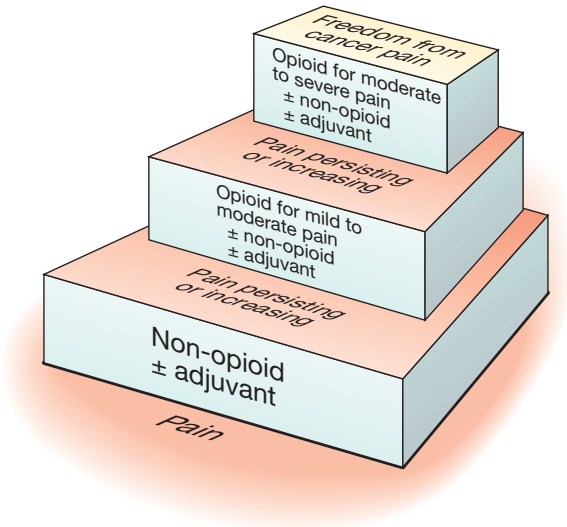

Fig. 12.3 The WHO analgesic ladder. From WHO 1996 – see p. 292.

sufficient or the patient has moderate pain, a weak opioid, such as codeine 60 mg 4 times daily, should be added (step 2). If adequate pain relief is still not achieved with the maximum recommended dosages or if the patient has severe pain, a strong opioid is substituted for the weak opioid (step 3). It is important not to move 'sideways' (change from one drug to another of equal potency) on a particular step of the ladder. All patients with severe pain should receive a full trial of strong opioids with appropriate adjuvant analgesia, as described below.

In addition to the regular dose, an extra dose of IR morphine should be prescribed 'as required' for when the patient has pain that is not controlled by the regular prescription (breakthrough pain). This should be one-sixth of the total 24-hour dose of opiate. The frequency of breakthrough doses should be dictated by their efficacy and any side-effects, rather than by a fixed time interval. A patient may require breakthrough analgesia as frequently as hourly if pain is severe, but this should lead to early review of the regular prescription. The patient and/or carer should note the timing of any breakthrough doses and the reason for them. These should be reviewed daily and the regular 4-hourly dose increased for the next 24 hours on the basis of:

- frequency of and reasons for breakthrough analgesia
- degree and acceptability of side-effects.

The regular dose should be increased by adding the total of the breakthrough doses over the previous 24 hours, unless there are significant problems with unacceptable side-effects. When the correct dose has been established, a CR preparation can be prescribed, usually twice daily.

Worldwide, the most effective and appropriate route of administration is oral, though transdermal preparations of strong opioids (usually fentanyl) are useful in certain situations, such as in patients with dysphagia or those who are reluctant to take tablets on a regular basis. Diamorphine is a highly soluble strong opioid used for subcutaneous infusions, particularly in the last few days of life, but is only available in certain countries.

12.4 Opioid side-effects

Side-effect	Management
Constipation	Regular laxative, such as co-danthramer or co-danthrusate (starting dose 2 capsules daily and titrate as needed) Opiates can be co-prescribed with oral naloxone
Dry mouth	Frequent sips of iced water, soft white paraffin to lips, chlorhexidine mouthwashes twice daily, sugar-free gum, water or saliva sprays
Nausea/ vomiting	Oral haloperidol 0.5–1 mg at night, oral metoclopramide 10 mg 3 times daily or oral domperidone 10 mg 3 times daily If constant, haloperidol or levomepromazine may be given parenterally to break the nausea cycle
Sedation	Explanation very important Symptoms usually settle in a few days Avoid other sedating medication where possible Ensure appropriate use of adjuvant analgesics which can have an opioid-sparing effect May require alternative opioid

Common side-effects of opioids are shown in Box 12.4. Nausea and vomiting occur initially but usually settle after a few days. Confusion and drowsiness are dose-related and reversible. In acute dosing, respiratory depression can occur but this is rare in those on regular opioids.

Opioid toxicity

All patients will develop dose-related side-effects, such as nausea, drowsiness, confusion or myoclonus; this is termed opiate toxicity. The dose at which this occurs varies from 10 to 5000 mg of morphine, depending on the patient and the type of pain. When opiates are being titrated, side-effects should be assessed regularly. The earliest side-effects are often visual hallucinations (often a sense of movement at the periphery of vision) and a distinct myoclonic movement. Pain should be re-assessed to ensure that appropriate adjuvants are being used. Parenteral rehydration is often helpful to speed up excretion of active metabolites of morphine. The dose of opioid may need to be reduced or changed to an alternative strong opiate.

Different opioids have different side-effect profiles in different people. If a patient develops side-effects, switching to an alternative strong opioid may be helpful. Options include oxycodone, transdermal fentanyl, alfentanil, hydromorphone and occasionally methadone, any of which may produce a better balance of benefit against side-effects. Fentanyl and alfentanil have no renally excreted active metabolites and may be particularly useful in patients with renal failure. Pethidine is used in acute pain management but not for chronic or cancer pain because of its short half-life and ceiling dose.

It is important to be very careful when switching opiates, as it is easy to make calculation mistakes and prescribe too much or too little.

Adjuvant analgesics

An adjuvant analgesic is a drug with a primary indication other than pain but which provides analgesia in some painful conditions and may enhance the effect of the primary analgesic. At each step of the WHO analgesic ladder, an adjuvant analgesic should be considered, the choice depending on the type of pain (Boxes 12.5 and 12.6).

Non-pharmacological and complementary treatments

Radiotherapy

Radiotherapy can improve pain from bone metastases and may be considered for cancer in other sites (see Box 12.2).

Physiotherapy

This helps to alleviate pain and restore function, through active mobilisation and specific physiotherapy techniques, such as spinal manipulation, massage, application of heat or cold, and exercise. Immediate application of cold with ice packs can reduce subsequent swelling and inflammation after a direct injury.

Psychological techniques

These include simple relaxation, hypnosis, cognitive behavioural therapies and biofeedback (pp. 240–241), which train the patient to use coping strategies and behavioural techniques. This is often more relevant in chronic non-malignant pain than in cancer pain.

EBM 12.5 Treatment of neuropathic pain

'Tricyclic antidepressants, a variety of anticonvulsants, and gabapentin are effective treatments for neuropathic pain.'

- Guideline 106. Scottish Intercollegiate Guidelines Network; 2008.

For further information: www.sign.ac.uk

Stimulation therapies

Acupuncture (Fig. 12.4) has been used successfully in Eastern medicine for centuries. It causes release of endogenous analgesics (endorphins) within the spinal cord. It can be particularly effective in pain related to muscle spasm. Transcutaneous electrical nerve stimulation (TENS) may have a similar mechanism of action to acupuncture and can be used in both acute and chronic pain.

Herbal medicine and homeopathy

These are widely used for pain, but often with little evidence for efficacy (p. 15). Safety regulations for these treatments are limited, compared with conventional drugs, and the doctor should be wary of unrecognised side-effects which may result.

Fig. 12.4 Acupuncture.

12.6 Adjuvant analgesics

Drug	Example	Indications	Side-effects*
NSAIDs	Diclofenac	Bone metastases, soft tissue infiltration, liver pain, inflammatory pain	Gastric irritation and bleeding, fluid retention, headache; caution in renal impairment
Corticosteroids	Dexamethasone 8–16 mg per day, titrated to lowest dose that controls pain	Raised intracranial pressure, nerve compression, soft tissue infiltration, liver pain	Gastric irritation if used together with NSAID, fluid retention, confusion, Cushingoid appearance, candidiasis, hyperglycaemia
Anticonvulsants	Evidence strongest for: Gabapentin Pregabalin Duloxetine	Neuropathic pain of any aetiology	Mild sedation, tremor, confusion
Tricyclic antidepressants	Amitriptyline	Neuropathic pain of any aetiology	Sedation, dizziness, confusion, dry mouth, constipation, urinary retention; avoid in cardiac disease
NMDA blockers	Ketamine	Severe neuropathic pain (only under specialist supervision)	Confusion, anxiety, agitation, hypertension

*In old age, all drugs can cause confusion.
(NMDA = N-methyl-D-aspartate)

Breathlessness

The sensation of breathlessness is the result of a complex interaction between different factors at the levels of production (the pathophysiological cause), perception (the severity of breathlessness perceived by the patient) and expression (the symptoms expressed by an individual patient). A patient's perception and expression of breathlessness can be significantly improved, even if there is no reversible 'cause' (Box 12.7). Assessment and treatment should therefore be targeted at modifying these factors, particularly when there is no reversible pathophysiology.

Clearly reversible causes of breathlessness (p. 655) should be identified and managed, but investigation and treatment should be appropriate to the prognosis and stage of disease. A therapeutic trial of corticosteroids (dexamethasone 8 mg for 5 days) and/or nebulised salbutamol may be helpful.

Breathlessness may be worsened by specific anxieties and beliefs; these should be explored. Many people with heart failure are concerned that exertional breathlessness will lead to worsening of their heart condition. Patients with advanced disease have specific panic–breathlessness cycles in which breathlessness leads to panic, which leads to worsening breathlessness and worsening panic. These should be identified and explained to the patient. Many fear that they will die during one of these episodes, and explanation of the panic cycle can be very reassuring. Another frequently expressed fear is that breathlessness will continue to worsen until it is continuous and unbearable, leading to a distressing and undignified death. Reassurance should again be given that this is uncommon and can be effectively managed with opioids and benzodiazepines.

A rapidly acting benzodiazepine, such as sublingual lorazepam, or non-drug measures, such as relaxation techniques, may help panic–breathlessness cycles. Attention to energy conservation (thinking clearly about using limited energy reserves sensibly) and pacing of activity is also extremely helpful. Physiotherapists are good at this and should be involved in developing an individual plan for each patient.

Perception of breathlessness may also be improved by night-time or regular morphine, or by regular benzodiazepines.

Oxygen does not help breathlessness unless the patient is hypoxic. An electric fan, piped air or an open window can be as effective as oxygen in patients who are breathless but not hypoxic. The patient's, family's or even professional beliefs about the benefits and need for oxygen may be the main reason for its apparent efficacy in non-hypoxic patients who feel less breathless when using oxygen.

EBM 12.7 Palliative treatment of breathlessness

'Interventions based on psychosocial support, breathing control and coping strategies can help patients to cope with the symptom of breathlessness and reduce physical and emotional distress.'

- Bredin M, et al. BMJ 1999; 318:901.

Cough

Cough can be a troubling symptom in cancer and other illnesses such as motor neuron disease, cardiac failure and COPD. There are many possible causes (p. 654). Management should focus on treating the underlying condition if possible. If this fails to bring about the desired response, antitussives, such as codeine linctus, are sometimes effective, particularly for cough at night.

Nausea and vomiting

The presentation of nausea and vomiting differs, depending on the underlying cause, of which there are many (p. 853). Large-volume vomiting with little nausea is common in intestinal obstruction, whereas constant nausea with little or no vomiting is often due to metabolic abnormalities or drugs. Vomiting related to raised intracranial pressure is worse in the morning.

Different receptors are activated, depending on the cause or causes of the nausea (Fig. 12.5). For example, dopamine receptors in the chemotactic trigger zone in the fourth ventricle are stimulated by metabolic and drug causes of nausea, whereas gastric irritation stimulates histamine receptors in the vomiting centre via the vagus nerve.

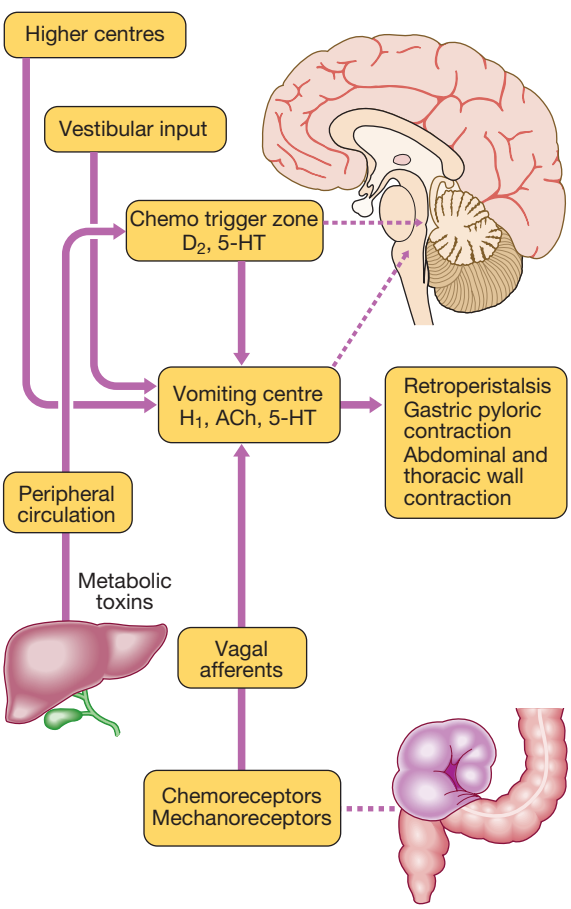

Fig. 12.5 Mechanisms of nausea. (ACh = acetylcholine; D_2 = dopamine; 5-HT = 5-hydroxytryptamine, serotonin; H_1 = histamine)

12.8 Receptor site activity of antiemetic drugs

Area	Receptors	Drugs
Chemo trigger zone	$Dopamine_2$ 5-HT	Haloperidol Metoclopramide
Vomiting centre	$Histamine_1$ Acetylcholine	Cyclizine Levomepromazine Hyoscine
Gut (gastric stasis)		Metoclopramide
Gut distension (vagal stimulation)	$Histamine_1$	Cyclizine
Gut (chemoreceptors)	5-HT	Levomepromazine

Reversible causes, such as hypercalcaemia and constipation, should be treated appropriately. Drug-induced causes should be considered and the offending drugs stopped if possible. As different classes of antiemetic drug act at different receptors, antiemetic therapy should be based on a careful assessment of the probable causes and a rational decision to use a particular class of drug (Box 12.8). The subcutaneous route is often required initially to overcome gastric stasis and poor absorption of oral medicines.

Gastrointestinal obstruction

Gastrointestinal obstruction is a frequent complication of intra-abdominal cancer. Patients may have multiple levels of obstruction and symptoms may vary greatly in nature and severity. Surgical mortality is high in patients with advanced disease and obstruction should normally be managed without surgery.

The key to effective management is to address the presenting symptoms – colic, abdominal pain, nausea, vomiting, intestinal secretions – individually or in combination, using drugs which do not cause or worsen other symptoms. This can be problematic when a specific treatment worsens another symptom. Cyclizine improves nausea and colic responds well to anticholinergic agents, such as hyoscine butylbromide, but both slow gut motility. Nausea will improve with metoclopramide, although this is contraindicated in the presence of colic because of its prokinetic effect. There is some evidence that corticosteroids (dexamethasone 8 mg) can shorten the length of obstructive episodes. Somatostatin analogues, such as octreotide, will reduce intestinal secretions and therefore large-volume vomits. Occasionally, a nasogastric tube is required to reduce gaseous or fluid distension.

Weight loss and general weakness

Patients with cancer lose weight due to an alteration of metabolism by the tumour known as the cancer cachexia syndrome. NSAIDs and megestrol may be helpful in early-stage disease but are unlikely to be effective in advanced cancer. Corticosteroids can temporarily boost appetite and general well-being, but may cause false weight gain by promoting fluid retention. Their benefits need to be weighed against the risk of side-effects.

Anxiety and depression

Depression is common in palliative care but diagnosis is more difficult, as the physical symptoms of depression are similar to those of advanced disease. Anxiety and depression may still respond to treatment with a combination of drugs and psychotherapeutic approaches (p. 243). Citalopram and mirtazapine are better tolerated in patients with advanced disease. It should not be assumed that depression is an 'understandable' consequence of the patient's situation.

Delirium and terminal agitation

Many patients become confused or agitated in the last days of life. It is important to identify and treat potentially reversible causes (pp. 173 and 280), unless the patient is too close to death for this to be feasible. Early diagnosis and effective management of delirium are extremely important. As in other palliative situations, it may not be possible to identify and treat the underlying cause, and the focus of management may be to ensure comfort. It is important to distinguish between behavioural change due to pain and that due to delirium, as opioids will improve one and worsen the other.

The management of delirium is detailed on page 174. It is important, even in palliative care to treat delirium with antipsychotic medicines such as haloperidol rather than regard it as distress or anxiety and use benzodiazepines only.

DEATH AND DYING

Talking about and planning towards dying

There have been dramatic improvements in medical treatment and care of patients with cancer and other illnesses over recent years, but the inescapable fact remains that everyone will die at some time. Planning for death is not required for people who die suddenly but should be actively considered in patients with chronic diseases when the death is considered to be foreseeable or inevitable. Doctors rarely know exactly when a patient will die but we are often aware that the risk of dying is increasing and that medical interventions are unlikely to prolong life or improve function. Many people wish their doctors to be honest about this situation to allow them time to think ahead, make plans and address practical issues. A smaller number do not wish to discuss future deterioration or death; this avoidance of discussion should be respected.

For doctors, it is helpful to understand an individual's wishes and values about medical interventions at this time, as this can help guide decisions about ceilings of intervention. Some interventions will not work in patients with far advanced disease. It is useful to distinguish between those that will not work (a medical decision) and those that do not confer sufficient benefit to be worthwhile (a decision that can only be reached with a patient's involvement and consent). A common example

of this would be decisions about not attempting cardiopulmonary resuscitation.

In general, people wish for a dignified and peaceful death and most prefer to die at home. Families also are grateful for the chance to prepare themselves for the death of a relative, by timely and gentle discussion with their doctor or other health professionals. Early discussion and effective planning improve the chances that an individual's wishes will be achieved.

Diagnosing dying

When patients with cancer become bed-bound, semi-comatose, unable to take tablets and only able to take sips of water, with no reversible cause, they are likely to be dying and many will have died within 2 days. Patients with other conditions also reach a stage where death is predictable and imminent. Doctors are sometimes poor at recognising this, and should be alert to the views of other members of the multidisciplinary team. A clear decision that the patient is dying should be agreed and recorded.

Management

Once the conclusion has been reached that a patient is going to die in the next few days, there is a significant shift in management (Box 12.9). Symptom control, relief of distress and care for the family become the most important elements of care. Medication and investigation are only justifiable if they contribute to these ends. When patients can no longer drink because they are dying, intravenous fluids are usually not necessary and may cause worsening of bronchial secretions. Medicines should always be prescribed for the relief of symptoms. For example, morphine or diamorphine may be used to control pain, levomepromazine to control nausea, haloperidol to treat confusion, diazepam or midazolam to treat distress, and hyoscine hydrobromide to reduce respiratory secretions. Side-effects, such as drowsiness, may be acceptable if the principal aim of relieving distress is achieved. It is important to discuss and agree the aims of care with the patient's family.

12.9 How to manage a patient who is dying

Patient and family awareness
• Assess patient's and family's awareness of the situation • Ensure family understands plan of care
Medical interventions
• Stop non-essential medications that do not contribute to symptom control • Stop inappropriate investigations and interventions, including routine observations
Resuscitation
• Complete Do Not Attempt Cardiopulmonary Resuscitation (DNACPR) form • Deactivate implantable defibrillator
Symptom control
• Ensure availability of parenteral medication for symptom relief
Support for family
• Make sure you have contact details for family, that you know when they want to be contacted and that they are aware of the facilities available to them
Religious and spiritual needs
• Make sure any particular wishes are identified and followed
Ongoing assessment
• Family's awareness of condition • Management of symptoms • Need for parenteral hydration
Care after death
• Make sure family know what they have to do • Notify other appropriate health professionals

Ethical issues at the end of life

In Europe, between 25 and 50% of all deaths are associated with some form of decision which may affect the length of a patient's life. The most common form of decision involves withdrawing or withholding further treatment: for example, not treating a chest infection in a patient who is clearly dying from advanced cancer. It is important to have a framework for considering such decisions (such as the four ethical principles: autonomy, beneficence, non-maleficence and justice, p. 10), which balances degrees of importance when there is conflict: for example, when a patient wishes to receive treatment which a doctor believes will be ineffective or which may cause harm. A decision has to be taken as to which principle is most important: whether it is better to respect a patient's wishes, even if it causes harm, or to reduce the risk of harm but not accede to those wishes.

A futile treatment is one which has no chance of achieving worthwhile benefit: that is, the treatment cannot achieve a result that the patient would consider, now or in the future, to be worthwhile. Doctors are not required to institute futile treatments, such as resuscitation, in the event of cardiac arrest in a patient with terminal cancer.

Incapacity and advance directives

Patients' wishes are very important in Western medical ethics, although other cultures emphasise the views of the family. If a patient is unable to express his or her view because of communication or cognitive impairment, that person lacks 'capacity'. In order to decide what the patient would have wished, as much information as possible should be gained about any previously expressed wishes, along with the views of relatives and other health professionals.

An advance directive is a previously recorded, written document of a patient's wishes (p. 171). It should carry the same weight in decision-making as a patient's contemporaneously expressed wishes, but may not be sufficiently specific to be used in a particular clinical situation. The legal framework for decision-making varies in different countries.

Hydration

Deciding whether to give intravenous fluids can be difficult when a patient is very unwell and the prognosis

is uncertain. If a patient is clearly dying and has a prognosis of a few days, rehydration may cause harm by increasing bronchial secretions, and will not benefit the patient by prolonging life. A patient with a major stroke, who is unable to swallow but expected to survive the event, will develop renal impairment and thirst if not given fluids and should be hydrated. Each decision should be individual and discussed with the patient's family.

Euthanasia

In the UK and Europe, between 3 and 6% of dying patients ask a doctor to end their life. Many of these requests are transient; some are associated with poor control of physical symptoms or a depressive illness. All expressions of a wish to die are an opportunity to help the patient discuss and address unresolved issues and problems.

Reversible causes, such as pain or depression, should be treated. Sometimes, patients may choose to discontinue life-prolonging treatments, such as diuretics or anticoagulation, following discussion and the provision of adequate alternative symptom control. However, there remain a small number of patients who have a sustained, competent wish to end their lives, despite good control of physical symptoms. Euthanasia is now permitted or legal in some countries but remains illegal in many others; public ethical and legal debate over this issue is likely to continue.

CLINICAL EXAMINATION OF PATIENTS WITH INFECTIOUS DISEASE

Fever

- *Documentation of fever.* 'Feeling hot' or sweaty does not necessarily signify fever. Fever is diagnosed only when a body temperature of over 38.0°C has been recorded. Axillary and aural measurement is less accurate than oral or rectal. Outpatients may be trained to keep a temperature chart.
- *Rigors.* Shivering (followed by excessive sweating) occurs with a rapid rise in body temperature from any cause.
- *Night sweats.* These are associated with particular infections (e.g. tuberculosis, infective endocarditis), but sweating from any cause is worse at night.
- *Excessive sweating.* Alcohol, anxiety, thyrotoxicosis, diabetes mellitus, acromegaly, lymphoma and excessive environmental heat all cause sweating without temperature elevation.
- *Recurrent fever.* There are various causes, e.g. *Borrelia recurrentis*, bacterial abscess.
- *Accompanying features.* HEADACHE. Severe headache and photophobia, although characteristic of meningitis, may accompany other infections. DELIRIUM. Mental confusion during fever is more common in young children or the elderly. MUSCLE PAIN. Myalgia may occur with viral infections, such as influenza, and with septicaemia, including meningococcal sepsis. SHOCK. Shock may accompany severe infections and sepsis (Ch. 8).

History-taking in suspected infectious disease*

Presenting complaint
- Diverse manifestations of infectious disease make accurate assessment of features and duration critical; e.g. fever and cough lasting 2 days imply an acute respiratory tract infection but suggest TB if they last 2 months

Review of systems
- Must be comprehensive

Past medical history
- Define the 'host' and likelihood of infection(s)
- Include surgical and dental procedures involving prosthetic materials
- Document previous infections

Medication history
- Include non-prescription drugs, use of antimicrobials and immunosuppressive drugs
- Identify medicines which interact with antimicrobials

Allergy history
- Esp. to antimicrobials, noting allergic manifestation (e.g. rash versus anaphylaxis)

Family and contact history
- Note infections and their time course
- Sensitively explore exposure to key infections, e.g. TB and HIV-1

Travel history
- Include countries visited and where previously resident (relevant to exposure and likely vaccination history, e.g. likelihood of BCG vaccination in childhood)

Occupation
- e.g. Anthrax in leather tannery workers

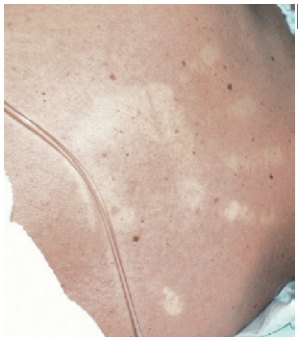
Recreational pursuits
- e.g. Leptospirosis in canoeists and windsurfers

Animal exposures
- Include pets, e.g. dog exposure and hydatid disease

Dietary history
- Consider undercooked meats, shellfish, unpasteurised dairy products or well water
- Establish who else was exposed, e.g. to food-borne pathogens

History of intravenous drug injection or receipt of blood products
- Risks for blood-borne viruses, e.g. HIV-1, and HBV and HCV

Sexual history
- Explore in a confidential and non-threatening way (Ch. 15); remember that the most common mechanism of HIV-1 transmission is heterosexual contact (Ch. 14)



Vaccination history and use of prophylactic medicines
- Consider occupation- or age-related vaccines
- In a traveller or infection-predisposed patient, establish compliance with prophylactic treatments

*Always consider non-infectious aetiologies in the differential diagnosis.
(HBV/HCV = hepatitis B/C virus; HIV-1 = human immunodeficiency virus-1; TB = tuberculosis)

1 Skin lesions in infectious diseases

- Diffuse erythema, e.g. A
- Migrating erythema, e.g. enlarging rash of erythema migrans in Lyme disease (see Fig. 13.20, p. 335)
- Purpuric or petechial rashes, e.g. B
- Macular or papular rashes, e.g. primary infection with HIV (Box 14.8, p. 395)
- Vesicular or blistering rash, e.g. C
- Erythema multiforme (Fig. 28.48 and Box 28.41, p. 1302)
- Nodules or plaques, e.g. Kaposi's sarcoma (p. 384)
- Erythema nodosum (D and Box 28.42, p. 1303)

A

Streptococcal toxic shock syndrome

B

Meningococcal sepsis

C

Shingles

D

Erythema nodosum

The principles of infection and its investigation and therapy are described in Chapter 6. This chapter and the following ones on human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) and sexually transmitted infection (STI) describe the approach to patients with potential infectious disease, the individual infections and the resulting syndromes.

PRESENTING PROBLEMS IN INFECTIOUS DISEASES

Infectious diseases present with myriad clinical manifestations. Many of these are described either in other chapters of this book or below.

Fever

'Fever' implies an elevated core body temperature of more than 38.0°C (p. 138). Fever is a response to cytokines and acute phase proteins (pp. 74 and 82) and occurs in infections and in non-infectious conditions.

Clinical assessment

The differential diagnosis is very broad so clinical features are used to guide the most appropriate investigations. The systematic approach described on pages 294–295 should be followed. Box 13.1 describes the assessment of elderly patients.

Investigations

If the clinical features do not suggest a specific infection, then initial investigations should include:

- a full blood count (FBC) with differential, including eosinophil count
- urea and electrolytes, liver function tests (LFTs), blood glucose and muscle enzymes
- inflammatory markers, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)
- a test for antibodies to HIV-1 (p. 392)
- autoantibodies, including antinuclear antibodies (ANA)
- chest X-ray and electrocardiogram (ECG)
- urinalysis and urine culture
- blood culture (p. 140)
- throat swab for culture
- other specimens, as indicated by history and examination, e.g. wound swab; sputum culture; stool culture, microscopy for ova and parasites, and *Clostridium difficile* toxin assay; if relevant, malaria films on 3 consecutive days or a malaria rapid diagnostic test (antigen detection, p. 355).

Subsequent investigations in patients with HIV-related (p. 396), immune-deficient (p. 301), nosocomial or travel-related (p. 309) pyrexia and in individuals with associated symptoms or signs of involvement of the respiratory, gastrointestinal or neurological systems are described elsewhere.

Management

Fever and its associated systemic symptoms can be treated with paracetamol, and by tepid sponging to cool the skin. Replacement of salt and water is important in patients with drenching sweats. Further management is focused on the underlying cause.

13.1 Fever in old age

- **Temperature measurement**: fever may be missed because oral temperatures are unreliable. Rectal measurement may be needed but core temperature is increasingly measured using eardrum reflectance.
- **Acute confusion**: common with fever, especially in those with underlying cerebrovascular disease or dementia.
- **Prominent causes of pyrexia of unknown origin**: include tuberculosis and intra-abdominal abscesses, complicated urinary tract infection and infective endocarditis. Non-infective causes include polymyalgia rheumatica/temporal arteritis and tumours. A smaller fraction of cases remain undiagnosed than in young people.
- **Pitfalls in the elderly**: conditions such as cerebrovascular accident or thromboembolic disease can cause fever but every effort must be made to exclude concomitant infection.
- **Common infectious diseases in the very frail** (e.g. nursing home residents): pneumonia, urinary infection, soft tissue infection and gastroenteritis.

Fever with localising symptoms or signs

In most patients, the site of infection is apparent after clinical evaluation (p. 294), and the likelihood of infection is reinforced by investigation results (e.g. neutrophilia with raised ESR and CRP in bacterial infections). Not all apparently localising symptoms are reliable, however; headache, breathlessness and diarrhoea can occur in sepsis without localised infection in the central nervous system (CNS), respiratory tract or gastrointestinal tract. Careful interpretation of the clinical features is vital (e.g. severe headache associated with photophobia, rash and neck stiffness suggests meningitis, whereas moderate headache with cough and rhinorrhoea is consistent with a viral upper respiratory tract infection).

Common infections that present with fever are shown in Figure 13.1. Further investigation and management are specific to the cause, but may include empirical antimicrobial therapy (p. 149) pending confirmation of the microbiological diagnosis.

Pyrexia of unknown origin

Pyrexia of unknown origin (PUO) is defined as a temperature persistently above 38.0°C for more than 3 weeks, without diagnosis, despite initial investigation during 3 days of inpatient care or after more than two outpatient visits. Subsets of PUO are described by medical setting: HIV-1 related, immune-deficient or nosocomial. Up to one-third of cases of PUO remain undiagnosed.

Clinical assessment

Major causes of PUO are outlined in Box 13.2. Rare causes, such as periodic fever syndromes (p. 85), should be considered in those with a positive family history. Children and younger adults are more likely to have infectious causes – in particular, viral infections. Older adults are more likely to have certain infectious and non-infectious causes (see Box 13.1). Detailed history and examination should be repeated at regular intervals

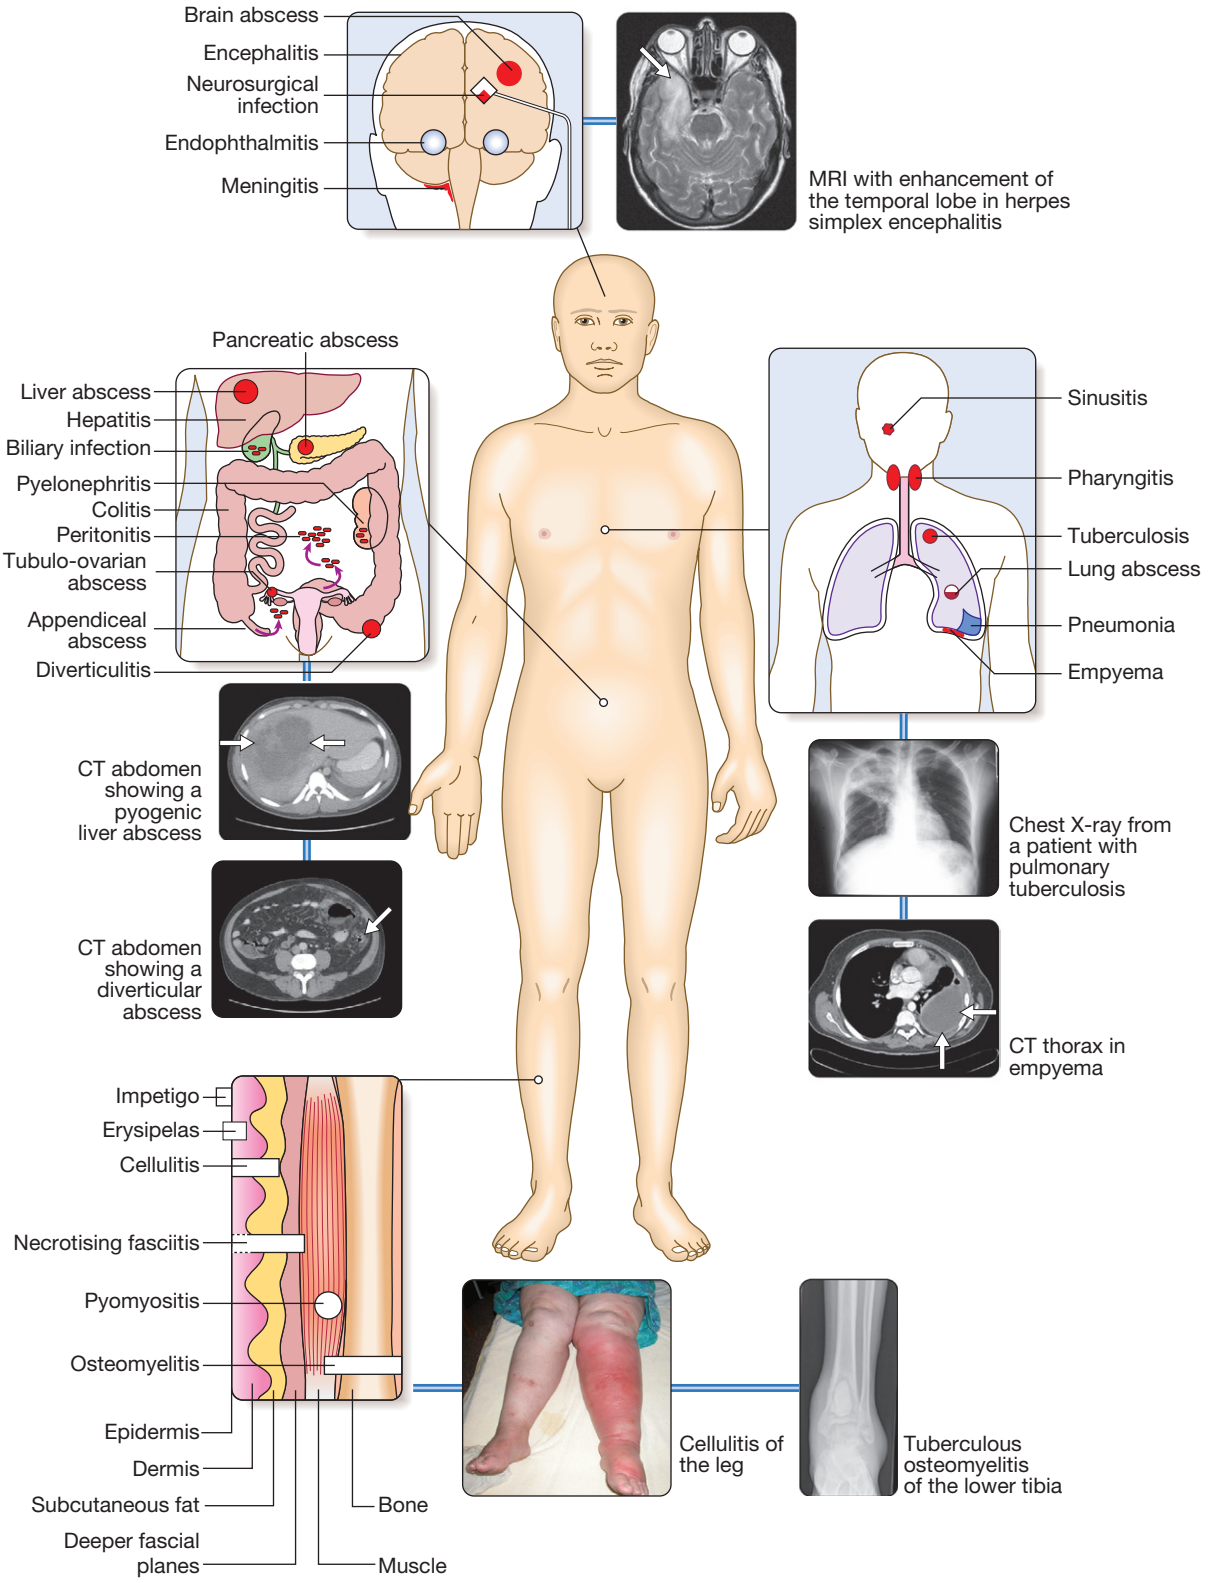


Fig. 13.1 Common infectious syndromes presenting with fever and localised features. Major causes are grouped by approximate anatomical location and include central nervous system infection; respiratory tract infections; abdominal, pelvic or urinary tract infections; and skin and soft tissue infections (SSTI) or osteomyelitis. For each site of infection, particular syndromes and their common causes are described elsewhere in the book. The causative organisms vary, depending on host factors, which include whether the patient has lived or resided in a tropical country or particular geographical location, has acquired the infection in a health-care environment or is immunocompromised.

13.2 Aetiology of pyrexia of unknown origin (PUO)

Infections (~30%)

Specific locations
- Abscesses: hepatobiliary*, diverticular*, urinary tract* (including prostate), pulmonary, CNS
- Infections of oral cavity (including dental), head and neck (including sinuses)
- Bone and joint infections
- Infective endocarditis*

Specific organisms
- Tuberculosis (particularly extrapulmonary)*
- HIV-1 infection
- Other viral infections (cytomegalovirus (CMV), Epstein–Barr virus (EBV))
- Fungal infections (e.g. *Aspergillus* spp., *Candida* spp. or dimorphic fungi)
- Infections with fastidious organisms (e.g. *Bartonella* spp., *Tropheryma whipplei*)

Specific patient groups
- Imported infections
  Malaria, dengue, rickettsial infections, *Brucella* spp., amoebic liver abscess, enteric fevers, *Leishmania* spp. (southern Europe, India, Africa and Latin America), *Burkholderia pseudomallei* (South-east Asia), HIV and respiratory tract infections
- Nosocomial infections
  Infections related to prosthetic materials and surgical procedures
- HIV-positive individuals
  Acute retroviral syndrome
  AIDS-defining infections (disseminated *Mycobacterium avium* complex (DMAC), *Pneumocystis jirovecii (carinii)* pneumonia, CMV and others)

Malignancy (~20%)

Haematological malignancy
- Lymphoma*, leukaemia and myeloma

Solid tumours
- Renal, liver, colon, stomach, pancreas, kidney

Connective tissue disorders (~15%)

Older adults
- Temporal arteritis/polymyalgia rheumatica*

Younger adults
- Still's disease (juvenile rheumatoid arthritis)*
- Systemic lupus erythematosus (SLE)
- Vasculitic disorders (including polyarteritis nodosa, rheumatoid disease with vasculitis and granulomatosis with polyangiitis (also known as Wegener's granulomatosis))
- Polymyositis
- Behçet's disease

Geographically restricted
- Rheumatic fever

Miscellaneous (~20%)

Cardiovascular
- Atrial myxoma, aortitis, aortic dissection

Respiratory
- Sarcoidosis, pulmonary embolism and other thromboembolic disease, extrinsic allergic alveolitis

Gastrointestinal
- Inflammatory bowel disease, granulomatous hepatitis, alcoholic liver disease, pancreatitis

Endocrine/metabolic
- Thyrotoxicosis, thyroiditis, hypothalamic lesions, phaeochromocytoma, adrenal insufficiency, hypertriglyceridaemia

Haematological
- Haemolytic anaemia, paroxysmal nocturnal haemoglobinuria, thrombotic thrombocytopenic purpura, myeloproliferative disorders, Castleman's disease, graft-versus-host disease (after allogeneic haematopoietic stem cell transplantation)

Inherited
- Familial Mediterranean fever and periodic fever syndromes

Drug reactions*
- e.g. Antibiotic fever, drug hypersensitivity reactions etc.

Factitious fever

Idiopathic (~15%)

*Most common causes within each group.

to detect emerging features (e.g. rashes, signs of infective endocarditis (p. 625) or features of vasculitis). In men, the prostate should be considered as a potential source of infection.

Clinicians should be alert to the possibility of factitious fever, in which high temperature recordings are engineered by the patient (Box 13.3).

Investigations

If initial investigation of fever (see above) is negative, a series of further microbiological and non-microbiological investigations should be considered (Boxes 13.4 and 13.5). These will usually include:
- induced sputum or other specimens for mycobacterial stains and culture
- serological tests
- imaging of the abdomen by ultrasonography or computed tomography (CT)
- echocardiography.

13.3 Clues to the diagnosis of factitious fever

- A patient who looks well
- Bizarre temperature chart with absence of diurnal variation and/or temperature-related changes in pulse rate
- Temperature > 41°C
- Absence of sweating during defervescence
- Normal ESR and CRP despite high fever
- Evidence of self-injection or self-harm
- Normal temperature during supervised (observed) measurement

Lesions identified on imaging should usually be biopsied in order to seek evidence of relevant pathogens by culture, histopathology or nucleic acid detection. The chance of a successful diagnosis is greatest if procedures for obtaining and transporting the correct samples in the appropriate media are carefully planned in advance;

13.4 Microbiological investigation of PUO

Microscopy

- Blood for atypical lymphocytes (EBV, CMV, HIV-1, hepatitis viruses or *Toxoplasma gondii*), trypanosomiasis, malaria, *Borrelia* spp.
- Respiratory samples for mycobacteria, fungi
- Stool for ova, cysts and parasites
- Biopsy for light microscopy (bacteria, mycobacteria, fungi, *Leishmania* and other parasites) and/or electron microscopy (viruses, protozoa (e.g. microsporidia) and other fastidious organisms (e.g. *T. whipplei*))
- Urine for white or red blood cells, schistosome ova, mycobacteria (early morning urine × 3)

Culture

- Aspirates and biopsies (e.g. joint, deep abscess, debrided tissues)
- Blood, including prolonged culture and special media conditions
- Sputum for mycobacteria
- Cerebrospinal fluid (CSF)
- Gastric aspirate for mycobacteria
- Stool
- Swabs
- Urine ± prostatic massage in older men

Antigen detection

- Blood, e.g. HIV p24 antigen, cryptococcal antigen, *Histoplasma* antigen (restricted availability) and *Aspergillus* galactomannan enzyme-linked immunosorbent assay (ELISA)
- CSF for cryptococcal antigen
- Bronchoalveolar lavage fluid for *Aspergillus* galactomannan
- Nasopharyngeal aspirate/throat swab for respiratory viruses
- Urine, e.g. for *Legionella* antigen

Nucleic acid detection

- Blood for *Bartonella* spp. and viruses
- CSF for viruses and key bacteria (meningococcus, pneumococcus)
- Nasopharyngeal aspirate/throat swab for respiratory viruses
- Bronchoalveolar lavage fluid, e.g. for respiratory viruses
- Tissue specimens, e.g. for *Tropheryma whipplei*
- Urine, e.g. for *Chlamydia trachomatis*, *Neisseria gonorrhoeae*
- Stool, e.g. for norovirus, rotavirus

Immunological tests

- Serology (antibody detection) for viruses, dimorphic fungi and some bacteria and protozoa
- Interferon-γ release assay for diagnosis of tuberculosis

Note This list does not apply to every patient with a PUO. Appropriate tests should be selected in a stepwise manner, according to specific predisposing factors, epidemiological exposures and local availability, and should be discussed with a microbiologist.

13.5 Additional investigations in PUO

Serological tests for connective tissue disorders

- Autoantibody screen
- Complement levels
- Immunoglobulins
- Cryoglobulins

Echocardiography

Ultrasound of abdomen

CT/MRI of thorax, abdomen and/or brain

Imaging of the skeletal system

- Plain X-rays
- CT/MRI spine
- Isotope bone scan

Labelled white cell scan

Positron emission tomography (PET)/single photon emission computed tomography (SPECT)

Biopsy

- Bronchoscopy and lavage ± transbronchial biopsy
- Lymph node aspirate or biopsy
- Biopsy of radiological lesion
- Biopsy of liver
- Bone marrow aspirate and biopsy
- Lumbar puncture
- Laparoscopy and biopsy
- Temporal artery biopsy

this requires discussion between the clinical team, the radiologist or surgeon performing the procedure, and the local microbiologist and histopathologist. Liver biopsy may be justified, e.g. to identify idiopathic granulomatous hepatitis, if there are biochemical or radiological abnormalities. Bone marrow biopsies have a diagnostic yield of up to 15%, most often revealing haematological malignancy, myelodysplasia or tuberculosis, and also identifying brucellosis, typhoid fever or visceral leishmaniasis. Bone marrow should be sent for culture, as well as microscopy. Laparoscopy is occasionally undertaken with biopsy of abnormal tissues. Splenic aspiration in specialist centres is the diagnostic test of choice for suspected visceral leishmaniasis. Temporal artery biopsy should be considered in patients over the age of 50 years, even in the absence of physical signs or a raised ESR. 'Blind' biopsy of other structures in the absence of localising signs, or laboratory or radiology results is unhelpful.

Prognosis

The overall mortality of PUO is 30–40%, mainly attributable to malignancy in older patients. If no cause is found, the long-term mortality is low and fever often settles spontaneously.

Fever in the injection drug-user

Intravenous injection of recreational drugs is widespread in many parts of the world (p. 240). Infective organisms are introduced by non-sterile (often shared) injection equipment (Fig. 13.2), and infection is facilitated by immunodeficiency due to malnutrition or the toxic effects of drugs. The risks increase with prolonged drug use and injection into large veins of the groin and neck because of progressive thrombosis of superficial peripheral veins. The most common causes of fever are soft tissue or respiratory infections.

Clinical assessment

The history should address the following risk factors:

- *Site of injection.* Femoral vein injection is associated with vascular complications such as deep venous thrombosis (50% of which are septic) and accidental arterial injection with false aneurysm formation or a compartment syndrome due to swelling within the fascial sheath. Local complications include iliopsoas abscess, and septic arthritis of the hip joint or sacroiliac joint. Injection of the jugular vein can be

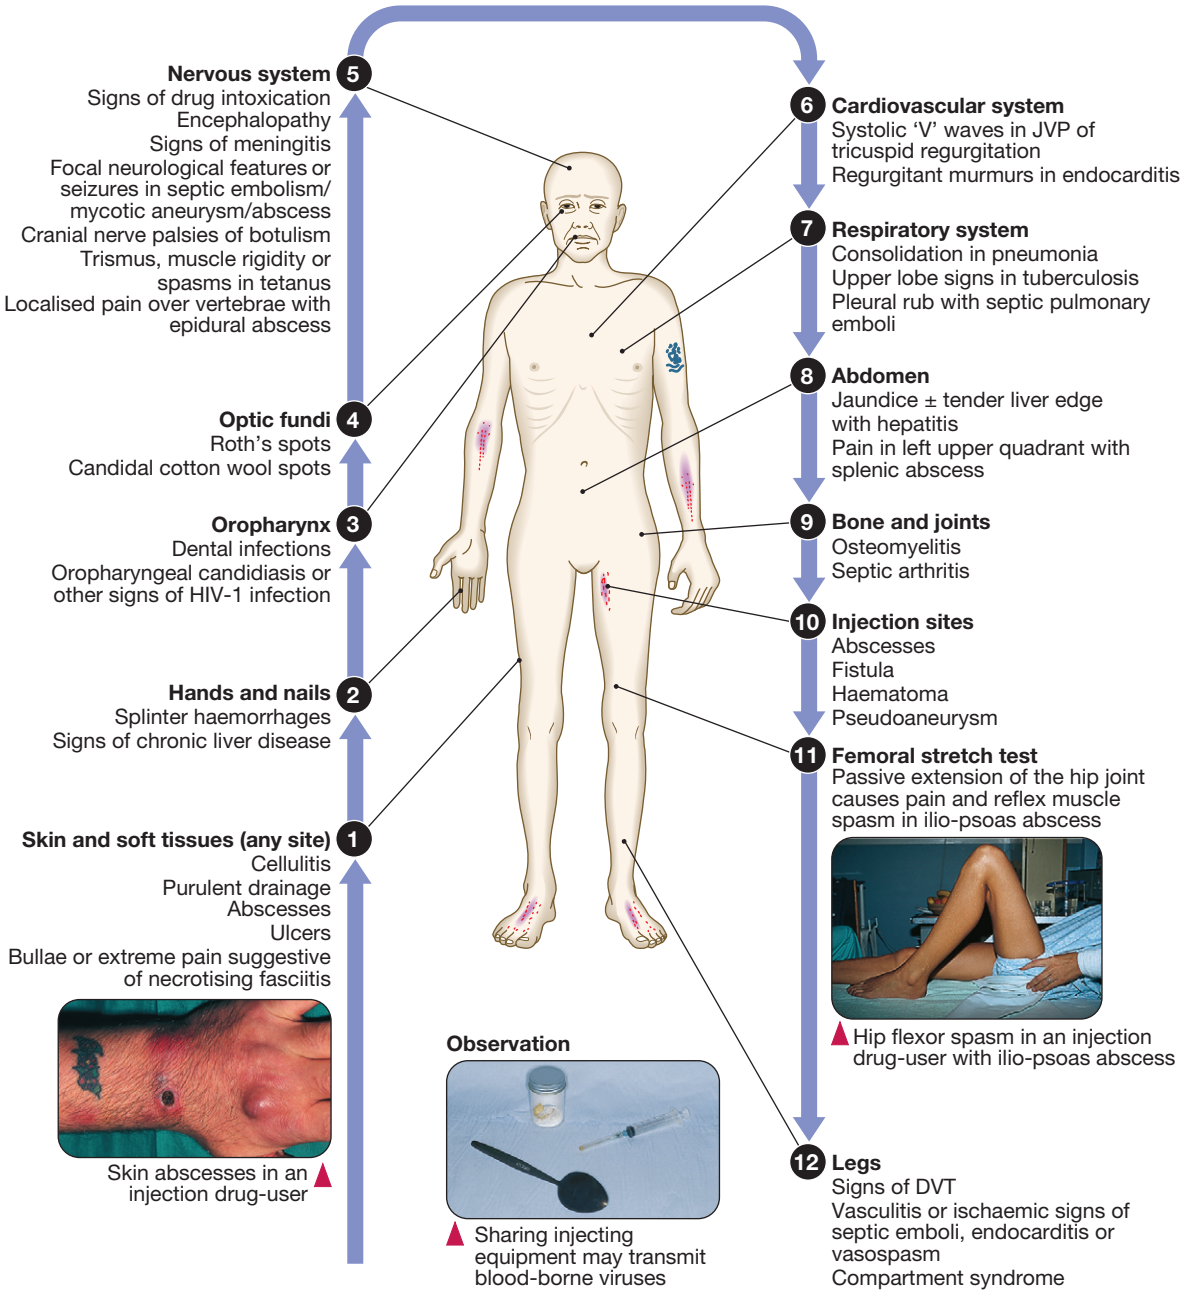

Fig. 13.2 Fever in the injection drug-user: key features of clinical examination. Full examination (p. 294) is required but features most common amongst injection drug-users are shown here. (DVT = deep venous thrombosis; JVP = jugular venous pulse)

associated with cerebrovascular complications. Subcutaneous and intramuscular injection has been related to infection by clostridial species, the spores of which contaminate heroin. *Clostridium novyi* causes a local lesion with significant toxin production, leading to shock and multi-organ failure. Tetanus, wound botulism and gas gangrene also occur.

- *Technical details of injection.* Sharing of needles and other injecting paraphernalia (including spoons and filters) greatly increases the risk of blood-borne virus infection (e.g. HIV-1, hepatitis B or C virus). Some users lubricate their needles by licking them prior to injection, thus introducing mouth organisms (e.g. anaerobic streptococci, *Fusobacterium* spp. and *Prevotella* spp). Contamination of commercially available lemon juice, used to dissolve heroin before injection, has been associated with blood-stream infection with *Candida* spp.
- *Substances injected.* Injection of cocaine is associated with a variety of vascular complications. Certain formulations of heroin have been linked with particular infections, e.g. wound botulism with black tar heroin. Drugs are often mixed with other substances, e.g. talc.
- *Blood-borne virus status.* Results of previous HIV-1 and hepatitis virus tests or vaccinations for hepatitis viruses should be recorded.

- *Surreptitious use of antimicrobials.* Addicts may use antimicrobials to self-treat infections, masking initial blood culture results.

Key findings on clinical examination are shown in Figure 13.2. It can be difficult to distinguish the effects of infection from the effects of drugs or drug withdrawal (excitement, tachycardia, sweating, marked myalgia, confusion). Stupor and delirium may result from drug administration but may also indicate meningitis or encephalitis. Non-infected venous thromboembolism is also common in this group.

Investigations

The initial investigations are as for any fever (see above), including a chest X-ray and blood cultures. Since blood sampling may be difficult, contamination is often a problem. Echocardiography to detect infective endocarditis should be performed in all injection drug-users with: bacteraemia due to *Staphylococcus aureus* or other organisms associated with endocarditis (Fig. 13.3A); thromboembolic phenomena; or a new or previously undocumented murmur. Endovascular infection should also be suspected if lung abscesses or pneumatocoeles are detected radiologically. Additional imaging should be focused on sites of injection or of localising symptoms and signs (Fig. 13.3B). Any pathological fluid collections should be sampled.

Urinary toxicology tests may suggest a non-infectious cause of the presenting complaint. While being investigated, all injection drug-users should be offered testing for infection with hepatitis B and C virus and HIV-1.

Microbiological results are crucial in guiding therapy. Injection drug-users may have more than one infection. Skin and soft tissue infections are most often due to *Staph. aureus* or streptococci, and sometimes to *Clostridium* spp. or anaerobes. Pulmonary infections are most often due to the common pathogens causing community-acquired pneumonia, tuberculosis or septic emboli (Fig. 13.3C). Endocarditis with septic emboli commonly involves *Staph. aureus* and viridans streptococci, but *Pseudomonas aeruginosa* and *Candida* spp. are also encountered.

Management

Empirical therapy of fever in the injection drug-user includes an antistaphylococcal penicillin (e.g. flucloxacillin) or, if meticillin-resistant *Staph. aureus* (MRSA) is prevalent in the community, a glycopeptide (e.g. vancomycin). Once a particular pathogen is identified, specific therapy is commenced, with modification when antimicrobial susceptibility is available. In injection drug-users, right-sided endocarditis due to *Staph. aureus* is customarily treated with high-dose intravenous flucloxacillin. In left-sided *Staph. aureus* endocarditis, aminoglycoside therapy may be added. Right-sided endocarditis caused by MRSA is usually treated with 4 weeks of vancomycin plus gentamicin for the first week. Specialist advice should be sought.

For localised infections of the skin and soft tissues, oral therapy with agents active against staphylococci, streptococci and anaerobes is appropriate (e.g. flucloxacillin plus co-amoxiclav or clindamycin). Non-adherence with prescribed antimicrobial regimens leads to a high rate of relapse for all infections in this patient group.

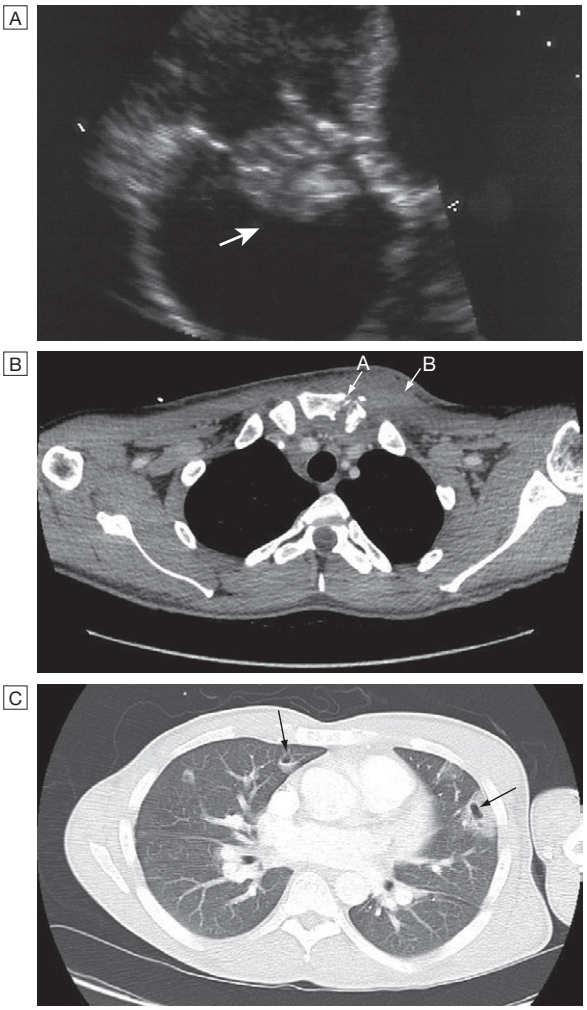

Fig. 13.3 Causes of fever in injection drug-users. **A** Endocarditis: large vegetation on the tricuspid valve (arrow). **B** Septic arthritis of the left sternoclavicular joint (arrow A) (note the erosion of the bony surfaces at the sternoclavicular joint) with overlying soft tissue collection (arrow B). **C** CT of the thorax showing *Staph. aureus* endocarditis of the tricuspid valve and haemoptysis, showing multiple embolic lesions with cavitation (arrows).

Fever in the immunocompromised host

Immunocompromised hosts include those with congenital immunodeficiency (p. 78), HIV infection (Ch. 14) and iatrogenic immunosuppression induced by chemotherapy (p. 276), transplantation (p. 95) or immunosuppressant medicines, including high-dose corticosteroids. Metabolic abnormalities, such as under-nutrition or hyperglycaemia, may also contribute. Multiple elements of the immune system are potentially compromised. A patient may have impaired neutrophil function from chemotherapy, impaired T-cell and/or B-cell responses due to underlying malignancy, T-cell and phagocytosis defects due to corticosteroids, mucositis from chemotherapy and an impaired skin barrier due to insertion of a central venous catheter.

Fever may result from infectious or from non-infectious causes, including drugs, vasculitis, neoplasm, organising pneumonitis, lymphoproliferative disease,

graft-versus-host disease (in recipients of haematopoietic stem cell transplants; p. 1017) or Sweet's syndrome (reddish nodules or plaques with fever and leucocytosis, in association with haematological malignancy).

Clinical assessment

The following should be addressed in the history:

- Identification of the immunosuppressant factors, and nature of the immune defect.
- Any past infections and their treatment. Infections may recur and antimicrobial resistance may have been acquired in response to prior therapy.
- Exposure to infections, including opportunistic infections that would not cause disease in an immunocompetent host.
- Prophylactic medicines and vaccinations administered.

Examination should include inspection of the normal physical barriers provided by skin and mucosal surfaces and, in particular, central venous catheters, the mouth, sinuses, ears and perianal area (digital rectal examination should be avoided). Disseminated infections can manifest as cutaneous lesions. The areas around fingernails and toenails should also be inspected closely.

Investigations

Initial screening tests are as described above (p. 296). Immunocompromised hosts often have decreased inflammatory responses leading to attenuation of physical signs, such as neck stiffness with meningitis, radiological features and laboratory findings, such as leucocytosis. Chest CT scan should be considered in addition to chest X-ray when respiratory symptoms occur. Abdominal imaging may also be warranted, particularly if there is right lower quadrant pain, which may indicate typhlitis (inflammation of the caecum) in neutropenic patients. Blood cultures from a central venous catheter, urine cultures, and stool cultures if diarrhoea is present are also recommended.

Nasopharyngeal aspirates are sometimes diagnostic, as immunocompromised hosts may shed respiratory viruses for prolonged periods. Skin lesions should be biopsied if nodules are present, and investigation should include fungal stains. Useful molecular techniques include polymerase chain reaction (PCR) for CMV and *Aspergillus* spp. DNA, and antigen assays (e.g. cryptococcal antigen (CrAg) for *Cryptococcus neoformans*, and galactomannan for *Aspergillus* spp. in blood or *Legionella pneumophila* type 1 in urine). Antibody detection is rarely useful in immunocompromised patients. Patients with respiratory signs or symptoms should be considered for bronchoscopy in order to obtain bronchoalveolar lavage fluid to detect pathogens, including *Pneumocystis jirovecii* (*carinii*), as well as bacteria, fungi and viruses.

Neutropenic fever

Neutropenic fever is strictly defined as a neutrophil count of less than 0.5×10^9/L (p. 1004) and a single axillary temperature above 38.5°C or three recordings above 38.0°C over a 12-hour period, although the infection risk increases progressively as the neutrophil count drops below 1.0×10^9/L. Patients with neutropenia are particularly prone to bacterial or fungal infection. Gram-positive organisms are the most common pathogens, particularly in association with in-dwelling catheters.

EBM 13.6 Treatment of neutropenic fever

'Broad spectrum β-lactam monotherapy is as effective as β-lactam-aminoglycoside combination therapy for neutropenic fever in many settings.'

- Paul M, et al. BMJ 2003; 326:1111.
- Del Favero A, et al. Clin Infect Dis 2001; 33:1295–1301.

Empirical broad-spectrum antimicrobial therapy is commenced as soon as neutropenic fever occurs and cultures have been obtained. The most common regimens for neutropenic sepsis are broad-spectrum penicillins, such as piperacillin–tazobactam IV. Although aminoglycosides are commonly used in combination, routine use is not supported by trial data (Box 13.6). If fever has not resolved after 3–5 days, empirical antifungal therapy (e.g. caspofungin) is added (p. 159). An alternative antifungal strategy is to use azole prophylaxis in high-risk patients and markers of early fungal infection, such as galactomannan antigen, to guide initiation of antifungal treatment (a 'pre-emptive approach').

Post-transplantation fever

Fever in transplant recipients may be due to infection, episodes of graft rejection in solid organ transplant recipients, or graft-versus-host disease following haematopoietic stem cell transplantation (HSCT; p. 1017).

Infections in solid transplant recipients are grouped according to the time of onset (Box 13.7). Those in the first month are related to the underlying condition or surgical complications. Those occurring 1–6 months after transplantation are characteristic of impaired T-cell function. Risk factors for CMV infection have

13.7 Infections in transplant recipients

Time post-transplantation	Infections
Solid organ recipients	
0–1 mth	Bacterial or fungal infections related to the underlying condition or surgical complications
1–6 mths	CMV, other opportunistic infections (e.g. *Pneumocystis jirovecii* pneumonia)
> 6 mths	Bacterial pneumonia, other bacterial community-acquired infections, shingles, cryptococcal infection, PTLD
Myeloablative haematopoietic stem cell transplant recipients	
Pre-engraftment (typically 0–4 wks)	Bacterial and fungal infections, respiratory viruses or HSV reactivation
Post-engraftment	
Early (< 100 days)	CMV, *Pneumocystis jirovecii* pneumonia, moulds or other opportunistic infections
Late (> 100 days)	Community-acquired bacterial infections, shingles, CMV, PTLD

(CMV = cytomegalovirus; HSV = herpes simplex virus; PTLD = post-transplant lymphoproliferative disorder)

been identified and patients commonly receive either prophylaxis or intensive monitoring involving regular testing for CMV DNA by PCR and early initiation of anti-CMV therapy using intravenous ganciclovir or oral valganciclovir if tests become positive.

Following HSCT, infections in the first 4 weeks are more common in patients receiving a myeloablative conditioning regimen (see Box 13.7). Later infections are more common if an allogeneic procedure is performed.

Post-transplant lymphoproliferative disorder (PTLD) is an Epstein–Barr virus (EBV)-associated lymphoma that can complicate transplantation, particularly when primary EBV infection occurs after transplantation.

Positive blood culture

Blood-stream infection (BSI) or bacteraemia is a frequent presentation of infection. This can be community-acquired or may arise in hospital ('nosocomial'). The most common causes are shown in Box 13.8. In immunocompromised hosts, a wider range of microorganisms may be isolated, e.g. fungi in neutropenic hosts.

Primary bacteraemia refers to cases in which the site of infection is unknown; this applies in approximately 10% of community-acquired cases and approximately 30% of nosocomial cases, and is more common in *Staph. aureus* bacteraemias. In community-acquired *Staph. aureus* bacteraemia, 20–30% of cases are associated with infectious endocarditis and up to 10% are due to osteomyelitis. Peripheral and central venous catheters are an important source of nosocomial BSI.

BSI has an associated mortality of 15–40%, depending on the setting, host and microbial factors.

Clinical assessment

The history should determine the setting in which BSI has occurred. Host factors predisposing to infection include skin disease, diabetes mellitus, injection drug use, the presence of a central venous, urinary or haemodialysis catheter, and surgical procedures, especially those involving the implantation of prosthetic materials (in particular, endovascular prostheses).

Physical examination should focus on signs of endocarditis (p. 625), evidence of bone or joint infection (tenderness or restriction of movement), and abdominal or flank tenderness. Central venous catheters should be examined for erythema or purulence at the exit site. Particularly in cases with *Candida* spp. infection or suspected infectious endocarditis, fundoscopy after pupil dilatation should be performed.

Investigations

Positive blood cultures may be caused by contaminants. When isolated from only one bottle, or from all bottles from one venesection, coagulase-negative staphylococci often represent contamination. Repeated isolation of this organism, however, should raise suspicion of infective endocarditis or, in a patient with any form of prosthetic material, prosthesis infection. Viridans streptococci occasionally cause transient non-significant bacteraemia or blood culture contamination but, in view of their association with infective endocarditis, significant infection must always be sought clinically. *Bacillus* spp. ('aerobic spore bearers') and *Clostridium* spp. often represent incidental transient bacteraemia or contamination, but certain species (e.g. *C. septicum*) may be genuine pathogens.

13.8 Common causes of blood-stream infection

Community-acquired	
• *Staph. aureus*, including MRSA	• Other streptococci
• *Streptococcus pneumoniae*	• *Escherichia coli*
Nosocomial	
• *Staph. aureus*, including MRSA	• Enterococci, including VRE
• Coagulase-negative staphylococci	• Gram-negative bacteria
	• *Candida* spp.

(MRSA = meticillin-resistant *Staph. aureus*; VRE = vancomycin-resistant enterococci)

Further investigations are influenced by the causative organism and setting. Initial screening tests are similar to those for fever (p. 296) and should include chest X-ray, urine culture and, in many cases, ultrasound or other imaging of the abdomen. Imaging should also include any areas of bone or joint pain and any prosthetic material, e.g. a prosthetic joint or an aortic graft.

Echocardiography should be considered for those patients with BSI who have valvular heart disease or clinical features of endocarditis (p. 625), those whose cultures reveal an organism that is a common cause of endocarditis (e.g. *Staph. aureus*, viridans streptococci or enterococci), those in whom multiple blood cultures are positive for the same organism, and those with rapid positive result on culture. The sensitivities of transthoracic echocardiography (TTE) and transoesophageal echocardiography (TOE) for the detection of vegetations are 50–90% and over 95%, respectively. Therefore, if TTE is negative, TOE should be performed (Box 18.115, p. 627).

Certain rare causes of BSI have specific associations that warrant further investigation. *Strep. bovis* (biotype I, *Strep. gallolyticus*) endocarditis and *C. septicum* BSI are both associated with colonic carcinoma and their isolation is an indication for colonoscopy.

Management

BSI requires antimicrobial therapy and attention to the source of infection, including surgical drainage if appropriate. Two weeks of therapy may be sufficient for *Staph. aureus* BSI from central and peripheral venous catheter infections when the source is identified and removed, for uncomplicated skin and soft tissue infections, and for uncomplicated right-sided infective endocarditis. Other *Staph. aureus* BSIs are usually treated for 4–6 weeks.

Central venous catheter infections

Infections of central venous catheters typically involve the catheter lumen and are associated with fever, positive blood cultures and, in some cases, signs of purulence or exudate at the site of insertion. Infection is more common in temporary catheters inserted into the groin or jugular vein than those in the subclavian vein. Tunnelled catheters, e.g. Hickman catheters, may also develop tunnel site infections.

Staphylococci account for 70–90% of catheter infections, with coagulase-negative staphylococci more

common than *Staph. aureus*. Other causes include enterococci and Gram-negative bacilli. Unusual Gram-negative organisms, such as *Citrobacter freundii* and *Pseudomonas fluorescens*, cause pseudo-outbreaks and raise the possibility of non-sterile infusion equipment or infusate. *Candida* spp. are a common cause of line infections, particularly in association with total parenteral nutrition. Non-tuberculous mycobacteria may cause tunnel infections.

Investigations and management

In bacteraemic patients with fever and no other obvious source of infection, a catheter infection is likely. Local evidence of erythema, purulence or thrombophlebitis supports the diagnosis. However, microbiological confirmation is essential (p. 140). Catheter-related infection is suggested by higher colony counts or shorter time to positivity in blood cultures obtained through the catheter than in peripheral blood cultures. If the line is removed, a semi-quantitative culture of the tip should confirm the presence of 15 or more colony-forming units, but this is retrospective and does not detect luminal infection.

For coagulase-negative staphylococcal line infections, the options are to remove the line or, particularly in the case of tunnelled catheters, to treat empirically with a glycopeptide antibiotic, e.g. vancomycin, with or without the use of antibiotic-containing lock therapy to the catheter for approximately 14 days. For *Staph. aureus* infection, the chance of curing an infection with the catheter in situ is low and the risks from infection are high. Therefore, unless the risks of catheter removal outweigh the benefits, treatment involves catheter removal, followed by 14 days of antimicrobial therapy; the same applies to infections with *Candida* spp. or *Bacillus* spp.

Infection prevention is a key component of the management of vascular catheters. Measures include strict attention to hand hygiene, optimal siting, full aseptic technique on insertion and subsequent interventions, skin antisepsis with chlorhexidine and isopropyl alcohol, daily assessment of catheter sites (e.g. with visual infusion phlebitis (VIP) score (p. 330)), and daily consideration of the continuing requirement for catheterisation. The use of catheters impregnated with antimicrobials such as chlorhexidine or silver is advocated in some settings.

Sepsis

Sepsis is discussed on page 200. It describes patients with evidence of infection and signs of the systemic inflammatory response syndrome (SIRS), which entails two of: temperature over 38°C or under 36°C; pulse rate more than 90 beats per minute; respiratory rate over 20 breaths per minute or PCO_2 below 4.3 kPa (32.5 mmHg); and white blood cell count over 12 or below 4×10^9/L (Box 8.2, p. 184). Septic shock describes sepsis plus hypotension (systolic blood pressure below 90 mmHg systolic or a fall of more than 40 mmHg from baseline that is not responsive to fluid challenge or due to another cause). It may be complicated by multi-organ failure and requires intensive care unit admission.

Sepsis largely results from host responses to microbial lipopolysaccharide, peptidoglycans, lipoproteins or

13.9 Causes of sepsis

Infection	Setting
Bacterial	
Staph. aureus, coagulase-negative staphylococci	Bacteraemia may be associated with endocarditis, intravascular cannula infection, or skin or bone foci
Streptococcus pneumoniae	Invasive pneumococcal disease, usually with pneumonia or meningitis
Other streptococci	Invasive streptococcal disease, especially necrotising fasciitis Viridans streptococci in neutropenic host with severe mucositis
Staphylococcal or streptococcal toxic shock syndrome	Toxin-mediated, blood cultures negative; clues include erythrodermic rash and epidemiological setting
Enterococci	Most often with abdominal focus
Neisseria meningitidis	Sepsis in children or young adults with petechial rash and/or meningitis
E. coli, other Gram-negative bacteria	Urinary or biliary tract infection, or other abdominal infections
Pseudomonas aeruginosa, multidrug-resistant Gram-negative bacteraemia	Nosocomial infection
Yersinia pestis	In plague
Burkholderia pseudomallei	Endemic in areas of Thailand; more likely to involve patients with diabetes mellitus or immunocompromised
Capnocytophaga canimorsus	Associated with dog bites and asplenic individuals
C. difficile	Severe colitis, particularly in the elderly
Polymicrobial infection with Gram-negatives and anaerobes	Bowel perforation
Mycobacterium tuberculosis, *M. avium complex* (MAC)	HIV-positive or immunocompromised with miliary TB or disseminated MAC
Fungal	
Candida spp.	Line infection or post-operative complication, nosocomial or immunocompromised host
Histoplasma capsulatum, other dimorphic fungi	Immunocompromised host
Parasitic	
Falciparum malaria	Malaria with high-level parasitaemia and multi-organ failure or as a complication of bacterial superinfection
Babesia microti	Asplenic individual
Strongyloides stercoralis hyperinfection syndrome	Gram-negative infection complicating *Strongyloides* infection in immunocompromised host

superantigens, and there are many infectious causes (Box 13.9). The results of blood cultures and known host factors guide initial investigations. Patients who are immunocompromised may have a broader range of causal pathogens which may be harder to culture, including mycobacteria and fungi. In any individual who has recently visited the tropics, malaria must also be considered.

Severe skin and soft tissue infections

Skin and soft tissue infections (SSTIs) are an important cause of sepsis. Cases can be classified as in Box 13.10, according to the clinical features and microbiological findings. In some cases, severe systemic features may be out of keeping with mild local features.

Necrotising fasciitis

In necrotising fascitis, cutaneous erythema and oedema progress to bullae or areas of necrosis. Unlike in cellulitis, pain may be disproportionately intense in relation to the visible cutaneous features. The infection spreads quickly along the fascial plane. Type 1 necrotising fasciitis is a mixed infection with Gram-negative bacteria and anaerobes, often seen post-operatively in diabetic or immunocompromised hosts. Subcutaneous gas may be present. Type 2 necrotising fasciitis is caused by group A or other streptococci. Approximately 60% of cases are associated with streptococcal toxic shock syndrome (p. 331).

Necrotising fasciitis is a medical emergency, requiring immediate surgical débridement with inspection of the involved muscle groups, in addition to antimicrobial therapy (Fig. 13.4). Empiric treatment is with broad-spectrum agents (e.g. piperacillin–tazobactam plus clindamycin and ciprofloxacin; meropenem monotherapy; or third-generation cephalosporin plus metronidazole). Hyperbaric oxygen therapy may be considered for polymicrobial infection. Group A streptococcal infection is treated with benzylpenicillin plus clindamycin, and often immunoglobulin.

Gas gangrene

Although *Clostridium* spp. may colonise or contaminate wounds, no action is required unless there is evidence of spreading infection. Infection may be limited to tissue that is already damaged (anaerobic cellulitis) or involve healthy muscle (gas gangrene).

In anaerobic cellulitis, usually that due to *C. perfringens* or to other strains infecting devitalised tissue following a wound, gas forms locally and extends along tissue planes but bacteraemia does not occur. Prompt surgical débridement of devitalised tissue and therapy with penicillin or clindamycin is usually effective.

Gas gangrene (clostridial myonecrosis) is defined as acute invasion of healthy living muscle undamaged by previous trauma, and is most commonly caused by *C. perfringens*. In at least 70% of cases, it follows deep penetrating injury sufficient to create an anaerobic (ischaemic) environment and allow clostridial introduction and proliferation. Severe pain at the site of the injury progresses rapidly over 18–24 hours. Skin colour changes from pallor to bronze/purple discoloration and the skin is tense, swollen, oedematous and exquisitely tender. Gas in tissues may be obvious, with crepitus on clinical examination, or visible on X-ray, CT or ultrasound. Signs of systemic toxicity develop rapidly, with high leucocytosis, multi-organ dysfunction, raised creatine kinase and evidence of disseminated intravascular coagulation and haemolysis. Antibiotic therapy with high-dose intravenous penicillin and clindamycin is recommended, coupled with aggressive surgical débridement of the affected tissues. Alternative agents include cephalosporins and metronidazole. Hyperbaric oxygen has a putative but controversial role.

Other SSTIs

'Synergistic gangrene' is a combined infection with anaerobes and other bacteria (*Staph. aureus* or Gram-negatives). When this affects the genital/perineal area, it is known as 'Fournier's gangrene'. Severe gangrenous cellulitis in immunocompromised hosts may involve Gram-negative bacteria or fungi. *Entamoeba histolytica* can cause soft tissue necrosis following abdominal surgery in areas of the world where infection is common. Contact with shellfish in tropical areas and regions such as the Gulf of Mexico can lead to infection with *Vibrio vulnificus*, which causes soft tissue necrosis and bullae. Patients with chronic liver disease are particularly susceptible.

13.10 Severe necrotising soft tissue infections

- Necrotising fasciitis (primarily confined to subcutaneous fascia and fat)
- Clostridial anaerobic cellulitis (confined to skin and subcutaneous tissue)
- Non-clostridial anaerobic cellulitis
- Progressive bacterial synergistic gangrene (*Staph. aureus* + micro-aerophilic streptococcus) ('Meleney's gangrene', primarily confined to skin)
- Pyomyositis (discrete abscesses within individual muscle groups)
- Clostridial myonecrosis (gas gangrene)
- Anaerobic streptococcal myonecrosis (non-clostridial infection mimicking gas gangrene)
- Group A streptococcal necrotising myositis

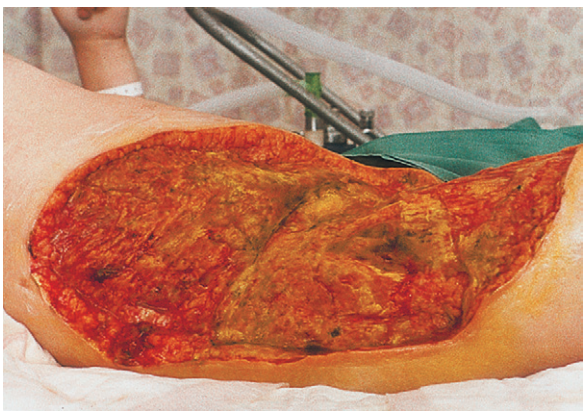

Fig. 13.4 Excision following necrotising fasciitis in an injection drug-user.

Acute diarrhoea and vomiting

Acute diarrhoea (p. 857), sometimes with vomiting, is the predominant symptom in infective gastroenteritis (Box 13.11). Acute diarrhoea may also be a symptom of other infectious and non-infectious diseases (Box 13.12). Stress, whether psychological or physical, can also produce loose stools.

The World Health Organization (WHO) estimates that there are more than 1000 million cases of acute diarrhoea annually in developing countries, with 3–4 million deaths, half of these in infants and children. In developed countries, diarrhoea remains an important problem and the elderly are most vulnerable (Box 13.13). The majority of episodes are due to infections spread by the faecal–oral route and transmitted either on fomites, on contaminated hands, or in food or water. Measures such as the provision of clean drinking water, appropriate disposal of human and animal sewage, and the application of simple principles of food hygiene can all limit gastroenteritis.

The clinical features of food-borne gastroenteritis vary. Some organisms (*Bacillus cereus*, *Staph. aureus* and *Vibrio cholerae*) elute exotoxins which cause vomiting and/or so-called 'secretory' diarrhoea (watery diarrhoea without blood or faecal leucocytes, reflecting small bowel dysfunction). In general, the time from ingestion to the onset of symptoms is short and, other than dehydration, little systemic upset occurs. Other organisms, such as *Shigella* spp., *Campylobacter* spp. and enterohaemorrhagic *E. coli* (EHEC), may directly invade the mucosa of the small bowel or produce cytotoxins that cause mucosal ulceration, typically affecting the terminal small bowel and colon. The incubation period is longer and more systemic upset occurs, with prolonged bloody diarrhoea. *Salmonella* spp. are capable of invading enterocytes, and of causing both a secretory response and invasive disease with systemic features. This is seen with *Salmonella typhi* and *S. paratyphi* (enteric fever), and, in the immunocompromised host, with non-typhoidal *Salmonella* spp.

13.11 Causes of infectious gastroenteritis

Toxin in food: < 6 hrs incubation

- *Bacillus cereus* (p. 341)
- *Staph. aureus* (p. 341)
- *Clostridium* spp. enterotoxin (p. 342)

Bacterial: 12–72 hrs incubation

- Enterotoxigenic *E. coli* (ETEC, p. 342)
- Shiga toxin-producing *E. coli* (EHEC, p. 343)*
- Enteroinvasive *E. coli* (EIEC, p. 342)*
- *Vibrio cholerae* (p. 344)
- *Salmonella* (p. 342)
- *Shigella** (p. 345)
- *Campylobacter** (p. 342)
- *C. difficile** (p. 343)

Viral: short incubation

- Rotavirus (p. 327)
- Norovirus (p. 327)

Protozoal: long incubation

- Giardiasis (p. 368)
- *Cryptosporidium* (pp. 369 and 399)
- Microsporidiosis (p. 399)
- Amoebic dysentery (p. 367)*
- Isosporiasis (p. 399)

*Associated with bloody diarrhoea.

Clinical assessment

The history should address foods ingested (Box 13.14), duration and frequency of diarrhoea, presence of blood or steatorrhoea, abdominal pain and tenesmus, and whether other people have been affected. Fever and bloody diarrhoea suggest an invasive, colitic, dysenteric process. An incubation period of less than 18 hours suggests toxin-mediated food poisoning, and longer than 5 days suggests diarrhoea caused by protozoa or helminths. Person-to-person spread suggests certain infections, such as shigellosis or cholera.

Examination includes assessment of the degree of dehydration by skin turgor, pulse and blood pressure measurement. The urine output and ongoing stool losses should be monitored.

13.12 Differential diagnosis of acute diarrhoea and vomiting

Infectious causes

- Gastroenteritis
- *C. difficile* infection (p. 343)
- Acute diverticulitis (p. 916)
- Sepsis (p. 304)
- Pelvic inflammatory disease (p. 418)
- Meningococcaemia (p. 1201)
- Pneumonia (especially 'atypical disease', p. 682)
- Malaria (p. 353)

Non-infectious causes

Gastrointestinal

- Inflammatory bowel disease (p. 897)
- Bowel malignancy (p. 910)
- Overflow from constipation (p. 917)
- Enteral tube feeding

Metabolic

- Diabetic ketoacidosis (p. 811)
- Thyrotoxicosis (p. 740)
- Uraemia (p. 483)
- Neuroendocrine tumours releasing (e.g.) VIP or 5-HT

Drugs and toxins

- NSAIDs
- Cytotoxic agents
- Antibiotics
- Proton pump inhibitors
- Dinoflagellates (p. 308)
- Plant toxins (p. 308)
- Heavy metals (p. 308)
- Ciguatera fish poisoning (p. 308)
- Scombrotoxic fish poisoning (p. 308)

(5-HT = 5-hydroxytryptamine, serotonin; NSAID = non-steroidal anti-inflammatory drugs; VIP = vasoactive intestinal peptide)

13.13 Infectious diarrhoea in old age

- **Incidence**: not increased but the impact is greater.
- **Mortality**: most deaths due to gastroenteritis in the developed world are in adults aged over 70. Most are presumed to be caused by dehydration leading to organ failure.
- ***C. difficile* infection (CDI)**: more common, especially in hospital and nursing home settings, usually following antibiotic exposure.

13.14 Foods associated with infectious illness, including gastroenteritis

Raw seafood	
• Norovirus • *Vibrio* spp.	• Hepatitis A
Raw eggs	
• *Salmonella* spp.	
Undercooked meat or poultry	
• *Salmonella* spp. • *Campylobacter* spp.	• EHEC • *C. perfringens*
Unpasteurised milk or juice	
• *Salmonella* spp. • *Campylobacter* spp.	• EHEC • *Y. enterocolitica*
Unpasteurised soft cheeses	
• *Salmonella* spp. • *Campylobacter* spp. • ETEC	• *Y. enterocolitica* • *L. monocytogenes*
Home-made canned goods	
• *C. botulinum*	
Raw hot dogs, pâté	
• *L. monocytogenes*	

13.15 Composition of oral rehydration solution and other replacement fluids*

Fluid	Na	K	Cl	Energy
WHO	90	20	80	54
Dioralyte	60	20	60	71
Pepsi®	6.5	0.8	–	400
7UP®	7.5	0.2	–	320
Apple juice	0.4	26	–	480
Orange juice	0.2	49	–	400
Breast milk	22	36	28	670

*mmol/L for electrolyte and kcal/L for energy components.

Investigations

These include stool inspection for blood and microscopy for leucocytes, and also an examination for ova, cysts and parasites if the history indicates former tropical residence or travel. Stool culture should be performed and *C. difficile* toxin sought. FBC and serum electrolytes indicate the degree of inflammation and dehydration. In a malarious area, a blood film for malaria parasites should be obtained. Blood and urine cultures and a chest X-ray may identify alternative sites of infection, particularly if the clinical features suggest a syndrome other than gastroenteritis.

Management

All patients with acute, potentially infective diarrhoea should be appropriately isolated to minimise person-to-person spread of infection. If the history suggests a food-borne source, public health measures must be implemented to identify the source and to establish whether other linked cases exist (p. 147).

Fluid replacement

Replacement of fluid losses in diarrhoeal illness is crucial and may be life-saving.

Although normal daily fluid intake in an adult is only 1–2 L, there is considerable additional fluid movement in and out of the gut in secretions (Fig. 22.7, p. 843). Altered gut resorption with diarrhoea can result in substantial fluid loss, e.g. 10–20 L of fluid may be lost in 24 hours in cholera. The fluid lost in diarrhoea is isotonic, so both water and electrolytes need to be replaced. Absorption of electrolytes from the gut is an active process requiring energy. Infected mucosa is capable of very rapid fluid and electrolyte transport if carbohydrate is available as an energy source. Oral rehydration solutions (ORS) therefore contain sugars, as well as water and electrolytes (Box 13.15). ORS can be just as effective as intravenous replacement fluid, even in the management of cholera. In mild to moderate gastroenteritis, adults should be encouraged to drink fluids and, if possible, continue normal dietary food intake. If this is impossible, e.g. due to vomiting, intravenous fluid administration will be required. In very sick patients, or those with cardiac or renal disease, monitoring of urine output and central venous pressure may be necessary.

The volume of fluid replacement required should be estimated based on the following considerations.

- *Replacement of established deficit*. After 48 hours of moderate diarrhoea (6–10 stools per 24 hours), the average adult will be 2–4 L depleted from diarrhoea alone. Associated vomiting will compound this. Adults with this symptomatology should therefore be given rapid replacement of 1–1.5 L, either orally (ORS) or by intravenous infusion (normal saline), within the first 2–4 hours of presentation. Longer symptomatology or more persistent/severe diarrhoea rapidly produces fluid losses comparable to diabetic ketoacidosis and is a metabolic emergency requiring active intervention.
- *Replacement of ongoing losses*. The average adult's diarrhoeal stool accounts for a loss of 200 mL of isotonic fluid. Stool losses should be carefully charted and an estimate of ongoing replacement fluid calculated. Commercially available rehydration sachets are conveniently produced to provide 200 mL of ORS; one sachet per diarrhoea stool is an appropriate estimate of supplementary replacement requirements.
- *Replacement of normal daily requirement*. The average adult has a daily requirement of 1–1.5 L of fluid in addition to the calculations above. This will be increased substantially in fever or a hot environment.

Antimicrobial agents

In non-specific gastroenteritis, antibiotics have been shown to shorten symptoms by only 1 day in an illness usually lasting 1–3 days. This benefit, when related to the potential for the development of antimicrobial resistance or side-effects, does not justify treatment, except if there is systemic involvement, a host with immunocompromise or significant comorbidity.

Evidence suggests that, in EHEC infections, the use of antibiotics may make the complication of haemolytic uraemic syndrome (HUS; p. 495) more likely due to

increased toxin release. Antibiotics should therefore not be used in this condition.

Conversely, antibiotics are indicated in *Sh. dysenteriae* infection and in invasive salmonellosis – in particular, typhoid fever. Antibiotics may also be advantageous in cholera epidemics, reducing infectivity and controlling the spread of infection.

Antidiarrhoeal, antimotility and antisecretory agents

These agents are not usually recommended in acute infective diarrhoea. Loperamide, diphenoxylate and opiates are potentially dangerous in dysentery in childhood, causing intussusception. Antisecretory agents, such as bismuth and chlorpromazine, may be effective but can cause significant sedation. They do not reduce stool fluid losses, although the stools may appear more bulky. Adsorbents, such as kaolin or charcoal, have little effect.

Non-infectious causes of food poisoning

Whilst acute food poisoning and gastroenteritis are most frequently caused by bacteria or their toxins, a number of non-infectious causes must be considered in the differential diagnosis.

Plant toxins

Legumes and beans produce oxidants which are toxic to people with glucose-6-phosphate dehydrogenase (G6PD) deficiency (p. 1029). Consumption produces headache, nausea and fever, progressing to potentially severe haemolysis, haemoglobinuria and jaundice (favism). Red kidney beans, if incompletely cooked, cause acute abdominal pain and diarrhoea from their lectin content. Adequate cooking abolishes this.

Alkaloids develop in potato tubers exposed to light, causing green discoloration. Ingestion induces acute vomiting and anticholinesterase-like activity.

Fungi and mushrooms of the *Psilocybe* spp. produce hallucinogens. Many fungal species induce a combination of gastroenteritis and cholinergic symptoms of blurred vision, salivation, sweating and diarrhoea. *Amanita phalloides* ('death cap') causes acute abdominal cramps and diarrhoea, followed by inexorable hepatorenal failure, often fatal.

Chemical toxins

Paralytic shellfish toxin

Saxitoxin from dinoflagellates, responsible for 'red tides', is concentrated in bivalve molluscs, e.g. mussels, clams, oysters, cockles and scallops. Consumption produces gastrointestinal symptoms within 30 minutes, followed by perioral paraesthesia and even respiratory paralysis. The UK water authorities ban the harvesting of molluscs at times of the year associated with excessive dinoflagellate numbers.

Ciguatera fish poisoning

Warm-water coral reef fish acquire ciguatoxin from dinoflagellates in their food chain. Consumption produces gastrointestinal symptoms 1–6 hours later, with associated paraesthesiae of the lips and extremities, distorted temperature sensation, myalgia and progressive flaccid paralysis. Autonomic dysfunction with hypotension may occur. In the South Pacific and Caribbean, there are 50 000 cases per year, with a case fatality of 0.1%. The gastrointestinal symptoms resolve rapidly but the neuropathic features may persist for months.

Scombrotoxic fish poisoning

Under poor storage conditions, histidine in scombroid fish – tuna, mackerel, bonito, skipjack and the canned dark meat of sardines – may be converted by bacteria to histamine and other chemicals. Consumption produces symptoms within minutes, with flushing, burning, sweating, urticaria, pruritus, headache, colic, nausea and vomiting, diarrhoea, bronchospasm and hypotension. Management is with salbutamol and antihistamines. Occasionally, intravenous fluid replacement is required.

Heavy metals

Thallium and cadmium can cause acute vomiting and diarrhoea resembling staphylococcal enterotoxin poisoning.

Antimicrobial-associated diarrhoea

Antimicrobial-associated diarrhoea (AAD) is a common complication of antimicrobial therapy, especially with broad-spectrum agents. It is most common in the elderly but can occur at all ages. Although the specific mechanism is unknown in most AAD, *C. difficile* is implicated in 20–25% of cases and is the most common cause amongst patients with evidence of colitis. Infection is diagnosed by detection of *C. difficile* toxins and is usually treated with metronidazole or vancomycin (p. 343). *C. perfringens* is a rarer cause which usually remains undiagnosed, and *Klebsiella oxytoca* is an occasional cause of antibiotic-associated haemorrhagic colitis.

Infections acquired in the tropics

Recent decades have seen unprecedented increases in long-distance business and holiday travel, as well as extensive migration. Although certain diseases retain their relatively fixed geographical distribution, being dependent on specific vectors or weather conditions, many travel with their human hosts and some may then be transmitted to other people. This means that the pattern of infectious diseases seen in each country changes constantly, and travel history and information on countries previously lived in, particularly during childhood, are crucial.

In general, the diversity of infectious diseases is greater in tropical than in temperate countries, and people in temperate countries have immunity to a narrower range of infections, reflecting less exposure in childhood and less ongoing boosting of immunity later in life, so that the most common travel-associated infections are those which are acquired by residents of temperate countries during visits to the tropics. In addition, those who have lived in tropical areas may lose immunity when they move to temperate countries and become susceptible when visiting their homeland.

Most travel-associated infections can be prevented. Pre-travel advice is tailored to the destination and the traveller (Box 13.16). It includes avoidance of insect bites (using at least 20% diethyltoluamide (DEET)), sun protection (sunscreen with a sun protection factor (SPF) of at least 15), food and water hygiene ('Boil it, cook it, peel

13.16 How to assess health needs in travellers before departure*

- Destination
- Personal details, including previous travel experience
- Dates of trip
- Itinerary and purpose of trip
- Personal medical history, including pregnancy, medication and allergies (e.g. to eggs, vaccines, antibiotics)
- Past vaccinations

  Childhood schedule followed? Diphtheria, tetanus, pertussis, polio, *N. meningitidis* type C, *Haemophilus influenzae* B (HiB)

  Travel-related? Typhoid, yellow fever, hepatitis A, hepatitis B, meningococcal ACW135Y, rabies, Japanese B encephalitis, tick-borne encephalitis
- Malaria prophylaxis: questions influencing the choice of antimalarial drugs are destination, past experience with antimalarials, history of epilepsy or psychiatric illness

*Further information is available at www fitfortravel.nhs.uk/

13.17 How to obtain a history from travellers to the tropics with fever

Questions	Factors to ascertain
Countries visited and dates of travel	Relate travel to known outbreaks of infection or antimicrobial resistance
Determine the environment visited	Travel to rural environments, forests, rivers or lakes
Clarify where the person slept	Sleeping in huts, use of bed nets, sleeping on the ground
Establish what he/she was doing	Exposure to people with medical illness, animals, soil, lakes, rivers
History of insect bites	Type of insect responsible, circumstances (location, time of day etc.), preventive measures
Dietary history	Ingestion of uncooked foods, salads and vegetables, meats (especially if undercooked), shellfish, molluscs, unpasteurised dairy products, unbottled water and sites at which food prepared
Sexual history	History of sexual intercourse with commercial sex workers, local population
Malaria prophylaxis	Type of prophylaxis
Vaccination history	Receipt of pre-travel vaccines and appropriateness to area visited
History of any treatments received while abroad	Receipt of medicines, local remedies, blood transfusions or surgical procedures

it or forget it!'), how to respond to travellers' diarrhoea (seek medical advice if bloody or lasts more than 48 hours) and, if relevant, safe sex (condom use).

Fever in travellers recently in the tropics

Presentation with unexplained fever is common in travellers who are visiting or have recently travelled to tropical areas. Frequent final diagnoses in such patients are malaria, typhoid fever, viral hepatitis and dengue fever. Travellers to West Africa may have viral haemorrhagic fevers (VHF), such as Lassa fever, Crimean–Congo haemorrhagic fever, Marburg and Ebola (see Box 13.39, p. 325). Those to South-east Asia may have avian influenza (H5N1), which requires special isolation precautions.

13.18 Specific exposures and causes of fever in the tropics

Exposure	Infection or disease
Mosquito bite	Malaria, dengue fever, Chikungunya, filariasis, tularaemia
Tsetse fly bite	African trypanosomiasis
Tick bite	Rickettsial infections, including typhus, Lyme disease, tularaemia, Crimean–Congo haemorrhagic fever, Kyasanur forest disease, babesiosis, tick-borne encephalitis
Louse bite	Typhus
Flea bite	Plague
Sandfly bite	Leishmaniasis, arbovirus infection
Reduviid bug	Chagas' disease
Animal contact	Q fever, brucellosis, anthrax, plague, tularaemia, viral haemorrhagic fevers, rabies
Fresh-water swimming	Schistosomiasis, leptospirosis, *Naegleria fowleri*
Exposure to soil	Inhalation: dimorphic fungi Inhalation or inoculation: *Burkholderia pseudomallei* Inoculation (most often when barefoot): hookworms, *Strongyloides stercoralis*
Raw or undercooked fruit and vegetables	Enteric bacterial infections, hepatitis A or E virus, *Fasciola hepatica*, *Toxocara* spp., *Echinococcus granulosus* (hydatid disease), *Entamoeba histolytica*
Undercooked pork	*Taenia solium* (cysticercosis)
Crustaceans or molluscs	Paragonimiasis, gnathostomiasis, *Angiostrongylus cantonensis* infection, hepatitis A virus, cholera
Unpasteurised dairy products	Brucellosis, salmonellosis, abdominal tuberculosis, listeriosis
Untreated water	Enteric bacterial infections, giardiasis, *Cryptosporidium* spp. (chronic in immunocompromised), hepatitis A or E virus

Clinical assessment

The approach to unexplained fever is described above and key questions are listed in Box 13.17. Medicines purchased in some countries may have reduced efficacy, e.g. for malaria prophylaxis. Consult reliable up-to-date sources about resistance to antimalarial drugs in the country visited. Vaccinations against yellow fever and hepatitis A and B are sufficiently effective to virtually exclude these infections. Oral and injectable typhoid vaccinations are 70–90% effective.

The differential diagnosis is guided by the clinical scenario, presence of specific exposures (Box 13.18) and the incubation period (Box 13.19). *Falciparum* malaria

13.19 Incubation times and illnesses in travellers*

< 2 wks

Non-specific fever

- Malaria
- Chikungunya
- Dengue
- Scrub typhus
- Spotted group rickettsiae
- Acute HIV
- Acute hepatitis C virus
- *Campylobacter*
- Salmonellosis
- Shigellosis
- East African trypanosomiasis
- Leptospirosis
- Relapsing fever
- Influenza
- Yellow fever

Fever and coagulopathy (usually thrombocytopenia)

- Malaria
- VHF
- Meningococcaemia
- Enteroviruses
- Leptospirosis and other bacterial pathogens associated with coagulopathy

Fever and CNS involvement

- Malaria
- Typhoid fever
- Rickettsial typhus (epidemic caused by *Rickettsia prowazekii*)
- Meningococcal meningitis
- Arboviral encephalitis
- East African trypanosomiasis
- Other causes of encephalitis or meningitis
- Angiostrongyliasis
- Rabies

Fever and pulmonary involvement

- Influenza
- Pneumonia, including *Legionella* pneumonia
- Acute histoplasmosis
- Acute coccidioidomycosis
- Q fever
- SARS

Fever and rash

- Viral exanthems (rubella, measles, varicella, mumps, HHV-6, enteroviruses
- Chikungunya
- Dengue
- Spotted or typhus group rickettsiosis
- Typhoid fever
- Parvovirus B19
- HIV-1

2–6 wks

- Malaria
- Tuberculosis
- Hepatitis A, B, C and E viruses
- Visceral leishmaniasis
- Acute schistosomiasis
- Amoebic liver abscess
- Leptospirosis
- African trypanosomiasis
- VHF
- Q fever
- Acute American trypanosomiasis
- Viral causes of mononucleosis syndromes

> 6 wks

- Non-*falciparum* malaria
- Tuberculosis
- Hepatitis B and E viruses
- HIV-1
- Visceral leishmaniasis
- Filariasis
- Onchocerciasis
- Schistosomiasis
- Amoebic liver abscess
- Chronic mycoses
- African trypanosomiasis
- Rabies
- Typhoid fever

*Adapted from Traveller's Health Yellow Book, CDC Health Information for International Travel 2008.
(HHV-6 = human herpes virus-6; SARS = severe acute respiratory syndrome; VHF = viral haemorrhagic fever)

tends to present between 7 and 28 days after exposure in an endemic area. VHF, dengue and rickettsial infection can usually be excluded if more than 21 days have passed between leaving the area and onset of illness.

13.20 Investigation of tropically acquired acute fever without localising signs

Features on FBC	Further investigations
Neutrophil leucocytosis	
Bacterial sepsis	Blood culture
Leptospirosis	Culture of blood and urine, serology
Borreliosis (tick- or louse-borne relapsing fever)	Blood film
Amoebic liver abscess	Ultrasound
Normal white cell count and differential	
Typhoid fever	Blood and stool culture
Typhus	Serology
Arboviral infection	Serology (PCR and viral culture)
Lymphocytosis	
Viral fevers	Serology
Infectious mononucleosis	Monospot test
Rickettsial fevers	Serology

(PCR = polymerase chain reaction)

Clinical examination is summarised on page 294. Particular attention should be paid to the skin, throat, eyes, nail beds, lymph nodes, abdomen and heart. Patients may be unaware of tick bites or eschars (p. 350). Body temperature should be measured at least twice daily.

Investigations and management

Initial investigations should start with thick and thin blood films for malaria parasites, FBC, urinalysis and chest X-ray if indicated. Box 13.20 lists diagnoses and investigations to consider in unexplained acute fever.

Management is directed at the underlying cause. In patients with suspected VHF (p. 324), strict infection control measures with isolation and barrier nursing are implemented to prevent contact with the patient's body fluids. The risk of VHF should be determined using epidemiological risk factors and clinical signs (Fig. 13.5), and further management undertaken as described on page 324.

Diarrhoea acquired in the tropics

Gastrointestinal illness is the most common infection amongst visitors to the tropics, with *Salmonella* spp., *Campylobacter* spp. and *Cryptosporidium* spp. infections prevalent worldwide (Box 13.21). Typhoid, paratyphoid, *Shigella* spp. and *Entamoeba histolytica* (amoebiasis) are usually encountered in visitors to the Indian subcontinent or sub-Saharan and southern Africa.

The approach to patients with acute diarrhoea is described on page 306. The benefits of treating travellers' diarrhoea with antimicrobials are marginal (Box 13.22). The differential diagnosis of diarrhoea persisting for more than 14 days is wide (Box 22.21, p. 857). Parasitic and bacterial causes, tropical malabsorption, inflammatory bowel disease and neoplasia should all be considered. Box 13.23 lists causes encountered particularly in visitors to the tropics. The work-up should include tests for parasitic causes of chronic diarrhoea,

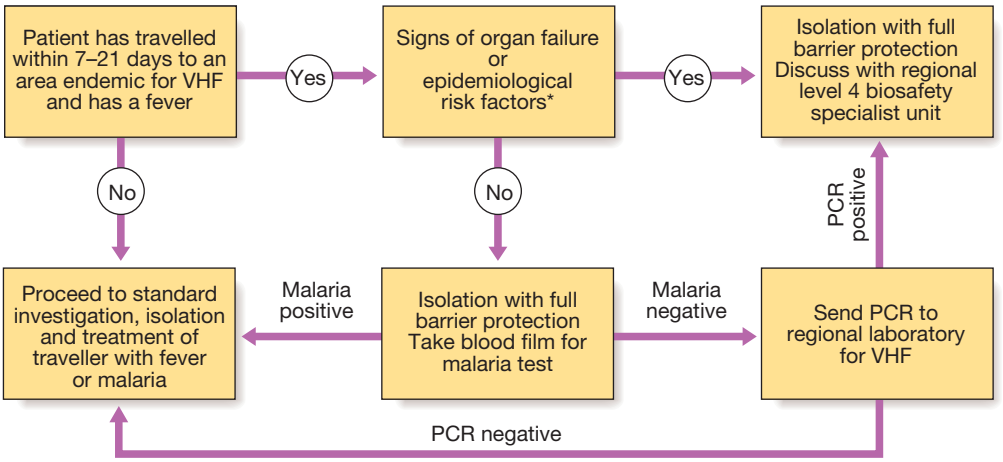

Fig. 13.5 Approach to the patient with suspected viral haemorrhagic fever (VHF). See page 324. *Epidemiological risk factors: staying with a febrile individual, caring for a sick individual, or contact with body fluids from a suspected human or animal case of VHF. (PCR = polymerase chain reaction)

13.21 Most common causes of travellers' diarrhoea

- Enterotoxigenic *E. coli* (ETEC)
- *Shigella* spp.
- *Campylobacter jejuni*
- *Salmonella* spp.
- *Plesiomonas shigelloides*
- Non-cholera *Vibrio* spp.
- *Aeromonas* spp.

EBM 13.22 Antimicrobials in travellers' diarrhoea

'Antimicrobials reduce the duration of acute non-bloody diarrhoea.'

- de Bruyn G, et al. Antibiotic treatment for travellers' diarrhoea. Cochrane Database of Systematic Reviews, 2000, issue 3. Art. no. CD002242.

For further information: www.cochrane.org/cochrane-reviews

13.23 Causes of chronic diarrhoea acquired in the tropics

- *Giardia lamblia*
- Strongyloidiasis
- Enteropathic *E. coli*
- HIV enteropathy
- Intestinal flukes
- Tropical sprue
- Chronic intestinal schistosomiasis
- Chronic calcific pancreatitis
- Hypolactasia (primary and secondary)

e.g. examination of stool and duodenal aspirates for ova and parasites, and serological investigation.

Tropical sprue is a malabsorption syndrome (p. 882) with no defined aetiology. It was typically associated with a long period of residence in the tropics or with overland travel but is now rarely seen. *Giardia lamblia* infection may progress to a malabsorption syndrome that mimics tropical sprue. If no cause is found, empirical treatment for *Giardia lamblia* infection with metronidazole is often helpful.

HIV-1 has now emerged as a major cause of chronic diarrhoea. This may be due to HIV enteropathy or infection with agents such as *Cryptosporidium* spp., *Isospora belli* or microsporidia (p. 399). However, many other causes of chronic AIDS-associated diarrhoea seen in the developed world are less common in tropical settings, e.g. CMV or disseminated *Mycobacterium avium* complex infections.

Eosinophilia acquired in the tropics

Eosinophilia occurs in a variety of haematological, allergic and inflammatory conditions discussed on p. 1004. It may also arise in HIV-1 and human T-cell lymphotropic virus (HTLV)-1 infection. However, eosinophils are important in the immune response to parasitic infections, in particular those involving parasites with a tissue migration phase. In the context of travel to or residence in the tropics, a patient with an eosinophil count of more than 0.4×10^9/L should be investigated for both non-parasitic (Box 24.9, p. 1004) and parasitic causes (Box 13.24).

The response to parasite infections is often different when travellers to and residents of endemic areas are compared. Travellers often have recent and light infections associated with eosinophilia. Residents have often been infected for a long time, have evidence of chronic pathology and no longer have eosinophilia.

Clinical assessment

A history of travel to known endemic areas for schistosomiasis, onchocerciasis and the filariases will indicate possible causes. Assessment should establish how long patients have spent in endemic areas and the history should address all the elements in Box 13.17.

Physical signs or symptoms that suggest a parasitic cause for eosinophilia include transient rashes (schistosomiasis or strongyloidiasis), fever (Katayama syndrome – p. 377), pruritus (onchocerciasis) or migrating subcutaneous swellings (loiasis, gnathostomiasis) (see Box 13.24). Paragonimiasis can give rise to haemoptysis and the migratory phase of intestinal nematodes or lymphatic filariasis may cause cough, wheezing and transient pulmonary infiltrates. Schistosomiasis induces transient respiratory symptoms with infiltrates in the acute stages and, when eggs reach the pulmonary vasculature in chronic infection, can result in shortness of breath with features of right heart failure due to pulmonary hypertension. Fever and hepatosplenomegaly are seen in schistosomiasis, *Fasciola hepatica* infection and

13.24 Parasite infections that cause eosinophilia

Infestation	Pathogen	Clinical syndrome with eosinophilia
Strongyloidiasis	*Strongyloides stercoralis*	Larva currens
Soil-transmitted helminthiases		
Hookworm	*Necator americanus*	Anaemia
	Ancylostoma duodenale	Anaemia
Ascariasis	*Ascaris lumbricoides*	Löffler's syndrome
Toxocariasis	*Toxocara canis*	Visceral larva migrans
Schistosomiasis	*Schistosoma haematobium*	Katayama fever
	S. mansoni, *S. japonicum*	Chronic infection
Filariases		
Loiasis	*Loa loa*	Skin nodules
Wuchereria bancrofti	*W. bancrofti*	Lymphangitis, lymphadenopathy, orchitis, intermittent bouts of cellulitis, lymphoedema and elephantiasis
Brugia malayi	*B. malayi*	Brugian elephantiasis similar but typically less severe than that caused by *W. bancrofti*
Mansonella perstans	*M. perstans*	Asymptomatic infection, occasionally subconjunctival nodules
Onchocerciasis	*Onchocerca volvulus*	Visual disturbance, dermatitis
Other nematode infections	*Trichinella spiralis*	Myositis
Cestode infections	*Taenia saginata*, *T. solium*	Usually asymptomatic; eosinophilia associated with migratory phase
	Echinococcus granulosus	Lesions in liver or other organ; eosinophilia associated with leakage from cyst
Liver flukes	*Fasciola hepatica*	Hepatic symptoms; eosinophilia associated with migratory phase
	Clonorchis sinensis	As for fascioliasis
	Opisthorchis felineus	As for fascioliasis
Lung fluke	*Paragonimus westermani*	Lung lesions

toxocariasis (visceral larva migrans). Intestinal worms, such as *Ascaris lumbricoides* and *Strongyloides stercoralis*, can cause abdominal symptoms, including intestinal obstruction and diarrhoea. In the case of heavy infestation with *Ascaris*, this may be due to fat malabsorption and there may be associated nutritional deficits. *Schistosoma haematobium* can cause haematuria or haematospermia. *Toxocara* spp. can give rise to choroidal lesions with visual field defects. *Angiostrongylus cantonensis* and gnathostomiasis induce eosinophilic meningitis, and the hyperinfection syndrome caused by *Strongyloides stercoralis* in immunocompromised hosts induces meningitis due to Gram-negative bacteria. Myositis is a feature of trichinellosis and cysticercosis, while periorbital oedema is found in trichinellosis.

Investigations

The diagnosis of a parasitic infestation requires direct visualisation of adult worms, larvae or ova. Serum antibody detection may not distinguish between active and past infection and is often unhelpful in those born in endemic areas. Radiological investigations may provide circumstantial evidence of parasite infestation. Box 13.25 describes initial investigations for eosinophilia.

Management

A specific diagnosis guides therapy. In the absence of a specific diagnosis, many clinicians will give an empirical course of praziquantel if the individual has been potentially exposed to schistosomiasis, or with albendazole/ivermectin if strongyloidiasis or intestinal nematodes are likely causes.

13.25 Initial investigation of eosinophilia

Investigation	Pathogens sought
Stool microscopy	Ova, cysts and parasites
Terminal urine	Ova of *Schistosoma haematobium*
Duodenal aspirate	Filariform larvae of *Strongyloides*, liver fluke ova
Day bloods	Microfilariae *Brugia malayi*, *Loa loa*
Night bloods	Microfilariae *Wuchereria bancrofti*
Skin snips	*Onchocerca volvulus*
Slit lamp examination	*Onchocerca volvulus*
Serology	Schistosomiasis, filariasis, strongyloidiasis, hydatid, trichinosis etc.

Skin conditions acquired in the tropics

Community-based studies in the tropics consistently show that skin infections (bacterial and fungal), scabies and eczema are the most common skin problems (Box 13.26). Scabies and eczema are discussed on pages 1280 and 1283. Cutaneous leishmaniasis and onchocerciasis have defined geographical distributions (pp. 365 and 374). In travellers, secondarily infected insect bites, pyoderma, cutaneous larva migrans and non-specific dermatitis are common.

13.26 Rash in tropical travellers/residents

Maculopapular rash

- Dengue
- HIV-1
- Typhoid
- *Spirillum minus*
- Rickettsial infections
- Measles

Petechial or purpuric rash

- Viral haemorrhagic fevers
- Yellow fever
- Meningococcal sepsis
- Leptospirosis
- Rickettsial spotted fevers
- Malaria

Vesicular rash

- Monkeypox
- Insect bites
- Rickettsial pox

Urticarial rash

- Katayama fever (schistosomiasis)
- *Toxocara* spp.
- *Strongyloides stercoralis*
- Fascioliasis

Ulcers

- Leishmaniasis
- *Mycobacterium ulcerans* (Buruli ulcer)
- Dracunculosis
- Anthrax
- Rickettsial eschar
- Tropical ulcer (*Fusobacterium ulcerans* and *Treponema vincentii*)
- Ecthyma (staphylococci, streptococci)

Papules

- Scabies
- Insect bites
- Prickly heat
- Ringworm
- Onchocerciasis

Nodules or plaques

- Leprosy
- Chromoblastomycosis
- Dimorphic fungi
- Trypanosomiasis
- Onchocerciasis
- Myiasis (larvae of Tumbu or botfly)
- Tungiasis (*Tunga penetrans*)

Migratory linear rash

- Cutaneous larva migrans (dog hookworms)
- *Strongyloides stercoralis*

Migratory papules/nodules

- *Loa loa*
- Gnathosomiasis
- Schistosomiasis

Thickened skin

- Mycetoma (fungi/*Nocardia* spp.)
- Elephantiasis (filariasis)

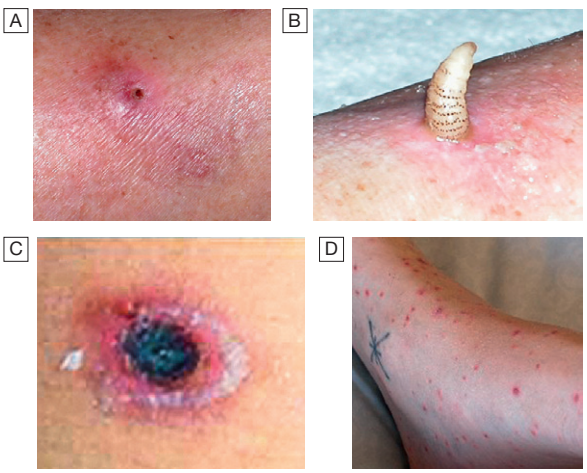

Fig. 13.6 Examples of skin lesions in patients with fever in the tropics. A Subcutaneous nodule due to botfly infection. B Emerging larva after treatment with petroleum jelly. C Eschar of scrub typhus. D Rat bite fever.

During the investigation of skin lesions, enquiry should be made about habitation, activities undertaken and regions visited (see Box 13.17). Examples of skin lesions in tropical disease are shown in Figure 13.6.

Skin biopsies are helpful in diagnosing aetiology. Culture of biopsy material may be needed to diagnose bacterial, fungal, parasitic and mycobacterial infections.

Infections in adolescence

Particular issues of relevance in adolescent patients are shown in Box 13.27.

13.27 Key issues in infectious diseases in adolescence

- **Common infectious syndromes**: include infectious mononucleosis, bacterial pharyngitis, whooping cough, pneumonia, staphylococcal skin and soft tissue infections, urinary tract infections, acute gastroenteritis.
- **Life-threatening infections**: include meningococcal meningitis and bacterial sepsis.
- **Sexually transmitted infections**: include HIV-1, hepatitis B virus and chlamydia. These may reflect either voluntary sexual activity or sexual coercion/abuse.
- **Travel-related infections**: diarrhoea, malaria etc. are relatively common.
- **Infections in susceptible groups**: patients with cystic fibrosis, congenital immunodeficiency, acute leukaemia and other adolescent malignancies are vulnerable to specific groups of infections.
- **Infections requiring prolonged antimicrobial use**: adherence to chronic therapy is challenging, for both oral (antituberculous or antiretroviral) and systemic (osteomyelitis, septic arthritis or post-operative infections) treatments. Outpatient antimicrobial therapy is preferred to minimise hospitalisation.
- **Vaccination**: engagement with age-specific vaccine programmes should be ensured, e.g. for human papillomavirus.
- **Risk reduction**: education relating to sexual health and alcohol and recreational drug usage is important.

Infections in pregnancy

Box 13.28 shows some of the infections encountered in pregnancy.

13.28 **Infections during pregnancy**

Infection	Consequence	Prevention and management
Rubella	Congenital malformation	Vaccination of non-immune mothers
Cytomegalovirus	Neonatal infection, congenital malformation	Limited prevention strategies
Varicella zoster virus	Neonatal infection, congenital malformation, severe infection in mother	VZ immune globulin (see Box 13.34, p. 318), or aciclovir if exposure > 4 days previously
Herpes simplex virus	Congenital or neonatal infection	Aciclovir and consideration of caesarean section for mothers who shed HSV from genital tract at time of delivery. Aciclovir for infected neonates
Hepatitis B virus	Chronic infection of neonate	Hepatitis B immune globulin and active vaccination of newborn
HIV-1	Chronic infection of neonate	Antiretrovirals for mother and infant and consideration of caesarean section if HIV-1 viral load detectable. Avoidance of breastfeeding
Parvovirus B19	Congenital infection	Avoid individuals with acute infection if pregnant
Measles	More severe infection in mother and neonate	Immunisation of mother
Dengue	Neonatal dengue if mother has infection < 5 wks prior to delivery	Vector (mosquito) control
Syphilis	Congenital malformation	Serological testing in pregnancy with prompt treatment of infected mothers
Neisseria gonorrhoeae* and *Chlamydia trachomatis	Neonatal conjunctivitis (*ophthalmia neonatorum*, p. 422)	Treatment of infection in mother and neonate
Listeriosis	Neonatal meningitis or bacteraemia, bacteraemia or PUO in mother	Avoidance of unpasteurised cheeses and other dietary sources
Brucellosis	Possibly increased incidence of fetal loss	Avoidance of unpasteurised dairy products
Group B streptococcal infection	Neonatal meningitis and sepsis. Sepsis in mother after delivery	Risk- or screening-based antimicrobial prophylaxis in labour (recommendations vary between countries)
Toxoplasmosis	Congenital malformation	Diagnosis and prompt treatment of cases, avoidance of undercooked meat while pregnant
Malaria	Fetal loss, intrauterine growth retardation, severe malaria in mother	Avoidance of insect bites. Intermittent preventative treatment during pregnancy to decrease incidence in high-risk countries

VIRAL INFECTIONS

Systemic viral infections with exanthem

Childhood exanthems are characterised by fever and widespread rash. Maternal antibody gives protection for the first 6–12 months of life and infection occurs thereafter. Comprehensive immunisation programmes have dramatically reduced the number of paediatric infections but incomplete uptake results in infections in later life.

Measles

The WHO has set the objective of eradicating measles globally using the live attenuated vaccine. However, vaccination of more than 95% of the population is required to prevent outbreaks. Natural illness produces life-long immunity.

Clinical features

Infection is by respiratory droplets with an incubation period of 6–19 days. A prodromal illness, 1–3 days before the rash, occurs, with upper respiratory symptoms, conjunctivitis and the presence of the pathognomonic Koplik's spots, small white spots surrounded by erythema on the buccal mucosa (Fig. 13.7A). As natural antibody develops, the maculopapular rash appears, spreading from the face to the extremities (Fig. 13.7B). Generalised lymphadenopathy and diarrhoea are common. Complications are more common in older children and adults, and include otitis media, bacterial pneumonia, transient hepatitis and clinical encephalitis (approximately 0.1% of cases). A rare late complication is subacute sclerosing panencephalitis (SSPE), which occurs up to 7 years after infection. Diagnosis is clinical (although this has become unreliable in areas where measles is no longer common) and by detection of antibody (serum IgM, seroconversion or salivary IgM).

Measles is a serious disease in the malnourished, vitamin-deficient or immunocompromised, in whom the typical rash may be missing and persistent infection with a giant cell pneumonitis or encephalitis may occur. In tuberculosis infection, measles suppresses cell-mediated immunity and may exacerbate disease; for this reason, measles vaccination should be deferred until after commencing antituberculous treatment. Measles does not cause congenital malformation but may be more severe in pregnant women.

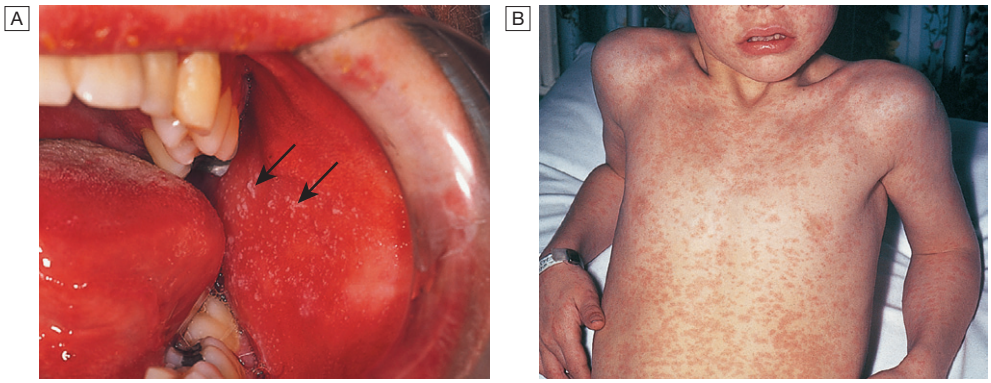

Fig. 13.7 Measles. A Koplik's spots (arrows) seen on buccal mucosa in the early stages of clinical measles. B Typical measles rash.

Mortality clusters at the extremes of age, averaging 1:1000 in developed countries and up to 1:4 in developing countries. Death usually results from a bacterial superinfection, occurring as a complication of measles, most often pneumonia, diarrhoeal disease or noma/cancrum oris, a gangrenous stomatitis. Death may also result from complications of measles encephalitis.

Management and prevention

Normal immunoglobulin attenuates the disease in the immunocompromised (regardless of vaccination status) and in non-immune pregnant women, but must be given within 6 days of exposure. Vaccination can be used in outbreaks and vitamin A may improve the outcome in uncomplicated disease. Antibiotic therapy is reserved for bacterial complications. All children aged 12–15 months should receive measles vaccination (as combined measles, mumps and rubella (MMR), a live attenuated vaccine), and a further MMR dose at age 4 years.

Rubella (German measles)

Rubella causes exanthem in the non-immunised.

Clinical features

Rubella is spread by respiratory droplet, with infectivity from up to 10 days before to 2 weeks after the onset of the rash. The incubation period is 15–20 days. In childhood, most cases are subclinical, although clinical features may include fever, maculopapular rash spreading from the face, and lymphadenopathy. Complications are rare but include thrombocytopenia and hepatitis. Encephalitis and haemorrhage are occasionally reported. In adults, arthritis involving hands or knees is relatively common, especially in women.

If transplacental infection takes place in the first trimester or later, persistence of the virus is likely and severe congenital disease may result (Box 13.29). Even if normal at birth, the infant has an increased incidence of other diseases developing later, e.g. diabetes mellitus.

Diagnosis

Laboratory confirmation of rubella is required if there has been contact with a pregnant woman. This is achieved either by detection of rubella IgM in serum or by IgG seroconversion. In the exposed pregnant woman, absence of rubella-specific IgG confirms the potential for congenital infection.

13.29 Rubella infection: risk of congenital malformation

Stage of gestation	Likelihood of malformations
1–2 mths	65–85% chance of illness, multiple defects/spontaneous abortion
3 mths	30–35% chance of illness, usually a single congenital defect (most frequently deafness, cataract, glaucoma, mental retardation or congenital heart disease, especially pulmonary stenosis or patent ductus arteriosus)
4 mths	10% risk of congenital defects, most commonly deafness
> 20 wks	Occasional deafness

Prevention

All children should be immunised with MMR, as above for measles. In view of the risks of congenital rubella syndrome, all women of child-bearing age should also be tested for rubella and vaccinated if seronegative.

Parvovirus B19

Parvovirus B19 causes exanthem and other clinical syndromes. Some 50% of children and 60–90% of adults are seropositive. Most infections are spread by the respiratory route, although spread via contaminated blood is also possible. The virus has particular tropism for red cell precursors.

Clinical features

Many infections are subclinical. Clinical manifestations result after an incubation period of 14–21 days (Box 13.30). The classic exanthem (erythema infectiosum) is preceded by a prodromal fever and coryzal symptoms. A 'slapped cheek' rash is characteristic but the rash is very variable (Fig. 13.8). In adults, polyarthropathy is common. Infected individuals have a transient block in erythropoiesis for a few days, which is of no clinical consequence, except in individuals with increased red cell turnover due to haemoglobinopathy or haemolytic anaemia. These individuals develop an acute anaemia which may be severe (transient aplastic crisis; p. 1032). Erythropoiesis usually recovers spontaneously after 10–14 days. Immunocompromised individuals,

13.30 Clinical features of parvovirus B19 infection

Affected age group	Clinical manifestations
Fifth disease (erythema infectiosum)	
Small children	Three clinical stages: a 'slapped cheek' appearance, followed by a maculopapular rash progressing to a reticulate eruption on the body and limbs, then a final stage of resolution. Often the child is quite well throughout
Gloves and socks syndrome	
Young adults	Fever and an acral purpuric eruption with a clear margin at the wrists and ankles. Mucosal involvement also occurs
Arthropathies	
Adults and occasionally children	Symmetrical small-joint polyarthropathy. In children it tends to involve the larger joints in an asymmetrical distribution
Impaired erythropoiesis	
Adults, those with haematological disease, the immunosuppressed	Mild anaemia; in an individual with an underlying haematological abnormality can precipitate transient aplastic crisis, or in the immunocompromised a more sustained but often milder pure red cell aplasia
Hydrops fetalis	
Transplacental fetal infection	Asymptomatic or symptomatic maternal infection can cause fetal anaemia with an aplastic crisis, leading to non-immune hydrops fetalis and spontaneous abortion

Fig. 13.8 Slapped cheek syndrome. The typical facial rash of parvovirus B19 infection.

including those with congenital immunodeficiency or AIDS, can develop a more sustained block in erythropoiesis in response to the chronic viraemia that results from their inability to clear the infection. Infection during the first two trimesters of pregnancy can result in intrauterine infection and impact on fetal bone marrow; it causes 10–15% of non-immune (non-Rhesus-related) hydrops fetalis, a rare complication of pregnancy.

Diagnosis

IgM to parvovirus B19 suggests recent infection but may persist for months and false positives occur. Seroconversion to IgG positivity confirms infection but in isolation a positive IgG is of little diagnostic utility. Detection of parvovirus B19 DNA in blood is particularly useful in immunocompromised patients. Giant pronormoblasts or haemophagocytosis may be demonstrable in the bone marrow.

Management

Infection is usually self-limiting. Symptomatic relief for arthritic symptoms may be required. Severe anaemia requires transfusion. Persistent viraemia in immunocompromised hosts may require immunoglobulin therapy to clear the virus.

Pregnant women should avoid contact with cases of parvovirus B19 infection; if they are exposed, serology should be performed to establish whether they are non-immune.

Passive prophylaxis with normal immunoglobulin has been suggested for non-immune pregnant women exposed to infection but there are limited data to support this recommendation. The pregnancy should be closely monitored by ultrasound scanning, so that hydrops fetalis can be treated by fetal transfusion.

Human herpesvirus 6 and 7

Human herpesvirus 6 (HHV-6) is a lymphotropic virus that causes a childhood viral exanthem (exanthem subitum), rare cases of an infectious mononucleosis-like syndrome and infection in the immunocompromised host. Infection is almost universal, with approximately 95% of children acquiring this virus by 2 years of age. Transmission is via saliva.

HHV-7 is very closely related to HHV-6, and is believed to be responsible for a proportion of cases of exanthem subitum. Like HHV-6, HHV-7 causes an almost universal infection in childhood, with subsequent latent infection and occasional infection in the immunocompromised host.

Clinical features

Exanthem subitum is also known as roseola infantum or sixth disease (Box 13.31). A high fever is followed by a maculopapular rash as the fever resolves. Fever and/or febrile convulsions may also occur without a rash. Rarely, older children or adults may develop an infectious mononucleosis-like illness, hepatitis or rash. In the immunocompromised, infection is rare but can cause fever, rash, hepatitis, pneumonitis, cytopenia or encephalitis.

Diagnosis and management

Exanthem subitum is usually a clinical diagnosis but can be confirmed by antibody and/or DNA detection. The disease is self-limiting. Treatment with ganciclovir or foscarnet is used in immunocompromised hosts infected with HHV-6.

Chickenpox (varicella)

Varicella zoster virus (VZV) is a dermotropic and neurotropic virus that produces primary infection, usually in childhood, which may reactivate in later life. VZV is spread by aerosol and direct contact. It is highly

13.31 Herpesvirus infections

Virus	Infection
***Herpesvirus hominis* (herpes simplex, HSV)**	
HSV-1 (p. 325)	Herpes labialis ('cold sores') Stomatitis, pharyngitis Corneal ulceration Finger infections ('whitlows') Eczema herpeticum Encephalitis
HSV-2 (p. 325)	Genital ulceration and neonatal infection (acquired during vaginal delivery) Acute meningitis or transverse myelitis. Rarely, encephalitis
Varicella zoster virus (VZV) (p. 316)	Chickenpox (varicella) Shingles (herpes zoster)
Cytomegalovirus (CMV) (p. 321)	Congenital infection Infectious mononucleosis (heterophile antibody-negative) Hepatitis Disease in immunocompromised patients: retinitis, encephalitis, pneumonitis, hepatitis, enteritis Fever with abnormalities in haematological parameters
Epstein–Barr virus (EBV) (p. 320)	Infectious mononucleosis Burkitt's and other lymphomas Nasopharyngeal carcinoma Oral hairy leucoplakia (AIDS patients) Other lymphomas
Human herpesvirus 6 and 7 (HHV-6, HHV-7)	Exanthem subitum Disease in immunocompromised patients
Human herpesvirus 8 (HHV-8) (p. 326)	Kaposi's sarcoma, primary effusion lymphoma, multicentric Castleman's disease

infectious to non-immune individuals. Disease in children is usually well tolerated. Manifestations are more severe in adults, pregnant women and the immunocompromised.

Clinical features

The incubation period is 11–20 days, after which a vesicular eruption begins (Fig. 13.9), often on mucosal surfaces first, followed by rapid dissemination in a centripetal distribution (most dense on trunk and sparse on limbs). New lesions occur every 2–4 days and each crop is associated with fever. The rash progresses from small pink macules to vesicles and pustules within 24 hours. Infectivity lasts from up to 4 days (but usually 48 hours) before the lesions appear until the last vesicles crust over. Due to intense itching, secondary bacterial infection from scratching is the most common complication of primary chickenpox. Self-limiting cerebellar ataxia and encephalitis are rare complications.

Adults, pregnant women and the immunocompromised are at increased risk of visceral involvement, which presents as pneumonitis, hepatitis or encephalitis. Pneumonitis can be fatal and is more likely to occur in smokers. Maternal infection in early pregnancy carries a 3% risk of neonatal damage with developmental abnormalities of eyes, CNS and limbs. Chickenpox within 5 days of delivery leads to severe neonatal varicella with visceral involvement and haemorrhage.

Diagnosis

Diagnosis is primarily clinical, by recognition of the rash. If necessary, this can be confirmed by detection of antigen (direct immunofluorescence) or DNA (PCR) of aspirated vesicular fluid. Serology is used to identify seronegative individuals at risk of infection.

Management and prevention

The benefits of antivirals for uncomplicated primary VZV infection in children are marginal and treatment is not required (Box 13.32). Antivirals are, however, used for uncomplicated chickenpox when the patient presents within 24–48 hours of onset of vesicles, in all patients with complications, and in those who are immunocompromised, including pregnant women, regardless of duration of vesicles (Box 13.33). More severe disease, particularly in immunocompromised hosts, requires initial parenteral therapy. Immunocompromised patients may have prolonged viral shedding and may require prolonged treatment until all lesions crust over.

EBM 13.32 Aciclovir for chickenpox/shingles

'Aciclovir shortens symptoms in chickenpox by an average of 1 day. In shingles, aciclovir reduces pain by 10 days and the risk of post-herpetic neuralgia by 8%. Aciclovir is therefore cost-effective in shingles but not chickenpox.'

- Nathwani D, et al. Infect Dis Clin Prac 1995; 4:138–145.
- Trying SK. Arch Fam Med; 2000; 9:863–869.

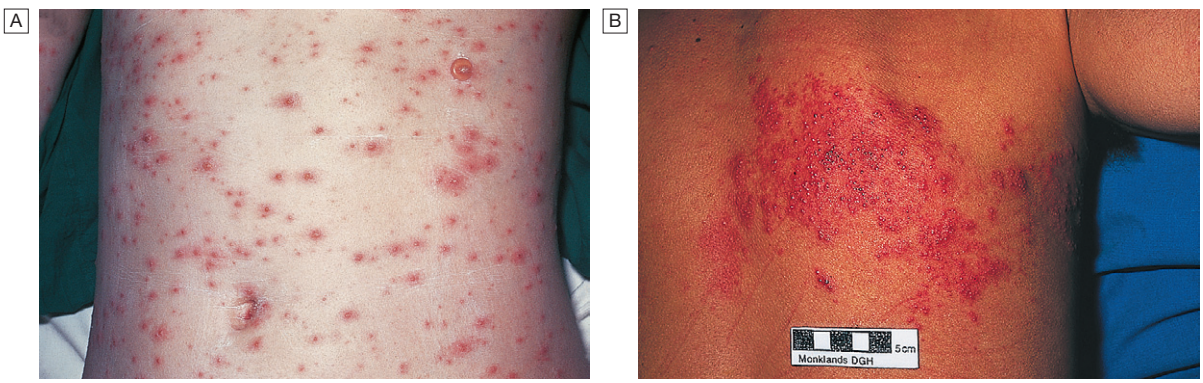

Fig. 13.9 Varicella zoster virus infection. A Chickenpox. B Shingles in a thoracic dermatome.

13.33 Therapy for herpes simplex and varicella zoster virus infection

Disease state	Treatment options
Primary genital HSV	Famciclovir 250 mg 3 times daily for 7–10 days Valaciclovir 1 g twice daily for 7–10 days Oral aciclovir 200 mg 5 times daily or 400 mg 3 times daily for 7–10 days
Severe and preventing oral intake	Aciclovir 5 mg/kg 3 times daily IV until patient can tolerate oral therapy
Recurrent genital HSV-1 or 2	Oral aciclovir 200 mg 5 times daily or 400 mg 3 times daily for 5 days Famciclovir 125 mg twice daily for 5 days Valaciclovir 500 mg twice daily for 3–5 days or 2 g twice daily for 1 day. Shorter durations increasingly favoured
Primary or recurrent oral HSV	Usually no treatment If required, usually short duration, e.g. valaciclovir 2 g twice daily for 1 day
Mucocutaneous HSV infection in immunocompromised host	Aciclovir 5 mg/kg 3 times daily IV for 7–10 days Oral aciclovir 400 mg 4 times daily for 7–10 days Famciclovir 500 mg 3 times daily for 7–10 days Valaciclovir 1 g twice daily for 7–10 days
Chickenpox in adult or child	Oral aciclovir 800 mg 5 times daily for 5 days Famciclovir 500 mg 3 times daily for 5 days Valaciclovir 1 g 3 times daily for 5 days
Immunocompromised host/pregnant woman	Aciclovir 5 mg/kg 3 times daily IV until patient is improving, then complete therapy with oral therapy until all lesions crusting over
Shingles	Treatment and doses as for chickenpox but duration typically 7–10 days
Visceral involvement (non-CNS) in HSV	Aciclovir IV 5 mg/kg 3 times daily for 14 days
Visceral involvement (non-CNS) in VZV	Aciclovir IV 5 mg/kg 3 times daily for 7 days
Severe complications (encephalitis, disseminated infection)	Aciclovir IV 10 mg/kg 3 times daily (up to 20 mg/kg in neonates) for 14–21 days
HSV disease suppression	Aciclovir 400 mg twice daily Famciclovir 250 mg twice daily Valaciclovir 500 mg daily

Human VZ immunoglobulin (VZIG) is used to attenuate infection in people who have had significant contact with VZV, are susceptible to infection (i.e. have no history of chickenpox or shingles and are seronegative for VZV IgG) and are at risk of severe disease (e.g. immunocompromised, steroid-treated or pregnant)

13.34 Indications for varicella zoster immunoglobulin (VZIG) in adults

An adult should satisfy all three of the following conditions:

1. Significant contact

Contact with chickenpox (any time from 48 hrs before the rash until crusting of lesions) or zoster (exposed, disseminated or, with immunocompromised contacts, localised zoster; between development of the rash until crusting) defined as:

- Prolonged household contact, sharing a room for ≥ 15 mins or face-to-face contact (includes direct contact with zoster lesions)
- Hospital contact with chickenpox in another patient, health-care worker or visitor
- Intimate contact (e.g. touching) with person with shingles lesions
- Newborn whose mother develops chickenpox no more than 5 days before delivery or 2 days after delivery

2. Susceptible contact

- Individual with no history of chickenpox, ideally confirmed by negative test for VZV IgG

3. Predisposition to severe chickenpox

- Immunocompromised due to disease (e.g. acute leukaemia, HIV, other primary or secondary immunodeficiency)
- Medically immunosuppressed (e.g. following solid organ transplant; current or recent (< 6 mths) cytotoxic chemotherapy or radiotherapy; current or recent (< 3 mths) high-dose corticosteroids; haematopoietic stem cell transplant)
- Pregnant (any stage)
- Infants: newborn whose mother has had chickenpox as above; premature infants < 28 wks

(Box 13.34). Ideally, VZIG should be given within 7 days of exposure, but it may attenuate disease even if given up to 10 days afterwards. Susceptible contacts who develop severe chickenpox after receiving VZIG should be treated with aciclovir.

A live, attenuated VZV vaccine is available and in routine use in the USA and other countries, but in the UK its use has been restricted to non-immune health-care workers and household contacts of immunocompromised individuals. Children receive one dose after 1 year of age and a second dose at 4–6 years of age; seronegative adults receive two doses at least 1 month apart. The vaccine may also be used prior to planned iatrogenic immunosuppression, e.g. before transplant.

Shingles (herpes zoster)

After initial infection, VZV persists in latent form in the dorsal root ganglion of sensory nerves and can reactivate in later life.

Clinical features

Burning discomfort occurs in the affected dermatome, where discrete vesicles appear 3–4 days later. This is associated with a brief viraemia, which can produce distant satellite 'chickenpox' lesions. Occasionally, paraesthesia occurs without rash ('zoster sine herpete'). Severe disease, a prolonged duration of rash, multiple dermatomal involvement or recurrence suggests underlying immune deficiency, including HIV. Chickenpox may be contracted from a case of shingles but not vice versa.

Although thoracic dermatomes are most commonly involved (Fig. 13.9B), the ophthalmic division of the trigeminal nerve is also frequently affected; vesicles may appear on the cornea and lead to ulceration. This condition can lead to blindness and urgent ophthalmology review is required. Geniculate ganglion involvement causes the Ramsay Hunt syndrome of facial palsy, ipsilateral loss of taste and buccal ulceration, plus a rash in the external auditory canal. This may be mistaken for Bell's palsy (p. 1163). Bowel and bladder dysfunction occur with sacral nerve root involvement. The virus occasionally causes cranial nerve palsy, myelitis or encephalitis. Granulomatous cerebral angiitis is a cerebrovascular complication that leads to a stroke-like syndrome in association with shingles, especially in an ophthalmic distribution.

Post-herpetic neuralgia causes troublesome persistence of pain for 1–6 months or longer, following healing of the rash. It is more common with advanced age.

Management

Early therapy with aciclovir or related agents has been shown to reduce both early- and late-onset pain, especially in patients over 65 years (see Box 13.32). Post-herpetic neuralgia requires aggressive analgesia, along with agents such as amitriptyline 25–100 mg daily or gabapentin (commencing at 300 mg daily and building slowly to 300 mg twice daily or more). Capsaicin cream (0.075%) may be helpful. Although controversial, corticosteroids have not been demonstrated to reduce post-herpetic neuralgia to date.

Enteroviral exanthems

Coxsackie or echovirus infections can lead to a maculopapular eruption or roseola-like rash that occurs after fever falls. Enteroviral infections are discussed further under viral infections of the skin (see below).

Systemic viral infections without exanthem

Other systemic viral infections present with features other than a rash suggestive of exanthem. Rashes may occur in these conditions but differ from those seen in exanthems or are not the primary presenting feature.

Mumps

Mumps is a systemic viral infection characterised by swelling of the parotid glands. Infection is endemic worldwide and peaks at 5–9 years of age. Vaccination has reduced the incidence in children but incomplete coverage and waning immunity with time have led to outbreaks in young adults. Infection is spread by respiratory droplets.

Clinical features

The median incubation period is 19 days, with a range of 15–24 days. Classical tender parotid enlargement, which is bilateral in 75%, follows a prodrome of pyrexia and headache (Fig. 13.10). Meningitis complicates up to 10% of cases. The CSF reveals a lymphocytic pleocytosis or, less commonly, neutrophils. Rare complications include encephalitis, transient hearing loss, labyrinthitis, electrocardiographic abnormalities, pancreatitis and arthritis.

Fig. 13.10 Typical unilateral mumps. A Note the loss of angle of the jaw on the affected (right) side. B Comparison showing normal (left) side.

Approximately 25% of post-pubertal males with mumps develop epididymo-orchitis but, although testicular atrophy occurs, sterility is unlikely. Oophoritis is less common. Abortion may occur if infection takes place in the first trimester of pregnancy. Complications may occur in the absence of parotitis.

Diagnosis

The diagnosis is usually clinical. In atypical presentations without parotitis, serology for mumps-specific IgM or IgG seroconversion (four-fold rise in IgG convalescent titre) confirms the diagnosis. Virus can also be cultured from urine in the first week of infection or detected by PCR in urine, saliva or CSF.

Management and prevention

Treatment is with analgesia. There is no evidence that corticosteroids are of value for orchitis. Mumps vaccine is one of the components of the combined MMR vaccine.

Influenza

Influenza is an acute systemic viral infection that primarily affects the respiratory tract; it carries a significant mortality. It is caused by influenza A virus or, in milder form, influenza B virus. Infection is seasonal, and variation in the haemagglutinin (H) and neuraminidase (N) glycoproteins on the surface of the virus leads to disease of variable intensity each year. Minor changes in haemagglutinin are known as 'genetic drift', whereas a switch in the haemagglutinin or neuraminidase antigen is termed 'genetic shift'. Nomenclature of influenza strains is based on these glycoproteins, e.g. H1N1, H3N2 etc. Genetic shift results in the circulation of a new influenza strain within a community to which few people are immune, potentially initiating an influenza epidemic or pandemic in which there is a high attack rate and there may be increased disease severity.

Clinical features

After an incubation period of 1–3 days, uncomplicated disease leads to fever, malaise and cough. Viral pneumonia may occur, although pulmonary complications

are most often due to superinfection with *Strep. pneumoniae*, *Staph. aureus* or other bacteria. Rare extrapulmonary manifestations include myositis, myocarditis, pericarditis and neurological complications (Reye's syndrome in children, encephalitis or transverse myelitis). Mortality is greatest in the elderly, those with medical comorbidities and pregnant women. Recently, polymorphisms in the gene encoding an antiviral protein, interferon-induced transmembrane protein 3 (IFITM3), have been associated with more severe influenza.

Diagnosis

Acute infection is diagnosed by viral antigen or RNA detection in a nasopharyngeal sample. The disease may also be diagnosed retrospectively by serology.

Management and prevention

Management involves early microbiological identification of cases and good infection control, with an emphasis on hand hygiene and preventing dissemination of infection by coughing and sneezing. Administration of neuraminidase inhibitor, oral oseltamivir (75 mg twice daily) or inhaled zanamivir (10 mg twice daily) for 5 days, can reduce the severity of symptoms if started within 48 hours of symptom onset (or possibly later in immunocompromised individuals). These agents have superseded routine use of amantadine and rimantadine. Antiviral drugs can also be used as prophylaxis in high-risk individuals during the 'flu' season. Resistance can emerge to all of these agents and so updated local advice should be followed.

Prevention relies on seasonal vaccination of the elderly and of individuals with chronic medical illnesses which place them at increased risk of the complications of influenza, such as chronic cardiopulmonary diseases or immune compromise, as well as their health-care workers. The vaccine composition changes each year to cover the 'predicted' seasonal strains but vaccination may fail when a new pandemic strain emerges.

Avian influenza

Avian influenza is caused by transmission of avian influenza A viruses to humans. Avian viruses, such as H5N1, possess alternative haemagglutinin antigens to seasonal influenza strains. Most cases have had contact with sick poultry, predominantly in South-east Asia, and person-to-person spread has been limited to date. Infections with H5N1 viruses have been severe, with enteric features and respiratory failure. Treatment depends on the resistance pattern but often involves oseltamivir. Vaccination against seasonal 'flu' does not adequately protect against avian influenza. There is a concern that adaptation of an avian strain to allow effective person-to-person transmission is likely to lead to a global pandemic of life-threatening influenza.

Swine influenza

Occasional cases of influenza are transmitted from pigs to humans. Re-assortment of swine, avian and human influenza strains can occur in pigs. Sometimes this can lead to an outbreak of swine 'flu' in humans, as occurred in 2009, when an outbreak of H1N1 influenza spread around the world from Mexico.

Infectious mononucleosis and Epstein–Barr virus

Infectious mononucleosis (IM) is a clinical syndrome characterised by pharyngitis, cervical lymphadenopathy, fever and lymphocytosis. It is most often caused by Epstein–Barr virus (EBV) but other infections can produce a similar clinical syndrome (Box 13.35).

EBV is a gamma herpesvirus. In developing countries, subclinical infection in childhood is virtually universal. In developed countries, primary infection may be delayed until adolescence or early adult life. Under these circumstances, about 50% of infections result in typical IM. The virus is usually acquired from asymptomatic excreters via saliva, either by droplet infection or environmental contamination in childhood, or by kissing among adolescents and adults. EBV is not highly contagious and isolation of cases is unnecessary.

Clinical features

EBV infection has a prolonged and undetermined incubation period, followed in some cases by a prodrome of fever, headache and malaise. This is succeeded by IM with severe pharyngitis, which may include tonsillar exudates and non-tender anterior and posterior cervical lymphadenopathy. Palatal petechiae, periorbital oedema, splenomegaly, inguinal or axillary lymphadenopathy, and macular, petechial or erythema multiforme rashes may occur. In most cases, fever resolves over 2 weeks, and fatigue and other abnormalities settle over a further few weeks. Complications are listed in Box 13.36. Death is rare but can occur due to respiratory obstruction, haemorrhage from splenic rupture or thrombocytopenia, or encephalitis.

The diagnosis of EBV infection outside the usual age in adolescence and young adulthood is more challenging. In children under 10 years the illness is mild and short-lived, but in adults over 30 years of age it can be severe and prolonged. In both groups, pharyngeal symptoms are often absent. EBV may present with jaundice, as a PUO or with a complication.

Long-term complications of EBV infection

Lymphoma complicates EBV infection in immunocompromised hosts, and some forms of Hodgkin's disease are EBV-associated (p. 1042). The endemic form of Burkitt's lymphoma complicates EBV infection in areas of sub-Saharan Africa where *falciparum* malaria is endemic. Nasopharyngeal carcinoma is a geographically restricted tumour seen in China and Alaska that is associated with EBV infection. X-linked lymphoproliferative (Duncan's) syndrome is a familial lymphoproliferative disorder that follows primary EBV infection in boys without any other history of immunodeficiency; it is due to mutation of the *SAP* gene, causing failure of T-cell and NK-cell activation and inability to contain EBV infection.

13.35 Causes of infectious mononucleosis syndrome

- Epstein–Barr virus infection
- Cytomegalovirus
- Human herpesvirus-6 or 7
- HIV-1 primary infection (p. 394)
- Toxoplasmosis

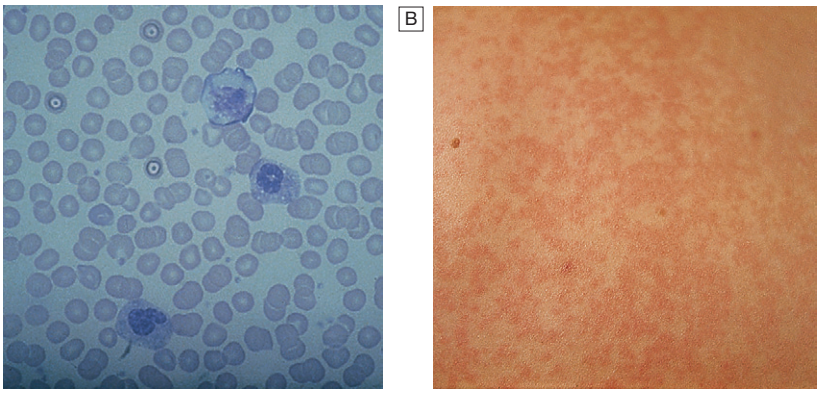

Fig. 13.11 Features of infectious mononucleosis. A Atypical lymphocytes in peripheral blood. B Skin reaction to ampicillin.

13.36 Complications of Epstein–Barr virus infection

Common

- Severe pharyngeal oedema
- Antibiotic-induced rash (80–90% with ampicillin)
- Hepatitis (80%)
- Prolonged post-viral fatigue (10%)
- Jaundice (< 10%)

Uncommon

Neurological

- Cranial nerve palsies
- Polyneuritis
- Transverse myelitis
- Meningoencephalitis

Haematological

- Haemolytic anaemia
- Thrombocytopenia

Renal

- Abnormalities on urinalysis
- Interstitial nephritis

Cardiac

- Myocarditis
- ECG abnormalities
- Pericarditis

Rare

- Ruptured spleen
- Respiratory obstruction
- Agranulocytosis
- X-linked lymphoproliferative syndrome

EBV-associated malignancy

- Nasopharyngeal carcinoma
- Burkitt's lymphoma
- Hodgkin's disease (certain subtypes only)
- Primary CNS lymphoma
- Lymphoproliferative disease in immunocompromised

Investigations

Atypical lymphocytes are common in EBV infection but also occur in other causes of IM, acute retroviral syndrome with HIV infection, viral hepatitis, mumps and rubella (Fig. 13.11A). A 'heterophile' antibody is present during the acute illness and convalescence, which is detected by the Paul–Bunnell or 'Monospot' test. Sometimes antibody production is delayed, so an initially negative test should be repeated. However, many children and 10% of adolescents with IM do not produce heterophile antibody at any stage.

Specific EBV serology confirms the diagnosis. Acute infection is characterised by IgM antibodies against the viral capsid, antibodies to EBV early antigen and the initial absence of antibodies to EBV nuclear antigen (anti-EBNA). Seroconversion of anti-EBNA at approximately 1 month after the initial illness may confirm the diagnosis in retrospect. CNS infections may be diagnosed by detection of viral DNA in cerebrospinal fluid.

Management

Treatment is largely symptomatic. If a throat culture yields a β-haemolytic streptococcus, penicillin should be given. Administration of ampicillin or amoxicillin in this condition commonly causes an itchy macular rash and should be avoided (Fig. 13.11B). When pharyngeal oedema is severe, a short course of corticosteroids, e.g. prednisolone 30 mg daily for 5 days, may help. Current antiviral drugs are not active against EBV.

Return to work or school is governed by physical fitness rather than laboratory tests; contact sports should be avoided until splenomegaly has resolved because of the danger of splenic rupture. Unfortunately, about 10% of patients with IM suffer a chronic relapsing syndrome.

Cytomegalovirus

Cytomegalovirus (CMV), like EBV, circulates readily among children. A second period of virus acquisition occurs among teenagers and young adults, peaking between the ages of 25 and 35 years, rather later than with EBV infection. CMV infection is persistent, and is characterised by subclinical cycles of active virus replication and by persistent low-level virus shedding. Most post-childhood infections are therefore acquired from asymptomatic excreters who shed virus in saliva, urine, semen and genital secretions. Sexual transmission and oral spread are common among adults, but infection may also be acquired by women caring for children with asymptomatic infections.

Clinical features

Most post-childhood CMV infections are subclinical, although some young adults develop an IM-like syndrome and some have a prolonged influenza-like illness lasting 2 weeks or more. Physical signs resemble those of IM, but in CMV infections hepatomegaly is more common, while lymphadenopathy, splenomegaly, pharyngitis and tonsillitis occur less often. Jaundice is uncommon and usually mild. Complications include meningoencephalitis, Guillain–Barré syndrome, autoimmune haemolytic anaemia, thrombocytopenia, myocarditis and skin eruptions, such as ampicillin-induced rash. Immunocompromised patients can develop hepatitis, oesophagitis, colitis, pneumonitis, retinitis, encephalitis and polyradiculitis.

Women who develop a primary CMV infection during pregnancy have about a 40% chance of passing CMV to the fetus, causing congenital infection and disease at any stage of gestation. Features include petechial rashes, hepatosplenomegaly and jaundice; 10% of infected infants will have long-term CNS sequelae, such as microcephaly, cerebral calcifications, chorioretinitis and deafness. Infections in the newborn usually are asymptomatic or have features of an IM-like illness, although some studies suggest that subtle sequelae affecting hearing or mental development may occur.

Investigations

Atypical lymphocytosis is not as prominent as in EBV infection and heterophile antibody tests are negative. LFTs are often abnormal, with an alkaline phosphatase level raised out of proportion to transaminases. Serological diagnosis depends on the detection of CMV-specific IgM antibody plus a four-fold rise or seroconversion of IgG. In the immunocompromised, antibody detection is unreliable and detection of CMV in an involved organ by PCR, culture or histopathology establishes the diagnosis. A positive culture of CMV in the blood may be useful in transplant populations but not in HIV-positive individuals, since in HIV infection CMV reactivates at regular intervals, but these episodes do not correlate well with episodes of clinical disease. Detection of CMV in urine is not helpful in diagnosing infection, except in neonates, since CMV is intermittently shed in the urine throughout life following infection.

Management

Only symptomatic treatment is required in the immunocompetent patient. Immunocompromised individuals are treated with ganciclovir 5 mg/kg IV twice daily or with oral valganciclovir 900 mg twice daily for at least 14 days. Foscarnet or cidofovir is also used in CMV treatment of immunocompromised patients who are resistant to or intolerant of ganciclovir-based therapy.

Dengue

Dengue is a febrile illness caused by a flavivirus transmitted by mosquitoes. It is endemic in Asia, the Pacific, Africa and the Americas (Fig. 13.12). Approximately 50 million infections occur annually and dengue is the most rapidly spreading mosquito-borne viral illness. The principal vector is the mosquito *Aedes aegypti*, which breeds in standing water; collections of water in containers, water-based air coolers and tyre dumps are a good environment for the vector in large cities. *Aedes albopictus* is a vector in some South-east Asian countries. There are four serotypes of dengue virus, all producing a similar clinical syndrome; type-specific immunity is life-long, but immunity against the other serotypes lasts only a few months. Dengue haemorrhagic fever (DHF) and dengue shock syndrome (DSS) occur in individuals who are immune to one dengue virus serotype and are then infected with another. Prior immunity results in increased uptake of virus by cells expressing the antibody Fc receptor and increased T-cell activation with resultant cytokine release, causing capillary leak and disseminated intravascular coagulation (DIC, pp. 201 and 1055).

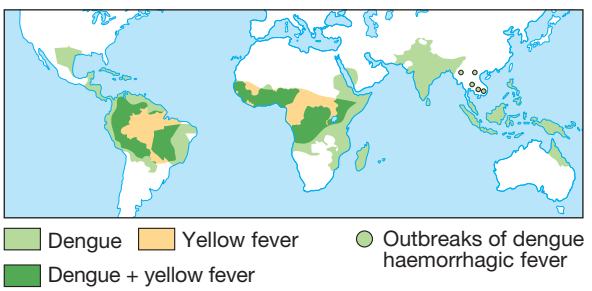

Fig. 13.12 Endemic zones of yellow fever and dengue. From Halstead 1997 – see p. 386.

Clinical features

Clinical features of dengue fever are listed in Box 13.37. Asymptomatic infections are common, particularly in children, but the disease is more severe in infants and the elderly. The initial febrile phase is frequently followed by a rash as the fever settles. Laboratory features include leucopenia, neutropenia, thrombocytopenia and elevated alanine aminotransferase (ALT) or aspartate aminotransferase (AST). Many symptomatic infections run an uncomplicated course, but complications or a protracted convalescence may ensue.

13.37 Clinical features of dengue fever

Incubation period
• 2–7 days
Prodrome
• 2 days of malaise and headache
Acute onset
• Fever, backache, arthralgias, headache, generalised pains ('break-bone fever'), pain on eye movement, lacrimation, scleral injection, anorexia, nausea, vomiting, pharyngitis, upper respiratory tract symptoms, relative bradycardia, prostration, depression, hyperaesthesia, dysgeusia, lymphadenopathy
Fever
• Continuous or 'saddle-back', with break on 4th or 5th day and then recrudescence; usually lasts 7–8 days
Rash
• Initial flushing faint macular rash in first 1–2 days. Maculopapular, scarlet morbilliform blanching rash from days 3–5 on trunk, spreading centrifugally and sparing palms and soles, onset often with fever defervescence. May desquamate on resolution or give rise to petechiae on extensor surfaces
Convalescence
• Slow and may be associated with prolonged fatigue syndrome, arthralgia or depression
Complications
• Dengue haemorrhagic fever and disseminated intravascular coagulation • Dengue shock syndrome • Hepatitis, cerebral haemorrhage or oedema, encephalitis, cranial nerve palsies, rhabdomyolysis, myocarditis • Vertical transmission if infection within 5 wks of delivery

The period 3–7 days after onset of fever is termed the 'critical' phase, during which signs of DHF or DSS may develop. In mild forms, petechiae occur in the arm when a blood pressure cuff is inflated to a point between systolic and diastolic blood pressure and left for 5 minutes (the positive 'tourniquet test') – a non-specific test of capillary fragility and thrombocytopenia. As the extent of capillary leak increases, there may be a raised haematocrit, tachycardia and hypotension, pleural effusions and ascites. This may progress to metabolic acidosis and multi-organ failure, including acute respiratory distress syndrome (ARDS, p. 192). Minor (petechiae, ecchymoses, epistaxis) or major (gastrointestinal or cerebrovascular) haemorrhage may occur.

13.38 WHO-proposed clinical definition of dengue

Probable dengue

- Exposure in an endemic area
- Fever
- Two of:
  - Nausea/vomiting
  - Rash
  - Aches/pains
  - Positive tourniquet test
  - Leucopenia
  - Any warning sign

Laboratory confirmation important

Needs regular medical observation and instruction in the warning signs

If there are no warning signs, need for hospitalisation is influenced by age, comorbidities, pregnancy and social factors

Dengue with warning signs

- Probable dengue plus one of:
  - Abdominal pain or tenderness
  - Persistent vomiting
  - Signs of fluid accumulation, e.g. pleural effusion or ascites
  - Mucosal bleed
  - Lethargy
  - Hepatomegaly > 2 cm
  - Rapid increase in haematocrit with fall in platelet count

Needs medical intervention, e.g. intravenous fluid

Severe dengue

- Severe plasma leakage leading to:
  - Shock (dengue shock syndrome)
  - Fluid accumulation with respiratory distress
- Severe haemorrhagic manifestations, e.g. GI haemorrhage
- Severe organ involvement:
  - Liver AST or ALT ≥ 1000 U/L
  - CNS: impaired consciousness
  - Cardiomyopathy
  - Other organs, e.g. renal impairment

Needs emergency medical treatment and specialist care with intensive care input

Adapted from http://www.who.int/csr/disease/dengue/en/ (ALT = alanine aminotransferase; AST = aspartate aminotransferase)

Diagnosis

In endemic areas, mild dengue must be distinguished from other viral infections. The WHO recently revised its clinical classification of dengue and is evaluating the usefulness of these categories in guiding diagnosis and treatment (Box 13.38). The diagnosis can be confirmed by seroconversion of IgM or a fourfold rise in IgG antibody titres. Serological tests may detect cross-reacting antibodies against other flaviviruses, including yellow fever vaccine. IgM/IgG ratios may be used to distinguish primary from secondary infection. Isolation of dengue virus from blood or detection of dengue virus RNA by PCR (p. 139) is available in specialist laboratories. Commercial enzyme-linked immunosorbent assay (ELISA) kits to detect the NS1 viral antigen, although less sensitive than PCR, are becoming more widely available in endemic areas.

Management and prevention

Treatment is supportive, emphasising fluid replacement and appropriate management of shock and organ dysfunction. With intensive care support, mortality rates are 1% or less. Aspirin should be avoided due to bleeding risk. Corticosteroids have not been shown to help. No existing antivirals are effective.

Breeding places of *Aedes* mosquitoes should be abolished and the adults destroyed by insecticides. There is no licensed vaccine available.

Yellow fever

Yellow fever is a haemorrhagic fever of the tropics, caused by a flavivirus. It is a zoonosis of monkeys in West and Central African, and South and Central American tropical rainforests, where it may cause devastating epidemics (see Fig. 13.12). Transmission is by tree-top mosquitoes *Aedes africanus* (Africa) and *Haemagogus* spp. (America). The infection is introduced to humans either by infected mosquitoes when trees are felled, or by monkeys raiding human settlements. In towns, yellow fever may be transmitted between humans by *Aedes aegypti*, which breeds efficiently in small collections of water. The distribution of this mosquito is far wider than that of yellow fever, and more widespread infection is a continued threat.

Yellow fever causes approximately 200 000 infections each year, mainly in sub-Saharan Africa, and the number is increasing. Overall mortality is around 15%, although this varies widely. Humans are infectious during the viraemic phase, which starts 3–6 days after the bite of the infected mosquito and lasts for 4–5 days.

Clinical features

After an incubation period of 3–6 days, yellow fever is often a mild febrile illness lasting less than 1 week, with headache, myalgia, conjunctival erythema and bradycardia. This is followed by fever resolution (defervescence), but in some cases, fever recurs after a few hours to days. In more severe disease, fever recrudescence is associated with lower back pain, abdominal pain and somnolence, prominent nausea and vomiting, bradycardia and jaundice. Liver damage and DIC lead to bleeding with petechiae, mucosal haemorrhages and gastrointestinal bleeding. Shock, hepatic failure, renal failure, seizures and coma may ensue.

Diagnosis

The differential diagnosis includes malaria, typhoid, viral hepatitis, leptospirosis, haemorrhagic fevers and aflatoxin poisoning. Diagnosis of yellow fever can be confirmed by viral isolation from blood in the first 24 days of illness, the presence of IgM or a fourfold rise in IgG antibody titre. Leucopenia is characteristic. Liver biopsy should be avoided in life due to the risk of fatal bleeding. Post-mortem features, such as acute mid-zonal necrosis and Councilman bodies with minimal inflammation in the liver, are suggestive but not specific. Immunohistochemistry for viral antigens improves specificity.

Management and prevention

Treatment is supportive, with meticulous attention to fluid and electrolyte balance, urine output and blood pressure. Blood transfusions, plasma expanders and peritoneal dialysis may be necessary. Patients should be isolated, as their blood and body products may contain virus particles.

A single vaccination with a live attenuated vaccine gives full protection for at least 10 years. Potential side-effects include hypersensitivity, encephalitis and systemic features of yellow fever (viscerotropic disease) caused by the attenuated virus. Vaccination is not recommended in people who are significantly immunosuppressed. The risk of vaccine side-effects must be balanced against the risk of infection for less immunocompromised hosts, pregnant women and older patients. An internationally recognised certificate of vaccination is sometimes necessary when crossing borders.

Viral haemorrhagic fevers

Viral haemorrhagic fevers (VHF) are zoonoses caused by several different viruses (Box 13.39). They are geographically restricted and occur in rural settings or in health-care facilities. All of these viral illnesses, except Ebola and Marburg, have mild self-limiting forms.

Serological surveys have shown that Lassa fever is widespread in West Africa and may lead to up to 500 000 infections annually. Mortality overall may be low, as 80% of cases are asymptomatic, but in hospitalised cases mortality averages 15%. Ebola outbreaks have occurred at a rate of approximately one per year, involving up to a few hundred cases. The largest outbreaks have been in the Democratic Republic of Congo, Uganda and Sudan. Marburg has been documented less frequently, with outbreaks in the Democratic Republic of Congo and Uganda, but the largest outbreak to date involved 163 cases in Angola in 2005. Mortality rates of Ebola and Marburg are high.

VHF have extended into Europe, with an outbreak of Congo–Crimean haemorrhagic fever in Turkey in 2006, and cases of haemorrhagic fever with renal syndrome in the Balkans and Russia. These conditions remain very rare in the UK, with about one case of Lassa fever arriving in the country every 2 years.

Kyasanur forest disease is a tick-borne VHF currently confined to a small focus in Karnataka, India; there are about 500 cases annually. Monkeys are the principal hosts, but with forest felling, there are fears that this disease will increase.

New outbreaks and new agents are identified sporadically. In 2008, Lujo virus, a novel arenavirus, caused an outbreak of VHF involving a woman from Zambia and several health-care workers associated with her care, and had 80% fatality. Details on recent disease outbreaks can be found at the WHO website (www.who.int).

Clinical features

VHF present with non-specific fever, malaise, body pains, sore throat and headache. On examination, conjunctivitis, throat injection, an erythematous or petechial rash, haemorrhage, lymphadenopathy and bradycardia may be noted. The viruses cause endothelial dysfunction with the development of capillary leak. Bleeding is due to endothelial damage and platelet dysfunction. Hypovolaemic shock and ARDS may develop (p. 192).

Haemorrhage is a late feature of VHF and most patients present with earlier features. In Lassa fever, joint and abdominal pain is prominent. A macular blanching rash may be present but bleeding is unusual, occurring in only 20% of hospitalised patients. Encephalopathy may develop and deafness affects 30% of survivors.

The clue to the viral aetiology comes from the travel and exposure history. Travel to an outbreak area, activity in a rural environment and contact with sick individuals or animals within 21 days all increase the risk of VHF. Enquiry should be made about insect bites, hospital visits and attendance at ritual funerals (Ebola virus infection). For Lassa fever, retrosternal pain, pharyngitis and proteinuria have a positive predictive value of 80% in West Africa.

Investigations and management

Non-specific findings include leucopenia, thrombocytopenia and proteinuria. In Lassa fever, an AST > 150 U/L is associated with a 50% mortality. It is important to exclude other causes of fever, especially malaria, typhoid and respiratory tract infections. Most patients suspected of having a VHF in the UK turn out to have malaria.

The diagnosis of VHF must be considered in all febrile individuals who present within 21 days of leaving an endemic area or who present with haemorrhage or organ failure. A febrile patient from an endemic area within the incubation period, who has specific epidemiological risk factors (see Fig. 13.5, p. 311) or who has signs of organ failure or haemorrhage, should be treated as being at high risk of VHF; appropriate infection control measures must be implemented and the patient transferred to a centre with biosafety level (BSL) 4 facilities. Individuals with a history of travel within 21 days and fever, but without the relevant epidemiological features or signs of VHF, are classified as medium-risk and should have an initial blood sample tested to exclude malaria. If this is negative, relevant specimens (blood, throat swab, urine and pleural fluid, if available) are collected and sent to an appropriate reference laboratory for nucleic acid detection (PCR), virus isolation, and serology. If patients are still felt to be at significant risk of VHF or if infection is confirmed, they should be transferred to a specialised high-security infectious disease unit. All further laboratory tests should be performed at BSL4. Transport requires an ambulance with BSL3 facilities.

13.39 Viral haemorrhagic fevers

Disease	Reservoir	Transmission	Incubation period	Geography	Mortality rate	Clinical features of severe disease[1]
Lassa fever	Multimammate rats (*Mastomys natalensis*)	Urine from rat Body fluids from patients	6–21 days	West Africa	15%	Haemorrhage, shock, encephalopathy, ARDS (responds to ribavirin) Deafness in survivors
Ebola fever	Undefined (?bats)	Body fluids from patients Handling infected primates	2–21 days	Central Africa Outbreaks as far north as Sudan	25–90%	Haemorrhage, hepatic and renal failure
Marburg fever	Undefined	Body fluids from patients Handling infected primates	3–9 days	Central Africa Outbreak in Angola	25–90%	Haemorrhage, diarrhoea, encephalopathy, orchitis
Yellow fever	Monkeys	Mosquitoes	3–6 days	See Fig. 13.12	~15%	Hepatic failure, renal failure, haemorrhage
Dengue	Humans	*Aedes aegypti*	2–7 days	See Fig. 13.12	< 10%[2]	Haemorrhage, shock
Crimean–Congo haemorrhagic fever	Small vertebrates Domestic and wild animals	*Ixodes* tick Body fluids	1–3 days up to 9 days 3–6 days up to 13 days	Africa, Asia, Eastern Europe	30%	Encephalopathy, haemorrhage, hepatic or renal failure, ARDS
Rift Valley fever	Domestic livestock	Contact with animals, mosquito or other insect bites	2–6 days	Africa, Arabian peninsula	1%	Haemorrhage, blindness, meningoencephalitis (complications only in a minority)
Kyasanur fever	Monkeys	Ticks	3–8 days	Karnataka State, India	5–10%	Haemorrhage, pulmonary oedema, neurological features, iridokeratitis in survivors
Bolivian and Argentinian haemorrhagic fever (Junin and Machupo viruses)	Rodents (*Calomys* spp.)	Urine, aerosols Body fluids from case (rare)	5–19 days (3–6 days for parenteral)	South America	15–30%	Haemorrhage, shock, cerebellar signs (may respond to ribavirin)
Haemorrhagic fever with renal syndrome (Hantaan fever)	Rodents	Aerosols from faeces	5–42 days (typically 14 days)	Northern Asia, northern Europe, Balkans	5%	Acute renal impairment, cerebrovascular accidents, pulmonary oedema, shock (hepatic failure and haemorrhagic features only in some variants)

[1]All potentially have circulatory failure. [2]Mortality of uncomplicated and haemorrhagic dengue fever, respectively.

In addition to general supportive measures, ribavirin is given intravenously (100 mg/kg, then 25 mg/kg daily for 3 days and 12.5 mg/kg daily for 4 days) when Lassa fever or South American haemorrhagic fevers are suspected.

Prevention

Ribavirin has been used as prophylaxis in close contacts in Lassa fever but there are no formal trials of its efficacy.

Viral infections of the skin

Herpes simplex virus 1 and 2

Herpes simplex viruses (HSV) cause recurrent mucocutaneous infection; HSV-1 typically involves the mucocutaneous surfaces of the head and neck (Fig. 13.13), whilst HSV-2 predominantly involves the genital mucosa (pp. 415 and 418), although there is overlap (see Box 13.31, p. 317). The seroprevalence of HSV-1 is 30–100%, varying by socioeconomic status, while that of HSV-2 is 20–60%. Infection is acquired by inoculation of viruses shed by an infected individual on to a mucosal surface in a susceptible person. The virus infects sensory and autonomic neurons and establishes latent infection in the nerve ganglia. Primary infection is followed by episodes of reactivation throughout life.

Clinical features

Primary HSV-1 or 2 infection is more likely to be symptomatic later in life, causing gingivostomatitis, pharyngitis or painful genital tract lesions. The primary

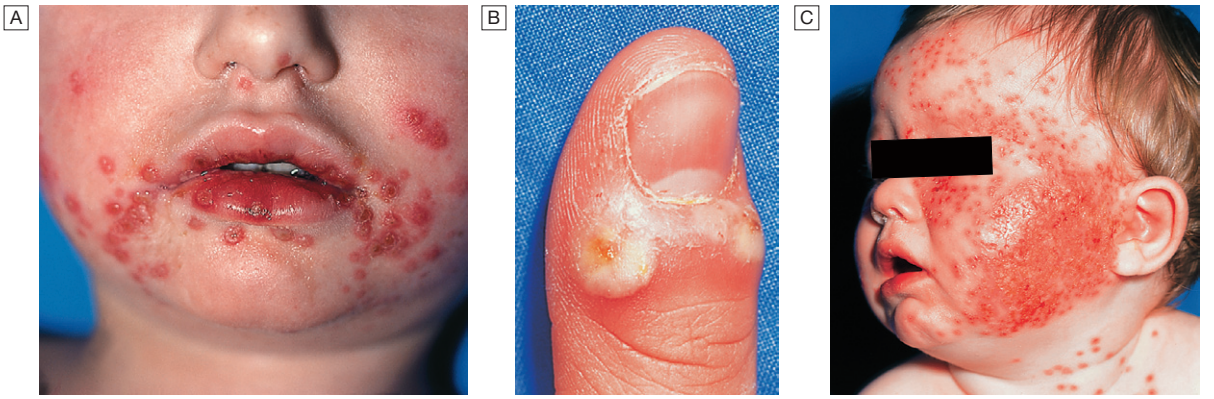

Fig. 13.13 Cutaneous manifestations of herpes simplex virus-1 (HSV-1). A Acute HSV-1. There were also vesicles in the mouth – herpetic stomatitis. B Herpetic whitlow. C Eczema herpeticum. HSV-1 infection spreads rapidly in eczematous skin.

attack may be associated with fever and regional lymphadenopathy.

Recurrence

Recurrent attacks occur throughout life, most often in association with concomitant medical illness, menstruation, mechanical trauma, immunosuppression, psychological stress or, for oral lesions, ultraviolet light exposure. HSV reactivation in the oral mucosa produces the classical 'cold sore' or 'herpes labialis'. Prodromal hyperaesthesia is followed by rapid vesiculation, pustulation and crusting. Recurrent HSV genital disease is a common cause of recurrent painful ulceration (pp. 415 and 418). An inoculation lesion on the finger gives rise to a paronychia termed a 'whitlow' in contacts of patients with herpetic lesions (Fig. 13.13B). It was formerly seen in health-care workers and dentists, but is prevented by protective gloves.

Complications

Disseminated cutaneous lesions can occur in individuals with underlying dermatological diseases, such as eczema (eczema herpeticum) (Fig. 13.13C). Herpes keratitis presents with pain and blurring of vision; characteristic dendritic ulcers are visible on slit-lamp examination and may produce corneal scarring and permanent visual impairment.

Primary HSV-2 can cause meningitis or transverse myelitis. HSV is the leading cause of sporadic viral encephalitis (p. 1205); this serious complication may occur following either primary or secondary disease, usually with HSV-1. A haemorrhagic necrotising temporal lobe cerebritis produces temporal lobe epilepsy and altered consciousness/coma. Without treatment, mortality is 80%. HSV is also implicated in the pathogenesis of Bell's palsy with a lower motor neuron VII nerve palsy, although antivirals have not been demonstrated to improve outcome.

Neonatal HSV disease is usually associated with primary infection of the mother at term (see Box 13.28, p. 314). In excess of two-thirds of cases develop disseminated disease with cutaneous lesions, hepatitis, pneumonitis and frequently encephalitis.

Immunocompromised hosts can develop visceral disease with oesophagitis, hepatitis, pneumonitis, encephalitis or retinitis.

Diagnosis

Differentiation from other vesicular eruptions is achieved by demonstration of virus in vesicular fluid, usually by direct immunofluorescence or PCR. HSV encephalitis is diagnosed by a positive PCR for HSV in CSF. Serology is of limited value, only confirming whether an individual has had previous infection.

Management

The acyclic antivirals are the treatment of choice for HSV infection (see Box 13.33, p. 318). Therapy of localised disease must commence in the first 48 hours of clinical disease (primary or recurrent); thereafter it is unlikely to influence clinical outcome. Oral lesions in an immunocompetent individual may be treated with topical aciclovir. All severe manifestations should be treated, regardless of the time of presentation. Suspicion of HSV encephalopathy is an indication for immediate empirical antiviral therapy. Aciclovir resistance is encountered occasionally in immunocompromised hosts, in which case foscarnet is the treatment of choice.

Human herpesvirus 8

Human herpesvirus 8 (HHV-8) (see Box 13.31, p. 317) causes Kaposi's sarcoma in both AIDS-related and endemic non-AIDS-related forms (p. 397). HHV-8 is spread via saliva, and men who have sex with men have increased incidence of infection. Seroprevalence varies widely, being highest in sub-Saharan Africa. HHV-8 also causes two rare haematological malignancies: primary effusion lymphoma and multicentric Castleman's disease. Current antivirals are not effective.

Enterovirus infections

Hand, foot and mouth disease

This systemic infection is usually caused by Coxsackie viruses or occasionally echoviruses. It affects children and occasionally adults, resulting in local or household outbreaks, particularly in the summer months. A relatively mild illness with fever and lymphadenopathy develops after an incubation period of approximately 10 days; 2–3 days later, a painful papular or vesicular rash appears on palmoplantar surfaces of hands and feet, with associated oral lesions on the buccal mucosa and tongue that ulcerate rapidly. A papular

erythematous rash may appear on buttocks and thighs. Antiviral treatment is not available and management consists of symptom relief with analgesics.

Herpangina

This infection, caused by Coxsackie viruses, primarily affects children and teenagers in the summer months. It is characterised by a small number of vesicles at the soft/hard palate junction, often associated with high fever, an extremely sore throat and headache. The lesions are short-lived, rupturing after 2–3 days and rarely persisting for more than 1 week. Treatment is with analgesics if required. Culture of the virus from vesicles or DNA detection by PCR differentiates herpangina from HSV.

Poxviruses

These DNA viruses are rare but potentially important pathogens.

Smallpox (variola)

This severe disease, which has high mortality, was eradicated worldwide by a global vaccination programme. Interest in the disease has re-emerged due to its potential as a bioweapon. The virus is spread by the respiratory route or contact with lesions, and is highly infectious.

The incubation period is 7–17 days. A prodrome with fever, headache and prostration leads, in 1–2 days, to the rash, which develops through macules and papules to vesicles and pustules, worst on the face and distal extremities. Lesions in one area are all at the same stage of development with no cropping (unlike chickenpox). Vaccination can lead to a modified course of disease with milder rash and lower mortality.

If a case of smallpox is suspected, national public health authorities must be contacted. Electron micrography (like Fig. 13.14) and DNA detection tests (PCR) are used to confirm smallpox or, using specific primers, an alternative poxvirus.

Monkeypox

Despite the name, the animal reservoirs for this virus are probably small squirrels and rodents. It causes a rare zoonotic infection in communities in the rainforest belt of Central Africa, producing a vesicular rash that is indistinguishable from smallpox, but differentiated by the presence of lymphadenopathy. Little person-to-person transmission occurs. Outbreaks outside Africa have been linked to importation of African animals as exotic pets. Diagnosis is by electron micrography and/or DNA detection (PCR).

Cowpox

Humans in contact with infected cows develop large vesicles, usually on the hands or arms and associated with fever and regional lymphadenitis. The reservoir is thought to be wild rodents, and the virus also produces symptomatic disease in cats and a range of other animals.

Vaccinia virus

This laboratory strain is the basis of the existing vaccine to prevent smallpox. Widespread vaccination is no longer recommended due to the likelihood of local spread from the vaccination site (potentially life-threatening in those with eczema (eczema vaccinatum) or immune deficiency) and of encephalitis. However, vaccination may still be recommended for key medical staff.

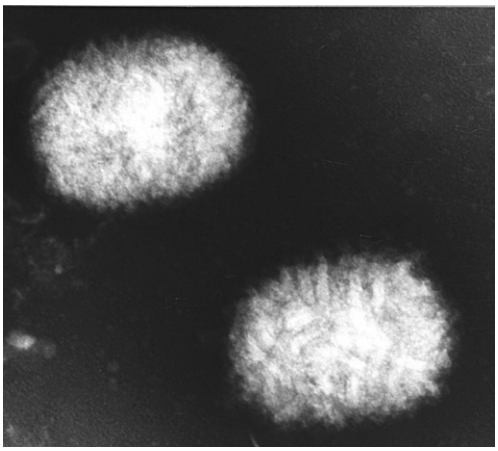

Fig. 13.14 Electron micrograph of molluscum contagiosum, a poxvirus.

Other poxviruses: orf and molluscum contagiosum

See page 1279 and Figure 13.14.

Gastrointestinal viral infections

Norovirus (Norwalk agent)

Norovirus is the most common cause of infectious gastroenteritis in the UK and causes outbreaks in closed communities, such as long-stay hospital wards, cruise ships and military camps. Food handlers may also transmit this virus, which is relatively resistant to decontamination procedures. The incubation period is 24–48 hours. High attack rates and prominent vomiting are characteristic. Diagnosis is by electron microscopy, antigen or DNA detection (PCR) in stool samples. The virus is highly infectious and cases should be isolated and environmental surfaces cleaned with detergents and disinfected with bleach.

Astrovirus

Astroviruses cause diarrhoea in small children and occasionally in immunocompromised adults.

Rotavirus

Rotaviruses are the major cause of diarrhoeal illness in young children worldwide and cause 10–20% of deaths due to gastroenteritis in developing countries. There are winter epidemics in developed countries, particularly in nurseries. Adults are less often infected but those in close contact with cases may develop disease. The virus infects enterocytes, causing decreased surface absorption. The incubation period is 48 hours and patients present with watery diarrhoea, vomiting, fever and abdominal pain. Dehydration is prominent. Diagnosis is aided by commercially available enzyme immunoassay kits, which require fresh or refrigerated stool samples. Immunity develops to natural infection. Monovalent and multivalent vaccines have been licensed in many

countries and have now demonstrated efficacy in large trials in Africa and the Americas. Increased rates of intussusception were observed with early rotavirus vaccines, but the benefits of the recently licensed vaccines outweigh this risk.

Hepatitis viruses (A–E)

See Chapter 23.

Other viruses

Adenoviruses are frequently identified from stool culture and implicated as a cause of diarrhoea in children. They have also been linked to cases of intussusception.

Respiratory viral infections

These infections are described on page 681.

Adenoviruses, rhinoviruses and enteroviruses (Coxsackie viruses and echoviruses) often produce nonspecific symptoms. Parainfluenza and respiratory syncytial viruses cause upper respiratory tract disease, croup and bronchiolitis in small children and pneumonia in the immunocompromised. Respiratory syncytial virus also causes pneumonia in nursing home residents and may be associated with nosocomial pneumonia. In recent years, metapneumovirus and bocavirus have been identified as causes of upper and occasionally lower respiratory tract infection. They may also cause pneumonia in immunosuppressed individuals, such as recipients of allogeneic haematopoietic stem cell transplants. The severe acute respiratory syndrome (SARS) caused by the SARS coronavirus emerged as a major respiratory pathogen during an outbreak in 2002–2003, with 8000 cases and 10% mortality (p. 683). In 2012, a novel coronavirus, distantly related to the SARS coronavirus, caused several deaths connected with pneumonia and acute renal failure in patients originating from the Middle East.

Viral infections with neurological involvement

See also page 1205.

Japanese B encephalitis

This flavivirus is an important cause of endemic encephalitis in Japan, China, Russia, South-east Asia, India and Pakistan; outbreaks also occur elsewhere. There are 10 000–20 000 cases reported to the WHO annually. Pigs and aquatic birds are the virus reservoirs and transmission is by mosquitoes. Exposure to rice paddies is a recognised risk factor.

Clinical features

The incubation period is 4–21 days. Most infections are subclinical in childhood and 1% or less of infections lead to encephalitis. Initial systemic illness with fever, malaise and anorexia is followed by photophobia, vomiting, headache and changes in brainstem function. Neurological features other than encephalitis include meningitis, seizures, cranial nerve palsies, flaccid or spastic paralysis, and extrapyramidal features. Mortality with neurological disease is 25%. Most children die from respiratory failure with infection of brainstem nuclei. Approximately 50% of survivors are left with neurological sequelae.

Investigations, management and prevention

Other infectious causes of encephalitis should be excluded (p. 1205). There is neutrophilia and often hyponatraemia. CSF analysis reveals lymphocytosis and elevated protein. Serological testing may be helpful and there is a CSF antigen test.

Treatment is supportive, anticipating and treating complications. Vaccination for travellers to endemic areas during the monsoon period is effective prophylaxis. Some endemic countries include this vaccination in their childhood schedules.

West Nile virus

This flavivirus has emerged as an important cause of neurological disease in an area that extends from Australia, India and Russia through Africa and Southern Europe and across to North America. The disease has an avian reservoir and a mosquito vector. The elderly are at increased risk of neurological disease.

Clinical features

Most infections are asymptomatic. After 2–6 days' incubation, a mild febrile illness and arthralgia constitute the most common clinical presentation. A prolonged incubation may be seen in immunocompromised individuals. Children may develop a maculopapular rash. Neurological disease is seen in 1% and is characterised by encephalitis, meningitis or asymmetric flaccid paralysis with 10% mortality.

Diagnosis and management

Diagnosis is by serology or detection of viral RNA in blood or CSF. Serological tests may show cross-reactivity with other flaviviruses, including vaccine strains. Treatment is supportive.

Enterovirus 71

Enterovirus 71 has caused outbreaks around the globe of enteroviral disease with hand, foot and mouth disease (p. 326) and aseptic meningitis. Some cases have been complicated by encephalitis with flaccid paralysis or by brainstem involvement and death. The virus can be isolated from vesicle fluid, stool or CSF, and viral RNA can be detected in CSF by reverse transcription (RT-)PCR.

Nipah virus encephalitis

In 1999, a newly discovered paramyxovirus in the Hendra group, the Nipah virus, caused an epidemic of encephalitis amongst Malaysian pig farmers. Infection is through direct contact with pig secretions. Mortality is around 30%. Antibodies to the Hendra virus are present in 76% of cases.

Human T-cell lymphotropic virus type I

Human T-cell lymphotropic virus type I (HTLV-1) is a retrovirus which causes chronic infection with development of adult T-cell leukaemia/lymphoma or HTLV-1-associated myelopathy (HAM) in a subset of those infected (p. 1043). It is found mainly in Japan, the Caribbean, Central and South America, and the Seychelles.

HAM or tropical spastic paraparesis occurs in less than 5% of those with chronic infection, and presents with gait disturbance, spasticity of the lower extremities, urinary incontinence, impotence and sensory disturbance. Myositis and uveitis may also occur with HTLV-1 infection. Serology confirms the diagnosis. Treatment is usually supportive for asymptomatic patients but can include zidovudine and interferon-alfa for leukaemia. The role of antivirals in other settings including HAM is being investigated.

Viral infections with rheumatological involvement

Rheumatological syndromes characterise a variety of viral infections ranging from exanthems, such as rubella and parvovirus B19 (p. 315), to blood-borne viruses, such as HBV and HIV-1.

Chikungunya virus

Chikungunya is an alphavirus that causes fever, rash and arthropathy. It is found principally in Africa and Asia, including India. Humans and non-human primates are the main reservoir and the main vector is the *Aedes aegypti* mosquito. Cases occur in epidemics on a background of sporadic cases. In 2007, an outbreak extended as far north as Italy.

The incubation period is 2–12 days. A period of fever may be followed by an afebrile phase and then recrudescence of fever. Children may develop a maculopapular rash. Adults are susceptible to arthritis, which causes early morning pain and swelling, most often in the small joints. Arthritis can persist for months and may become chronic in individuals who are positive for human leucocyte antigen (HLA)-B27. Related alphaviruses causing similar syndromes include Sindbis virus (Scandinavia and Africa), O'nyong-nyong virus (Central Africa), Ross River virus (Australia) and Mayaro virus (Caribbean and South America).

Diagnosis is by serology but cross-reactivity between alphaviruses occurs. Treatment is symptomatic.

PRION DISEASES

Prions (p. 134) cause transmissible spongiform encephalopathies in humans, sheep, cows and cats (Box 13.40 and p. 1211). The prion protein is not inactivated by cooking or conventional sterilisation, and transmission is thought to occur by consumption of infected CNS tissue or by inoculation (e.g. via depth EEG electrodes, corneal grafts, cadaveric dura mater grafts and pooled cadaveric growth hormone preparations). The same diseases can occur in an inherited form, due to mutations in the PrP gene.

The apparent transmission of bovine spongiform encephalopathy (BSE) to humans following an outbreak of BSE in the UK beginning in the late 1980s has caused great concern, leading to precautionary measures in the UK, such as leucodepletion of all blood used for transfusion, and the mandatory use of disposable surgical instruments wherever possible for tonsillectomy, appendicectomy and ophthalmological procedures.

13.40 Prion diseases affecting humans

Disease	Mechanism
Creutzfeldt–Jakob disease	
Sporadic	Spontaneous PrP^{c} to PrP^{Sc} conversion or somatic mutation
Familial	Mutations in the PrP gene
Variant	Infection from bovine spongiform encephalopathy
Gerstmann–Sträussler–Scheinker disease	Mutations in the PrP gene
Fatal familial insomnia	Mutations in the PrP gene
Sporadic fatal insomnia	Spontaneous PrP^{c} to PrP^{Sc} conversion or somatic mutation
Kuru	Cannibalism

BACTERIAL INFECTIONS

Bacterial infections of the skin, soft tissues and bones

Most infections of the skin, soft tissues and bone are caused by either staphylococci (mainly *Staph. aureus*) or streptococci (mainly *Strep. pyogenes*). Clinical manifestations are also described in Chapters 25 and 27.

Staphylococcal infections

Staphylococci are usually found colonising the anterior nares and skin. Traditionally, staphylococci were divided into two groups according to their ability to produce coagulase, an enzyme that converts fibrinogen to fibrin in rabbit plasma, causing it to clot. *Staph. aureus* is coagulase-positive, and most other species coagulase-negative. The coagulase test is now less commonly undertaken, with identification of *Staph. aureus* often achieved by other methods.

Staph. aureus is the main cause of staphylococcal infections. *Staph. intermedius* is another coagulase-positive staphylococcus, which causes infection following dog bites. Among coagulase-negative organisms, *Staph. epidermidis* is the predominant commensal organism of the skin, and can cause severe infections in those with central venous catheters or implanted prosthetic materials. *Staph. saprophyticus* is part of the normal vaginal flora and causes urinary tract infections in sexually active young women. Others implicated in human infections include *Staph. lugdunensis*, *Staph. schleiferi*, *Staph. haemolyticus* and *Staph. caprae*. Coagulase-negative staphylococci are not usually identified to species level.

Staphylococci are particularly dangerous if they gain access to the blood stream, having the potential to cause disease in many sites (Fig. 13.15). In any patient with staphylococcal bacteraemia, especially injection drug-users, the possibility of endocarditis must be considered (p. 625). Growth of *Staph. aureus* in blood cultures should not be dismissed as a 'contaminant' unless all possible underlying sources have been excluded and repeated

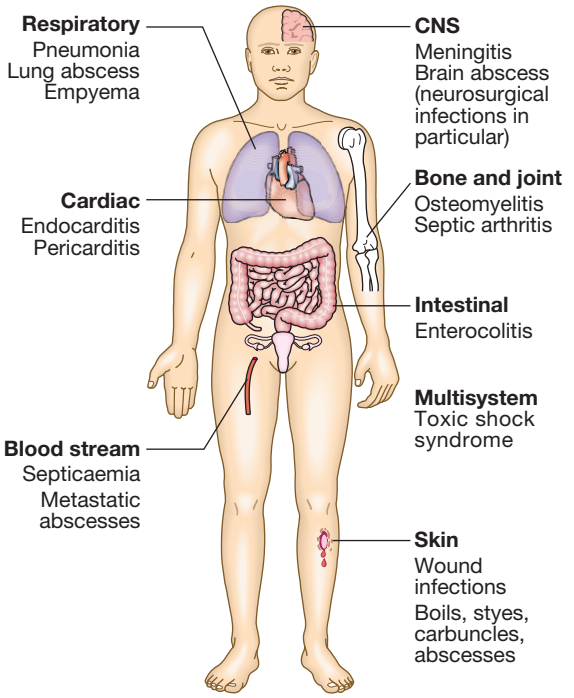

Fig. 13.15 Infections caused by *Staphylococcus aureus*.

blood culture is negative. Any evidence of spreading cellulitis indicates the urgent need for an antistaphylococcal antibiotic, such as flucloxacillin. This is particularly true for mid-facial cellulitis, which can result in cavernous sinus thrombophlebitis.

In addition, *Staph. aureus* can cause severe systemic disease due to the effects of toxin produced at superficial sites in the absence of tissue invasion by bacteria.

Skin infections

Staphylococcal infections cause ecthyma, folliculitis, furuncles, carbuncles, bullous impetigo and the scalded skin syndrome (pp. 1275–1276). They may also be involved in necrotising infections of the skin and subcutaneous tissues (p. 305).

Wound infections

Many wound infections are caused by staphylococci, which may significantly prolong post-operative hospital stays (Fig. 13.16A). Prevention involves careful attention to hand hygiene, skin preparation and aseptic technique, and the use of topical and systemic antibiotic prophylaxis.

Treatment is by drainage of any abscesses plus adequate dosage of antistaphylococcal antibiotics. These should be instituted early, particularly if prosthetic implants of any kind have been inserted.

Cannula-related infection

Staphylococcal infection associated with cannula sepsis (Fig. 13.16B and p. 304) and thrombophlebitis is an important and, unfortunately, extremely common reason for morbidity following hospital admission. The Visual Infusion Phlebitis (VIP) score is a useful way of monitoring cannulae (Box 13.41). Staphylococci have a predilection for plastic, rapidly forming a biofilm which remains as a source of bacteraemia as long as the plastic is in situ. Local poultice application may relieve

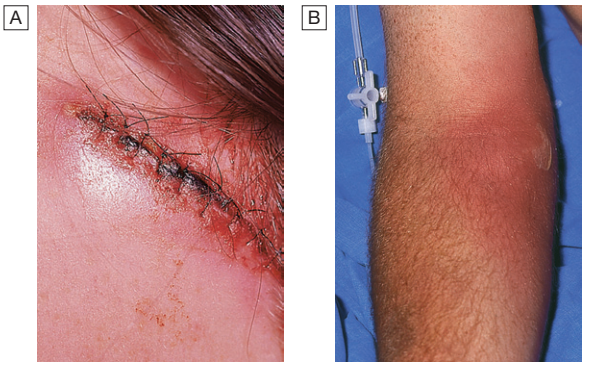

Fig. 13.16 Manifestations of skin infection with *Staph. aureus*. A Wound infection. B Cannula-related infection.

13.41 How to assess an intravenous cannula using the Visual Infusion Phlebitis score (VIP)*

Clinical features	Score	Assessment and management
IV site appears healthy	**0**	**No signs of phlebitis** Observe cannula
One of the following is evident: Slight pain near IV site Slight redness near IV site	**1**	**Possible first signs of phlebitis** Observe cannula
Two of the following are evident: Pain near IV site Erythema Swelling	**2**	**Early stage of phlebitis** Resite cannula
ALL of the following are evident and extensive: Pain along path of cannula Erythema Induration	**3**	**Medium stage of phlebitis** Resite cannula Consider treatment
ALL of the following are evident and extensive: Pain along path of cannula Erythema Induration Palpable venous cord	**4**	**Advanced stage of phlebitis or start of thrombophlebitis** Resite cannula Consider treatment
ALL of the following are evident: Pain along path of cannula Erythema Induration Palpable venous cord Pyrexia	**5**	**Advanced stage of thrombophlebitis** Initiate treatment Resite cannula

*Adapted from Jackson A. Nursing Times 1997; 94:68–71.

symptoms but cannula removal and antibiotic treatment with flucloxacillin (or a glycopeptide if MRSA is suspected) are necessary if there is any suggestion of spreading infection.

Meticillin-resistant Staph. aureus

Resistance to meticillin, due to a penicillin-binding protein mutation, has been recognised in *Staph. aureus* for more than 30 years. The recognition of resistance to vancomycin/teicoplanin (glycopeptides) in either glycopeptide intermediate *Staph. aureus* (GISA) or,

rarely, vancomycin-resistant (VRSA) strains threatens the ability to manage serious infections produced by such organisms. Meticillin-resistant *Staph. aureus* (MRSA) is now a major worldwide health care-acquired pathogen, accounting for up to 40% of staphylococcal bacteraemia in developed countries. Community-acquired MRSA (c-MRSA) currently accounts for 50% of all MRSA infections in the USA. These organisms have also acquired other virulence factors, such as Panton–Valentine leukocidin (PVL), which can cause rapidly fatal infection in young people. Clinicians must be aware of the potential danger of these infections and be prepared to take whatever appropriate infection control measures are locally advised (p. 145).

Treatment options for MRSA are shown in Box 6.17 (p. 151). Treatment should always be based on the results of antimicrobial susceptibility testing, since resistance to all these agents occurs. Milder MRSA infections may be treated with clindamycin, tetracyclines or co-trimoxazole. Glycopeptides, linezolid and daptomycin are reserved for treatment of more severe infections. PVL-producing *Staph. aureus* infections should be treated with protein-inhibiting antibiotics (clindamycin, linezolid).

Staphylococcal toxic shock syndrome

Staphylococcal toxic shock syndrome (TSS) is a serious and life-threatening disease associated with infection by *Staph. aureus*, which produces a specific toxin (toxic shock syndrome toxin 1, TSST1). It was commonly seen in young women in association with the use of highly absorbent intravaginal tampons but can occur with any *Staph. aureus* infection involving a relevant toxin-producing strain. The toxin acts as a 'superantigen', triggering significant T-helper cell activation and massive cytokine release.

TSS has an abrupt onset with high fever, generalised systemic upset (myalgia, headache, sore throat and vomiting), a generalised erythematous blanching rash resembling scarlet fever, and hypotension. It rapidly progresses over a matter of hours to multisystem involvement with cardiac, renal and hepatic compromise, leading to death in 10–20%. Recovery is accompanied at 7–10 days by desquamation (Fig. 13.17).

Fig. 13.17 Full-thickness desquamation after staphylococcal toxic shock syndrome.

The diagnosis is clinical and may be confirmed in menstrual cases by vaginal examination, the finding of a retained tampon, and microbiological examination by Gram stain demonstrating typical staphylococci. Subsequent culture and demonstration of toxin production are confirmatory.

Management

Treatment is with immediate and aggressive fluid resuscitation and an intravenous antistaphylococcal antibiotic (flucloxacillin or vancomycin), usually with the addition of a protein synthesis inhibitor (e.g. clindamycin) to inhibit toxin production. Intravenous immunoglobulin is occasionally added in the most severe cases on the basis of efficacy in streptococcal toxic shock. Women who recover should be advised not to use tampons for at least 1 year and should also be warned that, due to an inadequate antibody response to TSST1, the condition can recur.

Streptococcal infections

Streptococci are nasopharyngeal and gut commensals, which appear as Gram-positive cocci in chains (Fig. 6.3, p. 136). They are classified by the haemolysis they produce on blood agar (Fig. 6.4, p. 136) and by their serotypes (Box 13.42). Some streptococci (e.g. *Strep. milleri* group) defy simple classification.

Skin presentations of streptococcal infections

Group A streptococci (GAS) are the major cause of cellulitis, erysipelas and impetigo (pp. 1275 and 1277). Groups C and G streptococci cause cellulitis, in elderly, diabetic or immunocompromised patients in particular. Group B streptococcal (GBS) infection is an increasing problem at the extremes of age.

Streptococcal scarlet fever

Group A (or occasionally groups C and G) streptococci causing pharyngitis, tonsillitis or other infection may lead to scarlet fever, if the infecting strain produces a streptococcal pyrogenic exotoxin. Common in school-age children, scarlet fever can occur in young adults who have contact with young children. A diffuse erythematous rash occurs, which blanches on pressure (Fig. 13.18A), classically with circumoral pallor. The tongue, initially coated, becomes red and swollen ('strawberry tongue' – Fig. 13.18B). The disease lasts about 7 days, the rash disappearing in 7–10 days, followed by a fine desquamation. Residual petechial lesions in the antecubital fossa may be seen ('Pastia's sign' – Fig. 13.18C).

Treatment involves active therapy for the underlying infection (benzylpenicillin or orally available penicillin) plus symptomatic measures.

Streptococcal toxic shock syndrome

This is associated with severe group A (or occasionally group C or G) streptococcal skin infections producing one of a variety of toxins, such as pyogenic exotoxin A. Like staphylococcal toxic shock syndrome toxin (see above), these act as superantigens, stimulating a dramatic cytokine response. Initially, an influenza-like illness occurs with, in 50% of cases, signs of localised infection, most often involving the skin and soft tissues. A faint erythematous rash, mainly on the chest, rapidly

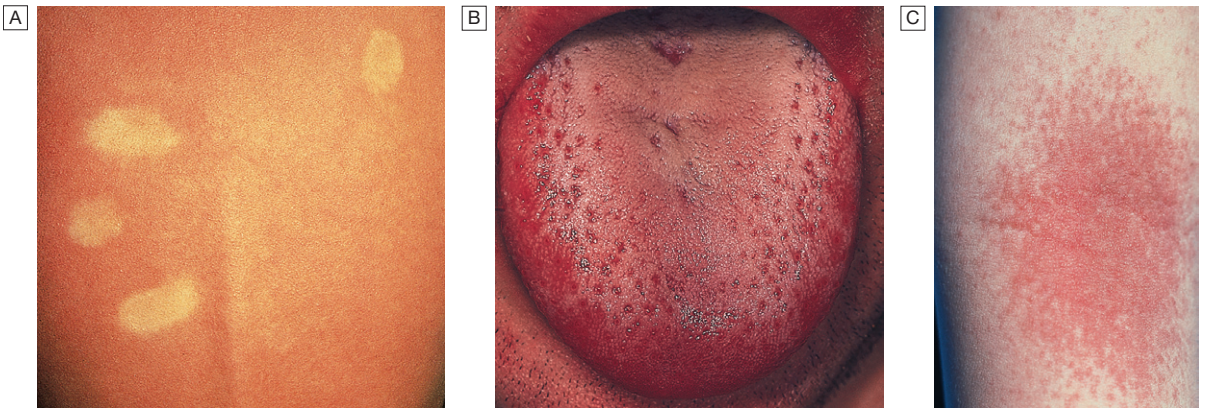

Fig. 13.18 Clinical features of scarlet fever. A Characteristic rash with blanching on pressure. B 'Strawberry tongue'. C Pastia's sign: a petechial rash in the cubital fossa.

13.42 Streptococcal and related infections

β-haemolytic group A (*Strep. pyogenes*)

- Skin and soft tissue infection (including erysipelas, impetigo, necrotising fasciitis)
- Streptococcal toxic shock syndrome
- Puerperal sepsis
- Scarlet fever
- Glomerulonephritis
- Rheumatic fever
- Bone and joint infection
- Tonsillitis

β-haemolytic group B (*Strep. agalactiae*)

- Neonatal infections, including meningitis
- Septicaemia
- Female pelvic infections
- Cellulitis

β-haemolytic group C (various zoonotic streptococci)

- Septicaemia
- Cellulitis
- Pharyngitis

α, β- or non-haemolytic group D enterococci (*E. faecalis/faecium*)

- Endocarditis
- Intra-abdominal infections
- Urinary tract infection

α, β- or non-haemolytic group D streptococci (*Strep. bovis*)

- Endocarditis
- Septicaemia
- Liver abscess
- Brain abscess

β-haemolytic group G streptococci

- Septicaemia
- Cellulitis
- Liver abscess

α-haemolytic viridans group (*Strep. mitis*, *sanguis*, *mutans*, *salivarius*)

- Septicaemia in immunosuppressed
- Endocarditis

α-haemolytic optochin-sensitive (*Strep. pneumoniae*)

- Pneumonia
- Meningitis
- Endocarditis
- Otitis media
- Septicaemia
- Spontaneous bacterial peritonitis

Anaerobic streptococci (*Peptostreptococcus* spp.)

- Peritonitis
- Dental infections
- Liver abscess
- Pelvic inflammatory disease

N.B. All streptococci can cause septicaemia.

progresses to circulatory shock. Without aggressive management, multi-organ failure will develop.

Fluid resuscitation must be undertaken, with parenteral antistreptococcal antibiotic therapy, usually with benzylpenicillin and a protein inhibitor, such as clindamycin, to inhibit toxin production. Intravenous immunoglobulin is usually administered in addition. If necrotising fasciitis is present, it should be treated as described on page 305 with urgent débridement.

Treponematoses

Syphilis

This disease is described on page 419.

Endemic treponematoses

Yaws

Yaws is a granulomatous disease, mainly involving the skin and bones; it is caused by *Treponema pertenue*, morphologically and serologically indistinguishable from the causative organisms of syphilis and pinta. It is important to establish the geographical origin and sexual history of patients to exclude a false-positive syphilis serology due to the endemic treponemal infections. Between 1950 and 1960, WHO campaigns treated over 60 million people and eradicated yaws from many areas, but the disease has persisted patchily throughout the tropics; there was resurgence in the 1980s and 1990s in West and Central Africa and the South Pacific.

Organisms are transmitted by bodily contact from a patient with infectious yaws through minor abrasions of the skin of another patient, usually a child. After an incubation period of 3–4 weeks, a proliferative granuloma containing numerous treponemes develops at the site of inoculation. This primary lesion is followed by secondary eruptions. In addition, there may be hypertrophic periosteal lesions of many bones, with underlying cortical rarefaction. Lesions of late yaws are characterised by destructive changes which closely resemble the osteitis and gummas of tertiary syphilis and which heal with much scarring and deformity. Investigations and management are outlined in Box 13.43.

The disease disappears with improved housing and cleanliness. In few fields of medicine have

13.43 Diagnosis and treatment of yaws, pinta and bejel

Diagnosis of early stages

- Detection of spirochaetes in exudate of lesions by dark ground microscopy

Diagnosis of latent and early stages

- Positive serological tests, as for syphilis (see Box 15.8, p. 421)

Treatment of all stages

- Single intramuscular injection of 1.2 g long-acting (e.g. benzathine) benzylpenicillin

chemotherapy and improved hygiene achieved such dramatic success as in the control of yaws.

Pinta and bejel

These two treponemal infections occur in poor rural populations with low standards of domestic hygiene, but are found in separate parts of the world. They have features in common, notably that they are transmitted by contact, usually within the family and not sexually, and in the case of bejel, through common eating and drinking utensils. Their diagnosis and management are as for yaws (see Box 13.43).

- *Pinta.* Pinta is probably the oldest of the human treponemal infections. It is found only in South and Central America, where its incidence is declining. The infection is confined to the skin. The early lesions are scaly papules or dyschromic patches on the skin. The late lesions are often depigmented and disfiguring.
- *Bejel.* Bejel is the Middle Eastern name for non-venereal syphilis, which has a patchy distribution across sub-Saharan Africa, the Middle East, Central Asia and Australia. It has been eradicated from Eastern Europe. Transmission is most commonly from the mouth of the mother or child and the primary mucosal lesion is seldom seen. The early and late lesions resemble those of secondary and tertiary syphilis (pp. 419–420) but cardiovascular and neurological disease is rare.

Tropical ulcer

Tropical ulcer is due to a synergistic bacterial infection caused by a fusobacterium (*F. ulcerans*, an anaerobe) and *Treponema vincentii*. It is common in hot, humid regions. The ulcer is most common on the lower legs and develops as a papule that rapidly breaks down to a sharply defined, painful ulcer. The base of the ulcer has a foul slough. Penicillin and metronidazole are useful in the early stages but rest, elevation and dressings are the mainstays of treatment.

Buruli ulcer

This ulcer is caused by *Mycobacterium ulcerans* and occurs widely in tropical rainforests. In 1999, a survey in Ghana found 6500 cases; there are an estimated 10 000 cases in West Africa as a whole.

The initial lesion is a small subcutaneous nodule on the arm or leg. This breaks down to form a shallow, necrotic ulcer with deeply undermined edges, which extends rapidly. Healing may occur after 6 months, but granuloma formation and the accompanying fibrosis cause contractures and deformity. Clumps of acid-fast bacilli can be detected in the ulcer floor.

A combination of rifampicin and streptomycin can cure the infection. Infected tissue should be removed surgically. Health campaigns in Ghana have successfully focused on early removal of the small, pre-ulcerative nodules.

Systemic bacterial infections

Brucellosis

Brucellosis is an enzootic infection (i.e. endemic in animals). Although six species of *Brucella* Gram-negative bacilli are known, only four are important to humans: *B. melitensis* (goats, sheep and camels in Europe, especially the Mediterranean basin, the Middle East, Africa, India, Central Asia and South America), *B. abortus* (cattle, mainly in Africa, Asia and South America), *B. suis* (pigs in South Asia) and *B. canis* (dogs). *B. melitensis* causes the most severe disease; *B. suis* is often associated with abscess formation.

Infected animals may excrete *Brucella* spp. in their milk for prolonged periods, and human infection is acquired by ingesting contaminated dairy products (especially unpasteurised milk), uncooked meat or offal. Animal urine, faeces, vaginal discharge and uterine products may act as sources of infection through abraded skin or via splashes and aerosols to the respiratory tract and conjunctiva.

Clinical features

Brucella spp. are intracellular organisms that survive for long periods within the reticulo-endothelial system. This explains many of the clinical features, including the chronicity of disease and tendency to relapse, even after antimicrobial therapy.

Acute illness is characterised by a high swinging temperature, rigors, lethargy, headache, joint and muscle pains, and scrotal pain. Occasionally, there is delirium, abdominal pain and constipation. Physical signs are non-specific, e.g. enlarged lymph nodes. Enlargement of the spleen may lead to hypersplenism and thrombocytopenia.

Localised infection (Fig. 13.19), which occurs in about 30% of patients, is more likely if diagnosis and treatment are delayed.

Diagnosis

Definitive diagnosis depends on the isolation of the organism. Blood cultures are positive in 75–80% of infections caused by *B. melitensis* and 50% of those caused by *B. abortus*. Bone marrow culture should not be used routinely but may increase the diagnostic yield, particularly if antibiotics have been given before specimens are taken. CSF culture in neurobrucellosis is positive in about 30% of cases. The laboratory should be alerted to a suspected diagnosis of brucellosis, as the organism has a propensity for infecting laboratory workers and must be cultured at an enhanced containment level.

Serology may also aid diagnosis. In endemic areas, a single high antibody titre of more than 1/320 or a four-fold rise in titre is needed to support a diagnosis of acute infection. The test usually takes several weeks to become

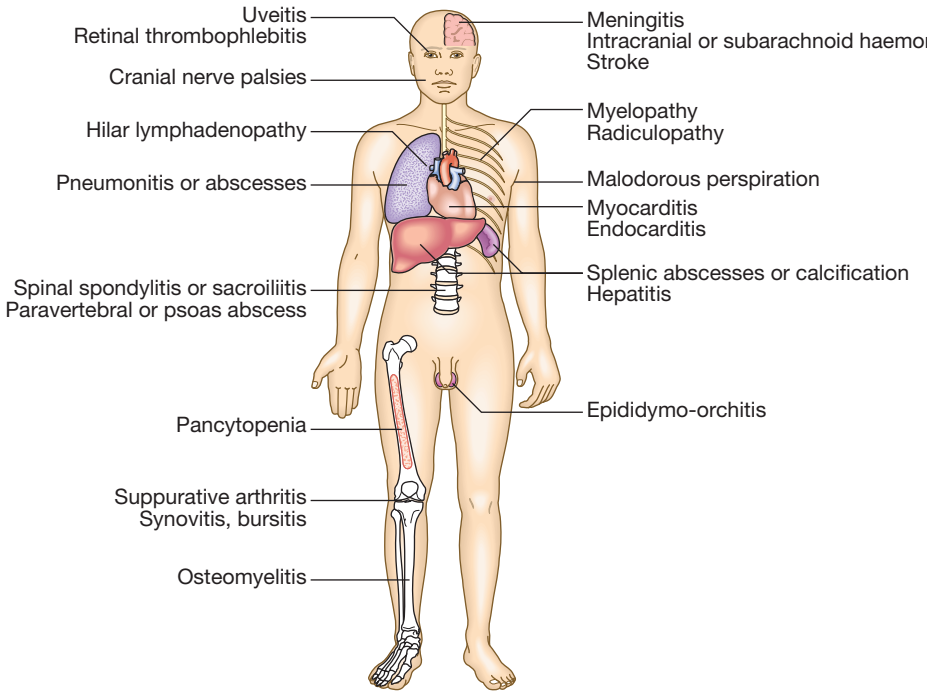

Fig. 13.19 Clinical features of brucellosis.

13.44 Treatment of brucellosis

Adults with non-localised disease

- Doxycycline 100 mg twice daily orally for 6 wks *plus* gentamicin 5 mg/kg IV once daily for 7 days

or

- Doxycycline 100 mg twice daily *plus* rifampicin 600–900 mg orally once daily for 6 wks

Bone disease

- Doxycycline 100 mg twice daily plus rifampicin 600–900 mg once daily orally for 6 wks *plus* gentamicin 5 mg/kg IV once daily for 7 days

or

- Ciprofloxacin 750 mg twice daily orally plus rifampicin 600–900 mg orally once daily for 3 mths

Neurobrucellosis

- Doxycycline 100 mg twice daily *plus* rifampicin 600–900 mg orally once daily for 6 wks *plus* ceftriaxone 2 g IV twice daily until CSF is clear (though susceptibility should be confirmed because sensitivity to third-generation cephalosporins varies amongst strains)

Endocarditis

- Almost always needs surgical intervention

plus

- Doxycycline 100 mg twice daily, rifampicin 600–900 mg orally once daily and co-trimoxazole 5 mg/kg of trimethoprim component for 6 mths *plus* gentamicin 5 mg/kg IV once daily for 2–4 wks

Pregnancy

- Rifampicin 600–900 mg orally once daily and co-trimoxazole 5 mg/kg of trimethoprim component for 4 wks, but caution in last week of pregnancy due to displacement of bilirubin from albumin by drugs and risk of kernicterus to the fetus

positive but should eventually detect 95% of acute infections.

Management

Aminoglycosides show synergistic activity with tetracyclines against brucellae. Treatment regimens for different forms of brucellosis are outlined in Box 13.44.

Borrelia infections

Borrelia are flagellated spirochaetal bacteria which infect humans after bites from ticks or lice. They cause a variety of human infections worldwide (Box 13.45).

Lyme disease

Lyme disease (named after the town of Old Lyme in Connecticut, USA) is caused by *B. burgdorferi,* which occurs in the USA, Europe, Russia, China, Japan and Australia. In Europe, two additional genospecies are also encountered, *B. afzelii* and *B. garinii.* The reservoir of infection is ixodid (hard) ticks that feed on a variety of large mammals, particularly deer. Birds may spread ticks over a wide area. The organism is transmitted to humans via the bite of infected ticks; larval, nymphal and adult forms are all capable of spreading infection.

Ehrlichiosis is a common co-infection with Lyme disease (*Anaplasma phagocytophila*, human granulocytic anaplasmosis (HGA); *Ehrlichia chaffeensis*, human monocytic ehrlichiosis (HME)).

Clinical features

There are three stages of disease. Progression may be arrested at any stage.

- *Early localised disease.* The characteristic feature is a skin reaction around the site of the tick bite, known as erythema migrans (Fig. 13.20). Initially, a red

13.45 Clinical diseases caused by *Borrelia* spp.

Species	Vector	Geographic distribution
Lyme disease		
B. burgdorferi sensu stricto	Tick: *Ixodes scapularis*	Northern and eastern USA
	I. pacificus	Western USA
B. afzelii	*I. ricinus*	Europe
	I. persulcatus	Asia
B. garinii	*I. ricinus*	Europe
	I. persulcatus	Asia
Louse-borne relapsing fever		
B. recurrentis	Human louse: *Pediculus humanus corporis*	Worldwide
Tick-borne relapsing fever		
B. hermsii	Tick: *Ornithodoros hermsii*	Western North America
B. turicatae	*O. turicatae*	Southwestern North America and northern Mexico
B. venezuelensis	*O. rudis*	Central America and northern South America
B. hispanica	*O. erraticus*	Iberian peninsula and northwestern Africa
B. crocidurae	*O. erraticus*	North Africa and Mediterranean region
B. duttonii	*O. moubata*	Central, eastern and southern Africa
B. persica	*O. tholozani*	Western China, India, central Asia, Middle East
B. latyschewii	*O. tartakovskyi*	Tajikistan, Uzbekistan

'bull's eye' macule or papule appears 2–30 days after the bite. It then enlarges peripherally with central clearing, and may persist for months. Atypical forms are fairly common. The lesion is not pathognomonic of Lyme disease since similar lesions can occur after tick bites in areas where Lyme disease does not occur. Other acute manifestations, such as fever, headache and regional lymphadenopathy, may develop with or without the rash.

- *Early disseminated disease*. Dissemination occurs via the blood stream and lymphatics. There may be a systemic reaction with malaise, arthralgia, and occasionally metastatic areas of erythema migrans (see Fig. 13.20). Neurological involvement may follow weeks or months after infection. Common features include lymphocytic meningitis, cranial nerve palsies (especially unilateral or bilateral facial nerve palsy) and peripheral neuropathy. Radiculopathy, often painful, may present a year or more after initial infection. Carditis, sometimes accompanied by atrioventricular conduction defects, is not uncommon in the USA but appears to be rare in Europe.
- *Late disease*. Late manifestations include arthritis, polyneuritis and encephalopathy. Prolonged arthritis, particularly affecting large joints, and brain parenchymal involvement causing neuropsychiatric abnormalities may occur, but are rare in the UK. Acrodermatitis chronica atrophicans is an uncommon late complication seen more frequently in Europe than North America. Doughy, patchy discoloration occurs on the peripheries, eventually leading to shiny atrophic skin. The lesions are easily mistaken for those of peripheral vascular disease. In patients from an endemic area or with risk factors, who have facial nerve palsy, Lyme disease should be considered.

Fig. 13.20 Rash of erythema migrans in Lyme disease with metastatic secondary lesions.

Diagnosis

The diagnosis of early Lyme borreliosis is often clinical. Culture from biopsy material is not generally available, has a low yield, and may take longer than 6 weeks. Antibody detection is frequently negative early in the course of the disease, but sensitivity increases to 90–100% in disseminated or late disease. Immunofluorescence or ELISA can give false-positive reactions in a number of conditions, including other spirochaetal infections, infectious mononucleosis, rheumatoid arthritis and systemic lupus erythematosus (SLE). Immunoblot (Western blot) techniques are more specific and, although technically demanding, should be used to confirm the diagnosis. Microorganism DNA detection by PCR has been applied to blood, urine, CSF, and biopsies of skin and synovium.

Management

Recent evidence suggests that asymptomatic patients with positive antibody tests should not be treated. However, erythema migrans always requires therapy because organisms may persist and cause progressive disease, even if the skin lesions resolve. Standard therapy consists of a 14-day course of doxycycline (200 mg daily) or amoxicillin (500 mg 3 times daily). Some 15% of patients with early disease will develop a mild Jarisch–Herxheimer reaction (JHR) during the first 24 hours of therapy (p. 421). In pregnant women and small children, or in those allergic to amoxicillin and doxycycline, 14-day treatment with cefuroxime axetil (500 mg twice daily) or erythromycin (250 mg 4 times daily) may be used.

Disseminated disease and arthritis require therapy for a minimum of 28 days. Arthritis may respond poorly, and prolonged or repeated courses may be necessary. Neuroborreliosis is treated with parenteral β-lactam

antibiotics for 3–4 weeks; the cephalosporins may be superior to penicillin in this situation.

Prevention

Protective clothing and insect repellents should be used in tick-infested areas. Since the risk of borrelial transmission is lower in the first few hours of a blood feed, prompt removal of ticks is advisable. Unfortunately, larval and nymphal ticks are tiny and may not be noticed. Where risk of transmission is high, a single 200 mg dose of doxycycline, given within 72 hours of exposure, has been shown to prevent erythema migrans. A recombinant OspA vaccine was developed but withdrawn due to side-effects.

Louse-borne relapsing fever

The human body louse, *Pediculus humanus*, causes itching. Borreliae (*B. recurrentis*) are liberated from infected lice when they are crushed during scratching, which also inoculates the borreliae into the skin. The disease occurs worldwide, with epidemic relapsing fever most often seen in Central/East Africa and South America.

The borreliae multiply in the blood, where they are abundant in the febrile phases, and invade most tissues, especially the liver, spleen and meninges. Hepatitis and thrombocytopenia are common.

Clinical features

Onset is sudden with fever. The temperature rises to 39.5–40.5°C, accompanied by a tachycardia, headache, generalised aching, injected conjunctivae (Fig. 13.21) and, frequently, a petechial rash, epistaxis and herpes labialis. As the disease progresses, the liver and spleen frequently become tender and palpable, and jaundice is common. There may be severe serosal and intestinal haemorrhage, mental confusion and meningism. The fever ends in crisis between the 4th and 10th days, often associated with profuse sweating, hypotension, and circulatory and cardiac failure. There may be no further fever but, in a proportion of patients, after an afebrile period of about 7 days, there are one or more relapses, which are usually milder and less prolonged. In the absence of specific treatment, the mortality rate is up to 40%, especially among the elderly and malnourished.

Investigations and management

The organisms are demonstrated in the blood during fever either by dark ground microscopy of a wet film or in Wright–Giemsa stained thick and thin films.

Fig. 13.21 Louse-borne relapsing fever. Injected conjunctivae.

The problems of treatment are to eradicate the organism, to minimise the severe JHR which inevitably follows successful chemotherapy, and to prevent relapses. The safest treatment is procaine penicillin 300 mg IM, followed the next day by 0.5 g tetracycline. Tetracycline alone is effective and prevents relapse, but may give rise to a worse reaction. Doxycycline 200 mg once orally in place of tetracycline has the advantage of also being curative for typhus, which often accompanies epidemics of relapsing fever. JHR is best managed in a high-dependency unit with expert nursing and medical care.

The patient, clothing and all contacts must be freed from lice, as in epidemic typhus.

Tick-borne relapsing fever

Soft ticks (*Ornithodoros* spp.) transmit *B. duttonii* (and several other borrelia species) through saliva while feeding on their host. People sleeping in mud houses are at risk, as the tick hides in crevices during the day and feeds on humans during the night. Rodents are the reservoir in all parts of the world except East Africa, where humans are the reservoir. Clinical manifestations are similar to those seen with the louse-borne disease, but spirochaetes are detected in fewer patients on dark field microscopy. A 7-day course (due to a higher relapse rate than in louse-borne relapsing fever) of treatment with either tetracycline (500 mg 4 times daily) or erythromycin (500 mg 4 times daily) is needed.

Leptospirosis

Microbiology and epidemiology

Leptospirosis is one of the most common zoonotic diseases, favoured by a tropical climate and flooding during the monsoon but occurring worldwide. Leptospires are tightly coiled, thread-like organisms about 5–7 µm in length, which are actively motile; each end is bent into a hook. *Leptospira interrogans* is pathogenic for humans. The genus can be separated into more than 200 serovars (subtypes) belonging to 23 serogroups.

Leptospirosis appears to be ubiquitous in wildlife and in many domestic animals. The organisms persist indefinitely in the convoluted tubules of the kidney and are shed into the urine in massive numbers, but infection is asymptomatic in the host. The most frequent hosts are rodents, especially the common rat (*Rattus norvegicus*). Particular leptospiral serogroups are associated with characteristic animal hosts; for example, *L. icterohaemorrhagiae* is the classical parasite of rats and *L. canicola* of dogs. There is nevertheless considerable overlap in host–serogroup associations.

Leptospires can enter their human hosts through intact skin or mucous membranes, but entry is facilitated by cuts and abrasions. Prolonged immersion in contaminated water will also favour invasion, as the spirochaete can survive in water for months. Leptospirosis is common in the tropics and also in freshwater sports enthusiasts.

Clinical features

After a relatively brief bacteraemia, invading organisms are distributed throughout the body, mainly in kidneys, liver, meninges and brain. The incubation period averages 1–2 weeks. Four main clinical syndromes can be discerned and clinical features can involve multiple different organ systems (Fig. 13.22).

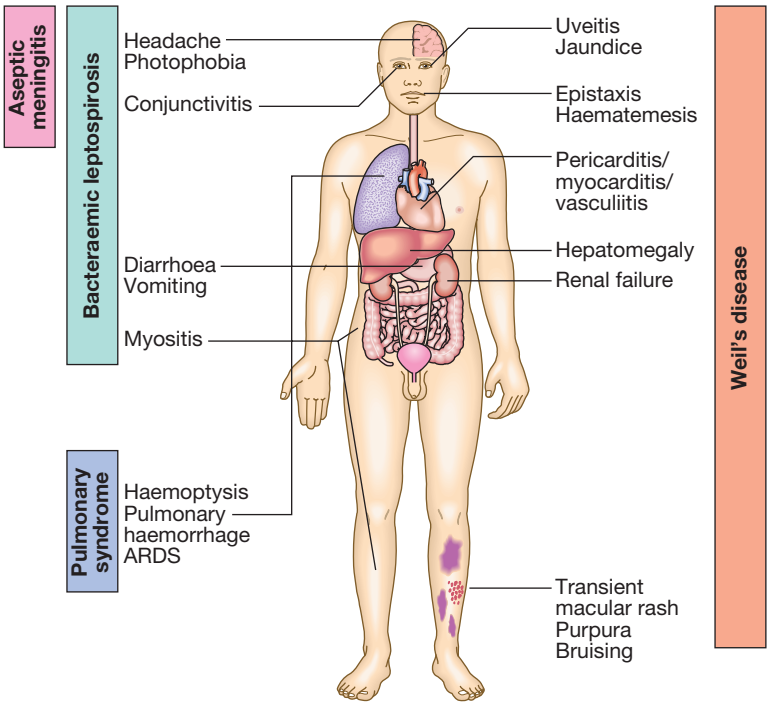

Fig. 13.22 Clinical syndromes of leptospirosis. (ARDS = acute respiratory distress syndrome)

Bacteraemic leptospirosis

Bacteraemia with any serogroup can produce a non-specific illness with high fever, weakness, muscle pain and tenderness (especially of the calf and back), intense headache and photophobia, and sometimes diarrhoea and vomiting. Conjunctival congestion is the only notable physical sign. The illness comes to an end after about 1 week, or else merges into one of the other forms of infection.

Aseptic meningitis

Classically associated with *L. canicola* infection, this illness is very difficult to distinguish from viral meningitis. The conjunctivae may be congested but there are no other differentiating signs. Laboratory clues include a neutrophil leucocytosis, abnormal LFTs, and the occasional presence of albumin and casts in the urine.

Icteric leptospirosis (Weil's disease)

Fewer than 10% of symptomatic infections result in severe icteric illness. Weil's disease is a dramatic life-threatening event, characterised by fever, haemorrhages, jaundice and renal impairment. Conjunctival hyperaemia is a frequent feature. The patient may have a transient macular erythematous rash, but the characteristic skin changes are purpura and large areas of bruising. In severe cases there may be epistaxis, haematemesis and melaena, or bleeding into the pleural, pericardial or subarachnoid spaces. Thrombocytopenia, probably related to activation of endothelial cells with platelet adhesion and aggregation, is present in 50% of cases. Jaundice is deep and the liver is enlarged, but there is usually little evidence of hepatic failure or encephalopathy. Renal failure, primarily caused by impaired renal perfusion and acute tubular necrosis, manifests as oliguria or anuria, with the presence of albumin, blood and casts in the urine.

Weil's disease may also be associated with myocarditis, encephalitis and aseptic meningitis. Uveitis and iritis may appear months after apparent clinical recovery.

Pulmonary syndrome

This syndrome has long been recognised in the Far East, and has been described during an outbreak of leptospirosis in Nicaragua. It is characterised by haemoptysis, patchy lung infiltrates on chest X-ray, and respiratory failure. Total bilateral lung consolidation and ARDS (p. 192) with multi-organ dysfunction may develop, with a high mortality (over 50%).

Diagnosis

A polymorphonuclear leucocytosis is accompanied in severe infection by thrombocytopenia and elevated blood levels of creatine kinase. In jaundiced patients, there is hepatitis and the prothrombin time may be prolonged. The CSF in leptospiral meningitis shows a variable cellular response, a moderately elevated protein level and normal glucose content. Acute renal failure due to interstitial nephritis is common.

In the tropics, dengue, malaria, typhoid fever, scrub typhus and hantavirus infection are important differential diagnoses.

Definitive diagnosis of leptospirosis depends upon isolation of the organism, serological tests or the detection of specific DNA. In general, however, it is probably under-diagnosed.

- Blood cultures are most likely to be positive if taken before the tenth day of illness. Special media are required and cultures may have to be incubated for several weeks.
- Leptospires appear in the urine during the second week of illness, and in untreated patients may be recovered on culture for several months.

- Serological tests are diagnostic if seroconversion or a fourfold increase in titre is demonstrated. The microscopic agglutination test (MAT) is the test of choice and can become positive by the end of the first week. IgM ELISA and immunofluorescent techniques are, however, easier to perform, while rapid immunochromatographic tests are specific but of only moderate sensitivity in the first week of illness.
- Detection of leptospiral DNA by PCR is possible in blood in early symptomatic disease, and in urine from the eighth day of illness and for many months thereafter.

Management and prevention

The general care of the patient is critically important. Blood transfusion for haemorrhage and careful attention to renal failure, the usual cause of death, are especially important. Renal failure is potentially reversible with adequate support, such as dialysis. The optimal antimicrobial regimen has not been established. Most infections are self-limiting. Therapy with either oral doxycycline (100 mg twice daily for 1 week) or intravenous penicillin (900 mg 4 times daily for 1 week) is effective but may not prevent the development of renal failure. Parenteral ceftriaxone (1 g daily) is as effective as penicillin. A Jarisch–Herxheimer reaction may occur during treatment but is usually mild. Uveitis is treated with a combination of systemic antibiotics and local corticosteroids. There is no role for the routine use of corticosteroids in the management of leptospirosis.

Trials in military personnel have shown that infection with *L. interrogans* can be prevented by taking prophylactic doxycycline 200 mg weekly.

Plague

Plague is caused by *Yersinia pestis*, a small Gram-negative bacillus that is spread between rodents by their fleas. If domestic rats become infected, infected fleas may bite humans. Hunters and trappers can contract plague from handling rodents. In the late stages of human plague, *Y. pestis* may be expectorated and spread between humans by droplets, causing 'pneumonic plague'.

Epidemics of plague, such as the 'Black Death', have occurred since ancient times. It is often said that the first sign of plague is the appearance of dead rats. Plague foci are widely distributed throughout the world, including the USA; human cases are reported from about ten countries per year (Fig. 13.23).

Y. pestis is a potential bioweapon because of its capacity for mass production and aerosol transmission, and the high fatality rate associated with pneumonic plague.

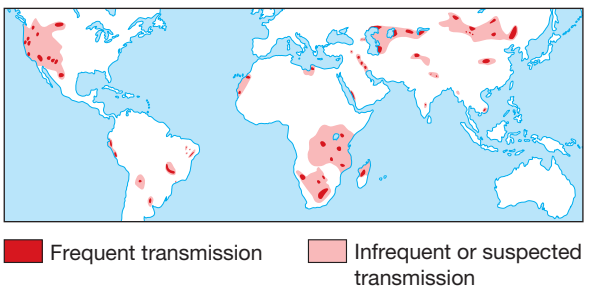

Fig. 13.23 Foci of the transmission of plague. Reproduced by permission of WHO.

Clinical features

Organisms inoculated through the skin are taken rapidly to the draining lymph nodes, where they elicit a severe inflammatory response that may be haemorrhagic. If the infection is not contained, septicaemia ensues and necrotic, purulent or haemorrhagic lesions develop in many organs. Oliguria and shock follow, and disseminated intravascular coagulation may result in widespread haemorrhage. Inhalation of *Y. pestis* causes alveolitis. The incubation period is 3–6 days, but shorter in pneumonic plague.

Bubonic plague

In this, the most common form of the disease, onset is usually sudden, with a rigor, high fever, dry skin and severe headache. Soon, aching and swelling at the site of the affected lymph nodes begin. The groin is the most common site of this 'bubo', made up of the swollen lymph nodes and surrounding tissue. Some infections are relatively mild but, in the majority of patients, toxaemia quickly increases, with a rapid pulse, hypotension and mental confusion. The spleen is usually palpable.

Septicaemic plague

Those not exhibiting a bubo usually deteriorate rapidly and have a high mortality. The elderly are more prone to this form of illness. The patient is toxic and may have gastrointestinal symptoms, such as nausea, vomiting, abdominal pain and diarrhoea. DIC may occur, manifested by bleeding from various orifices or puncture sites, along with ecchymoses. Hypotension, shock, renal failure and ARDS may lead to further deterioration. Meningitis, pneumonia and expectoration of blood-stained sputum containing *Y. pestis* may complicate septicaemic, or occasionally bubonic, plague.

Pneumonic plague

Following primary infection in the lung, the onset of disease is very sudden, with cough and dyspnoea. The patient soon expectorates copious blood-stained, frothy, highly infective sputum, becomes cyanosed and dies. Chest radiology reveals bilateral infiltrates which may be nodular and progress to an ARDS-like picture.

Investigations

The organism may be cultured from blood, sputum and bubo aspirates. For rapid diagnosis, Gram, Giemsa and Wayson's stains (the latter containing methylene blue) are applied to smears from these sites. *Y. pestis* is seen as bipolar staining coccobacilli, sometimes referred to as having a 'safety pin' appearance. Smears are also subjected to antigen detection by immunofluorescence, using *Y. pestis* F1 antigen-specific antibodies. The diagnosis may be confirmed by seroconversion or a single high titre (> 128) of anti-F1 antibodies in serum. DNA detection by PCR is under evaluation.

Plague is a notifiable disease under international health regulations (p. 147).

Management

If the diagnosis is suspected on clinical and epidemiological grounds, treatment must be started as soon as, or even before, samples have been collected for laboratory

diagnosis. Streptomycin (1 g twice daily) or gentamicin (1 mg/kg 3 times daily) is the drug of choice. Tetracycline (500 mg 4 times daily) and chloramphenicol (12.5 mg/kg 4 times daily) are alternatives. Fluoroquinolones (ciprofloxacin and levofloxacin) may be as effective, but there is less clinical experience. Treatment may also be needed for acute circulatory failure, DIC and hypoxia.

Prevention and infection control

Rats and fleas should be controlled. In endemic areas, people should avoid handling and skinning wild animals. The patient should be isolated for the first 48 hours or until clinical improvement begins. Attendants must wear gowns, masks and gloves. Exposed symptomatic or asymptomatic people who have been in close contact with a patient with pneumonic plague should receive post-exposure antibiotic prophylaxis (doxycycline 100 mg or ciprofloxacin 500 mg twice daily) for 7 days.

A formalin-killed vaccine is available for those at occupational risk but offers little protection against pneumonic plague. A recombinant subunit vaccine (protein antigens F1 + V) is in development.

Listeriosis

Listeria monocytogenes is an environmental Gram-positive bacillus which can contaminate food. Outbreaks have been associated with raw vegetables, soft cheeses, undercooked chicken, fish, meat and pâtés. The bacterium demonstrates 'cold enrichment', outgrowing other contaminating bacteria during refrigeration. Although foodborne outbreaks of gastroenteritis have been reported in immunocompetent individuals, *Listeria* causes more significant invasive infection, especially in pregnancy, the elderly (over 55 years) and the immunocompromised.

In pregnancy, in addition to systemic symptoms of fever and myalgia, listeriosis causes chorioamnionitis, fetal deaths, abortions and neonatal infection. In other susceptible individuals, it causes systemic illness due to bacteraemia without focal symptoms. Meningitis, similar to other bacterial meningitis but with normal CSF glucose, is the next most common presentation; CSF usually shows increased neutrophils but occasionally only the mononuclear cells are increased (p. 1201).

Investigations and management

Diagnosis is made by blood and CSF culture. The organism grows readily in culture media.

The most effective regimen consists of a combination of an intravenous aminopenicillin (amoxicillin or ampicillin) plus an aminoglycoside. A sulfamethoxazole/trimethoprim combination can be used in those with penicillin allergy. Cephalosporins are of no use in this infection, as the organism is inherently resistant, an important consideration when empirically treating meningitis.

Proper treatment of foods before eating is the key to preventing listeriosis. Pregnant women are advised to avoid high-risk products, including soft cheeses.

Typhoid and paratyphoid (enteric) fevers

Typhoid and paratyphoid fevers, which are transmitted by the faecal–oral route, are important causes of fever in India, sub-Saharan Africa and Latin America. Elsewhere, they are relatively rare. Enteric fevers are caused by infection with *Salmonella typhi* and *S. paratyphi* A and B. After a few days of bacteraemia, the bacilli localise, mainly in the lymphoid tissue of the small intestine, resulting in typical lesions in the Peyer's patches and follicles. These swell at first, then ulcerate and usually heal. After clinical recovery, about 5% of patients become chronic carriers (i.e. continue to excrete the bacteria after 1 year); the bacilli may live in the gallbladder for months or years and pass intermittently in the stool and, less commonly, in the urine.

Clinical features

Typhoid fever

Clinical features are outlined in Box 13.46. The incubation period is typically about 10–14 days but can be longer, and the onset may be insidious. The temperature rises in a stepladder fashion for 4 or 5 days with malaise, increasing headache, drowsiness and aching in the limbs. Constipation may be caused by swelling of lymphoid tissue around the ileocaecal junction, although in children diarrhoea and vomiting may be prominent early in the illness. The pulse is often slower than would be expected from the height of the temperature, i.e. a relative bradycardia.

At the end of the first week, a rash may appear on the upper abdomen and on the back as sparse, slightly raised, rose-red spots, which fade on pressure. It is usually visible only on white skin. Cough and epistaxis occur. Around the 7th–10th day, the spleen becomes palpable. Constipation is then succeeded by diarrhoea and abdominal distension with tenderness. Bronchitis and delirium may develop. If untreated, by the end of the second week the patient may be profoundly ill.

Paratyphoid fever

The course tends to be shorter and milder than that of typhoid fever and the onset is often more abrupt with acute enteritis. The rash may be more abundant and the intestinal complications less frequent.

Complications

These are given in Box 13.47. Haemorrhage from, or a perforation of, the ulcerated Peyer's patches may occur at the end of the second week or during the third week of the illness. A drop in temperature to normal or subnormal levels may be falsely reassuring in patients with intestinal haemorrhage. Additional complications may

involve almost any viscus or system because of the septicaemia present during the first week. Bone and joint infection is common in children with sickle-cell disease.

Investigations

In the first week, diagnosis may be difficult because, in this invasive stage with bacteraemia, the symptoms are those of a generalised infection without localising features. A white blood count may be helpful, as there is typically a leucopenia. Blood culture is the most important diagnostic method. The faeces contain the organism more frequently in the second and third weeks.

Management

Antibiotic therapy must be guided by in vitro sensitivity testing. Chloramphenicol (500 mg 4 times daily), ampicillin (750 mg 4 times daily) and co-trimoxazole (2 tablets or IV equivalent twice daily) are losing their effect due to resistance in many areas of the world, especially India and South-east Asia. The fluoroquinolones are the drugs of choice (e.g. ciprofloxacin 500 mg twice daily) if the organism is susceptible, but resistance is common, especially in the Indian subcontinent and also in the UK. Extended-spectrum cephalosporins (ceftriaxone and cefotaxime) are useful alternatives but have a slightly increased treatment failure rate. Azithromycin (500 mg once daily) is an alternative when fluoroquinolone resistance is present but has not been validated in severe disease. Treatment should be continued for 14 days. Pyrexia may persist for up to 5 days after the start of specific therapy. Even with effective chemotherapy, there is still a danger of complications, recrudescence of the disease and the development of a carrier state.

Chronic carriers were formerly treated for 4 weeks with ciprofloxacin but may require an alternative agent and duration, as guided by antimicrobial sensitivity testing. Cholecystectomy may be necessary.

Prevention

Improved sanitation and living conditions reduce the incidence of typhoid. Travellers to countries where enteric infections are endemic should be inoculated with one of the three available typhoid vaccines (two inactivated injectable and one oral live attenuated).

Tularaemia

Tularaemia is primarily a zoonotic disease of the northern hemisphere. It is caused by a highly infectious Gram-negative bacillus, *Francisella tularensis*. *F. tularensis* is passed transovarially (ensuring transmission from parent to progeny) in ticks, which allows persistence in nature without the absolute requirement for an infected animal reservoir. It is a potential weapon for bioterrorism. Wild rabbits, rodents, and domestic dogs or cats are some of the many potential reservoirs, and ticks, mosquitoes or other biting flies are the vectors.

Infection is introduced either through an arthropod or animal bite or via contact with infected animals, soil or water through skin abrasions. This results in the most common 'ulceroglandular' variety of the disease (70–80%), characterised by skin ulceration with regional lymphadenopathy. There is also a purely 'glandular' form. Alternatively, inhalation of the infected aerosols may result in pulmonary tularaemia, presenting as pneumonia. Rarely, the portal of entry of infection may be the conjunctiva, leading to a nodular, ulcerated conjunctivitis with regional lymphadenopathy (an 'oculoglandular' form).

Investigations and management

Demonstration of a single high titre (≥ 1:160) or a fourfold rise in 2–3 weeks in the tularaemia tube agglutination test confirms the diagnosis. Bacterial yield from the lesions is extremely poor. DNA detection methods to enable rapid diagnosis are in development.

Treatment consists of a 7–10-day course of parenteral aminoglycosides, streptomycin (7.5–10 mg/kg twice daily) or gentamicin (1.7 mg/kg 3 times daily). *F. tularensis* is not susceptible to most other antibiotics.

Melioidosis

Melioidosis is caused by *Burkholderia pseudomallei*, a saprophyte found in soil and water (rice paddy fields). Infection is by inoculation or inhalation, leading to bacteraemia, which is followed by the formation of abscesses in the lungs, liver and spleen. Patients with diabetes, renal stones, thalassaemia or severe burns are particularly susceptible. The disease is most common in South India, East Asia and northern Australia, and carries a significant mortality. Disease may present many years or decades after the initial exposure.

Clinical features

There is high fever, prostration and sometimes diarrhoea, with signs of pneumonia and enlargement of the liver and spleen. The chest X-ray resembles that of acute caseous tuberculosis. In more chronic forms, multiple abscesses occur in subcutaneous tissue and bone, and profound wasting is a major problem.

Investigations and management

Culture of blood, sputum or pus may yield *B. pseudomallei*. Indirect haemagglutination testing can be helpful in travellers; however, most people in endemic areas are seropositive.

In the acute illness, prompt treatment, without waiting for confirmation by culture, may be life-saving. Ceftazidime 100 mg/kg (2 g 3 times daily), imipenem 50 mg/kg (1 g 4 times daily) or meropenem (0.5–1 g 3 times daily) is given for 2–3 weeks. This is followed by maintenance therapy of doxycycline 200 mg daily, plus co-trimoxazole (sulfamethoxazole 1600 mg plus trimethoprim 320 mg twice daily) for a minimum of 12 weeks. Abscesses should be drained surgically.

Actinomycete infections

Nocardiosis

Nocardiosis is an uncommon Gram-positive bacterial infection caused by aerobic actinomycetes of the genus *Nocardia* found in the soil. Infection occurs most frequently by direct traumatic inoculation or occasionally via inhalation or ingestion. Nocardiosis can result in localised cutaneous ulcers or nodules, most often in the lower limbs. Chronic destructive infection in tropical countries can result in actinomycetoma, involving soft tissues with occasional penetration to the bone. Actinomycetoma may also be caused by other bacteria, and a similar clinical syndrome, termed eumycetoma, is caused by fungi (p. 382). Systemic *Nocardia* infection, most likely in immunocompromised individuals, results in suppurative disease with lung and brain abscesses.

On microscopy, *Nocardia* spp. appear as long, filamentous, branching Gram-positive rods which are also weakly acid-fast. They are easily grown in culture but require prolonged incubation.

Treatment is guided by susceptibility testing. Systemic infection typically requires combinations of ceftriaxone, meropenem, amikacin and co-trimoxazole, often for 6–12 months or longer. Abscesses are drained surgically when this is feasible. Localised cutaneous infection is usually treated with a single agent for 1–3 months.

Actinomycetoma is also treated with prolonged antibiotic combinations. There is no universal consensus on the most appropriate drug or combination. The usual combination is streptomycin and dapsone, with dapsone replaced by co-trimoxazole in cases with intolerance or refractory disease. Success has also been reported with co-trimoxazole plus amikacin, with rifampicin added in difficult cases and to prevent recurrence.

Actinomyces israelii

Actinomyces israelii can cause deep infection in the head and neck, and also suppurating disease in the pelvis associated with intrauterine contraceptive devices (IUCDs). Treatment is usually with penicillin or doxycycline.

Gastrointestinal bacterial infections

The differential diagnosis and approach to patients presenting with acute gastroenteritis are described on page 306.

Staphylococcal food poisoning

Staph. aureus transmission takes place via the hands of food handlers to foodstuffs such as dairy products, including cheese, and cooked meats. Inappropriate storage of these foods allows growth of the organism and production of one or more heat-stable enterotoxins which cause the symptoms.

Nausea and profuse vomiting develop within 1–6 hours. Diarrhoea may not be marked. The toxins that cause the syndrome act as 'superantigens', inducing a significant neutrophil leucocytosis that may be clinically misleading. Superantigens are secreted proteins (exotoxins) that exhibit highly potent lymphocyte-transforming (mitogenic) activity directed towards T lymphocytes. Most cases settle rapidly but severe dehydration can occasionally be life-threatening.

Antiemetics and appropriate fluid replacement are the mainstays of treatment. Suspect food should be cultured for staphylococci and demonstration of toxin production. The public health authorities should be notified if food vending is involved.

Bacillus cereus food poisoning

Ingestion of the pre-formed heat-stable exotoxins of *B. cereus* causes rapid onset of vomiting and some diarrhoea within hours of food consumption, which resolves within 24 hours. Fried rice and freshly made sauces are frequent sources; the organism grows and produces enterotoxin during storage (Fig. 13.24). If viable bacteria are ingested and toxin formation takes place within the gut lumen, then the incubation period is longer (12–24 hours) and watery diarrhoea and cramps are the predominant symptoms. The disease is self-limiting but can be quite severe.

Rapid and judicious fluid replacement and appropriate notification of the public health authorities are all that is required.

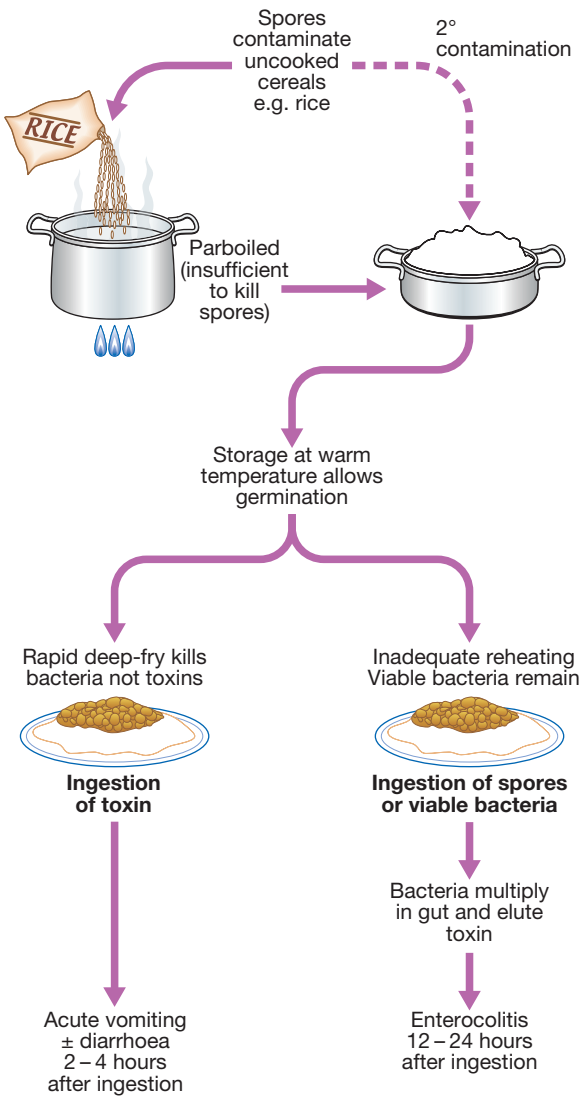

Fig. 13.24 ***Bacillus cereus*** **food poisoning.**

Clostridium perfringens food poisoning

Spores of *C. perfringens* are widespread in the guts of large animals and in soil. If contaminated meat products are incompletely cooked and stored in anaerobic conditions, *C. perfringens* spores germinate and viable organisms multiply to give large numbers. Subsequent reheating of the food causes heat-shock sporulation of the organisms, during which they release an enterotoxin. Symptoms (diarrhoea and cramps) occur some 6–12 hours following ingestion. The illness is usually self-limiting.

Clostridial enterotoxins are potent and most people who ingest them will be symptomatic. 'Point source' outbreaks, in which a number of cases all become symptomatic following ingestion, classically occur after school or canteen lunches where meat stews are served.

Clostridial necrotising enteritis (CNE) or pigbel is an often-fatal type of food poisoning caused by a β-toxin of *C. perfringens*, type C. The toxin is normally inactivated by certain proteases or by normal cooking. Pigbel is more likely in protein malnutrition or in the presence of trypsin inhibitors, either in foods such as sweet potatoes or during infection with *Ascaris* sp. roundworms.

Campylobacter jejuni infection

This infection is essentially a zoonosis, although contaminated water may be implicated, as the organism can survive for many weeks in fresh water. The most common sources of the infection are chicken, beef and contaminated milk products. There has been an association with pet puppies. *Campylobacter* infection is now the most common cause of bacterial gastroenteritis in the UK, accounting for some 100 000 cases per annum, most of which are sporadic.

The incubation period is 2–5 days. Colicky abdominal pain, which may be quite severe and mimic surgical pathology, occurs with nausea, vomiting and significant diarrhoea, frequently containing blood. The majority of *Campylobacter* infections affect fit young adults and are self-limiting after 5–7 days. About 10–20% will have prolonged symptomatology, occasionally meriting treatment with antibiotics such as erythromycin, as many organisms are resistant to ciprofloxacin.

Approximately 1% of cases will develop bacteraemia and possible distant foci of infection. *Campylobacter* spp. have been linked to Guillain–Barré syndrome and post-infectious reactive arthritis (pp. 1224 and 1107).

Salmonella spp. infection

Salmonella serotypes other than *S. typhi* and *S. paratyphi* (p. 339), of which there are more than 2000, are subdivided into five distinct subgroups which produce gastroenteritis. They are widely distributed throughout the animal kingdom. Two serotypes are most important worldwide: *S. enteritidis* phage type 4 and *S. typhimurium* dt.104. The latter may be resistant to commonly used antibiotics such as ciprofloxacin. Some strains have a clear relationship to particular animal species, e.g. *S. arizonae* and pet reptiles. Transmission is by contaminated water or food, particularly poultry, egg products and related fast foods, direct person-to-person spread or the handling of exotic pets such as salamanders, lizards or turtles. The incidence of *Salmonella* enteritis is falling in the UK due to an aggressive culling policy in broiler chicken stocks, coupled with vaccination.

EBM 13.48 Antibiotics in *Salmonella* gastroenteritis

'In otherwise healthy adults or children with non-severe *Salmonella* diarrhoea, antibiotics have no clinical benefit over placebo, increase side-effects and prolong *Salmonella* detection.'

- Sirinavin S, Garner P. Antibiotics for treating salmonella gut infections. Cochrane Database of Systematic Reviews, 1999, issue 1. Art. no.: CD001167.

For further information: www.cochrane.org/cochrane-reviews

The incubation period of *Salmonella* gastroenteritis is 12–72 hours and the predominant feature is diarrhoea, sometimes with passage of blood. Vomiting may be present at the outset. Approximately 5% of cases are bacteraemic. Reactive (post-infective) arthritis occurs in approximately 2%.

Antibiotics are not indicated for uncomplicated *Salmonella* gastroenteritis (Box 13.48). However, evidence of bacteraemia is a clear indication for antibiotic therapy, as salmonellae are notorious for persistent infection and often colonise endothelial surfaces such as an atherosclerotic aorta or a major blood vessel. Mortality, as with other forms of gastroenteritis, is higher in the elderly (see Box 13.13, p. 306).

Escherichia coli infection

Many serotypes of *E. coli* are present in the human gut at any given time. Production of disease depends on either colonisation with a new or previously unrecognised strain, or the acquisition by current colonising bacteria of a particular pathogenicity factor for mucosal attachment or toxin production. Travel to unfamiliar areas of the world allows contact with different strains of endemic *E. coli* and the development of travellers' diarrhoea. Enteropathogenic strains may be found in the gut of healthy individuals and, if these people move to a new environment, close contacts may develop symptoms.

At least five different clinico-pathological patterns of diarrhoea are associated with specific strains of *E. coli* with characteristic virulence factors.

Enterotoxigenic E. coli

Enterotoxigenic *E. coli* (ETEC) cause the majority of cases of travellers' diarrhoea in developing countries, although there are other causes (see Box 13.21, p. 311). The organisms produce either a heat-labile or a heat-stable enterotoxin, causing marked secretory diarrhoea and vomiting after 1–2 days' incubation. The illness is usually mild and self-limiting after 3–4 days. Antibiotics, such as ciprofloxacin, have been used to limit the duration of symptoms (see Box 13.22, p. 311) but are of questionable value.

Entero-invasive E. coli

Illness caused by entero-invasive *E. coli* (EIEC) is very similar to *Shigella* dysentery (p. 345) and is caused by invasion and destruction of colonic mucosal cells. No enterotoxin is produced. Acute watery diarrhoea, abdominal cramps and some scanty blood-staining of the stool are common. The symptoms are rarely severe and are usually self-limiting.

Enteropathogenic E. coli

Enteropathogenic *E. coli* (EPEC) organisms are very important in infant diarrhoea. They are able to attach to the gut mucosa, inducing a specific 'attachment and effacement' lesion, and causing destruction of microvilli and disruption of normal absorptive capacity. The symptoms vary from mild non-bloody diarrhoea to quite severe illness, but without bacteraemia.

Entero-aggregative E. coli

Entero-aggregative *E. coli* (EAEC) strains adhere to the mucosa but also produce a locally active enterotoxin and demonstrate a particular 'stacked brick' aggregation to tissue culture cells when viewed by microscopy. They have been associated with prolonged diarrhoea in children in South America, South-east Asia and India.

Enterohaemorrhagic E. coli

A number of distinct 'O' serotypes of *E. coli* possess both the genes necessary for adherence (see 'EPEC' above) and plasmids encoding for two distinct enterotoxins (verotoxins) which are identical to the toxins produced by *Shigella* ('shiga toxins 1 and 2'). *E. coli* O157:H7 is perhaps the best-known of these verotoxin-producing *E. coli* (VTEC), but others, including types O126 and O11, are also implicated. In 2011, an outbreak of food-borne illness linked to fenugreek seeds occurred in Germany and was due to *E. coli* O104:H4, an EAEC strain that had acquired genes encoding shiga toxin 2a. Although the incidence of enterohaemorrhagic *E. coli* (EHEC) is considerably lower than that of *Campylobacter* and *Salmonella* infection, it is increasing in the developing world.

The reservoir of infection is in the gut of herbivores. The organism has an extremely low infecting dose (10–100 organisms). Runoff water from pasture lands where cattle have grazed, which is used to irrigate vegetable crops, as well as contaminated milk, meat products (especially hamburgers which have been incompletely cooked), lettuce, radish shoots and apple juice, have all been implicated as sources (Fig. 13.25).

The incubation period is between 1 and 7 days. Initial watery diarrhoea becomes frankly and uniformly blood-stained in 70% of cases and is associated with severe and often constant abdominal pain. There is little systemic upset, vomiting or fever.

Enterotoxins have both a local effect on the bowel and a distant effect on particular body tissues, such as glomerular apparatus, heart and brain. The potentially life-threatening haemolytic uraemic syndrome (HUS, p. 495) occurs in 10–15% of sufferers from this infection, arising 5–7 days after the onset of symptoms. It is most likely at the extremes of age, is heralded by a high peripheral leucocyte count, and may be induced, particularly in children, by antibiotic therapy.

HUS is treated by dialysis if necessary and may be averted by plasma exchange. Antibiotics should be avoided since they can stimulate toxin release.

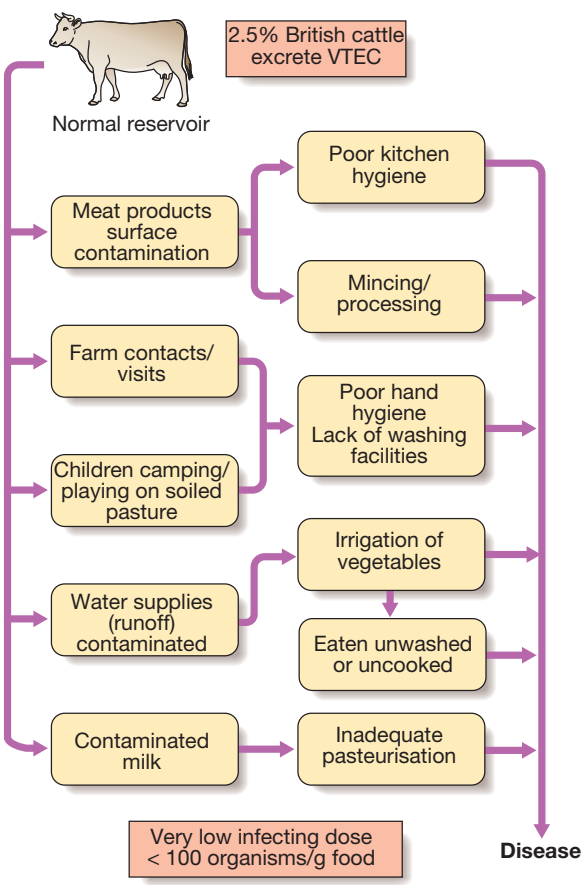

Fig. 13.25 Verocytotoxigenic *E. coli* (VTEC) infections.

Clostridium difficile infection

C. difficile is the most commonly diagnosed cause of antibiotic-associated diarrhoea (p. 308), and is an occasional constituent of the normal intestinal flora. *C. difficile* is capable of producing two toxins (A and B). *C. difficile* infection (CDI) usually follows antimicrobial therapy, which alters the composition of the gastrointestinal flora and may result in colonisation with *C. difficile* if the patient is exposed to *C. difficile* spores. The combination of toxin production and the ability to produce environmentally stable spores accounts for the clinical features and transmissibility of CDI. A hypervirulent strain of *C. difficile*, ribotype 027, has emerged, which produces more toxin than other *C. difficile* strains and thus more severe disease.

Clinical features

Disease manifestations range from diarrhoea to life-threatening pseudomembranous colitis. Around 80% of cases occur in people over 65 years of age, many of whom are frail with comorbid diseases. Symptoms usually begin in the first week of antibiotic therapy but can occur at any time up to 6 weeks after treatment has finished. The onset is often insidious, with lower abdominal pain and diarrhoea which may become profuse and watery. The presentation may resemble acute ulcerative colitis with bloody diarrhoea, fever and even toxic dilatation and perforation. Ileus is also seen in pseudomembranous colitis.

Investigations

C. difficile can be isolated from stool culture in 30% of patients with antibiotic-associated diarrhoea and over 90% of those with pseudomembranous colitis, but also from 5% of healthy adults and up to 20% of elderly patients in residential care. The diagnosis of CDI

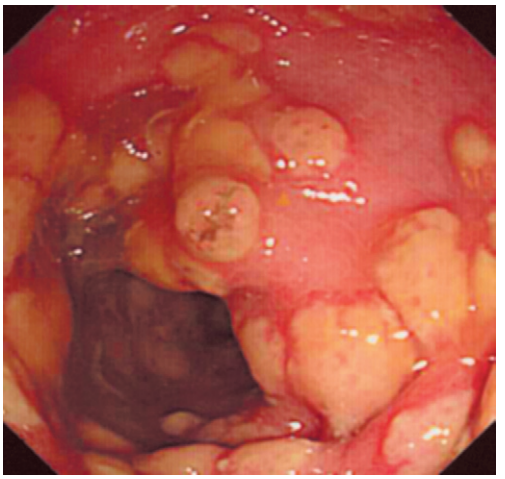

Fig. 13.26 *Clostridium difficile* infection. Colonoscopic view showing numerous adherent 'pseudomembranes' on the mucosa.

therefore rests on detection of toxins A or B in the stool. Current practice in the UK is to screen stool from patients with a compatible clinical syndrome by detection either of glutamate dehydrogenase (GDH), an enzyme produced by *C. difficile*, or of *C. difficile* nucleic acid (e.g. by PCR); if screening is positive, a *C. difficile* toxin ELISA or a tissue culture cytotoxicity assay is performed.

The rectal appearances at sigmoidoscopy may be characteristic, with erythema, white plaques or an adherent pseudomembrane (Fig. 13.26). Appearances may also resemble those of ulcerative colitis. In some cases, the rectum is spared and abnormalities are observed in the proximal colon. Patients who are ill may require abdominal and erect chest X-rays to exclude perforation or toxic dilatation. CT may be useful when the diagnosis is in doubt.

Management

The precipitating antibiotic should be stopped and the patient should be isolated. Supportive therapy with intravenous fluids and resting of the bowel is often needed. CDI is treated with antibiotics. The options for first-line therapy are metronidazole (500 mg orally 3 times daily for 10 days) or vancomycin (125 mg orally 4 times daily for 7–10 days). Although vancomycin is more effective than metronidazole against hypervirulent *C. difficile* strains (e.g. ribotype 027), it is more expensive and may drive the emergence of vancomycin resistance in other organisms (e.g. enterococci, *Staph. aureus*). For these reasons, some authorities reserve its use for relapse (15–30% of patients), failure of initial response or severe infection. A new agent, fidaxomicin, is associated with a lower relapse rate than vancomycin. Intravenous immunoglobulin and/or corticosteroids are sometimes given in the most severe or refractory cases and faecal transplantation is also emerging as a therapy in relapsing patients. Surgical intervention is sometimes needed and needs to be considered early in severe cases.

Yersinia enterocolitica infection

This organism, commonly found in pork, causes mild to moderate gastroenteritis and can produce significant mesenteric adenitis after an incubation period of 3–7 days. It predominantly causes disease in children but adults may also be affected. The illness resolves slowly, with 10–30% of cases complicated by persistent arthritis or Reiter's syndrome (p. 1107).

Cholera

Cholera, caused by *Vibrio cholerae* serotype O1, is the archetypal toxin-mediated bacterial cause of acute watery diarrhoea. The enterotoxin activates adenylate cyclase in the intestinal epithelium, inducing net secretion of chloride and water. *V. cholerae* O1 has two biotypes, classical and El Tor, and each of these has two distinct serotypes, Inaba and Ogawa. Following its origin in the Ganges valley, devastating epidemics have occurred, often in association with large religious festivals, and pandemics have spread worldwide. The seventh pandemic, due to the El Tor biotype, began in 1961 and spread via the Middle East to become endemic in Africa. In 1990, it reached Peru and spread throughout South and Central America. Since 2005, numbers of cases of cholera have been increasing. There are recurrent outbreaks and epidemics in Africa, often related to flooding. El Tor is more resistant to commonly used antimicrobials than classical *Vibrio*, and causes prolonged carriage in 5% of infections. A new classical toxigenic strain, serotype O139, established itself in Bangladesh in 1992 and started a new pandemic.

Infection spreads via the stools or vomit of symptomatic patients or of the much larger number of subclinical cases. Organisms survive for up to 2 weeks in fresh water and 8 weeks in salt water. Transmission is normally through infected drinking water, shellfish and food contaminated by flies, or on the hands of carriers.

Clinical features

Severe diarrhoea without pain or colic begins suddenly and is followed by vomiting. Following the evacuation of normal gut faecal contents, typical 'rice water' material is passed, consisting of clear fluid with flecks of mucus. Classical cholera produces enormous loss of fluid and electrolytes, leading to intense dehydration with muscular cramps. Shock and oliguria develop but mental clarity remains. Death from acute circulatory failure may occur rapidly unless fluid and electrolytes are replaced. Improvement is rapid with proper treatment.

The majority of infections, however, cause mild illness with slight diarrhoea. Occasionally, a very intense illness, 'cholera sicca', occurs, with loss of fluid into dilated bowel, killing the patient before typical gastrointestinal symptoms appear. The disease is more dangerous in children.

Diagnosis and management

Clinical diagnosis is easy during an epidemic. Otherwise, the diagnosis should be confirmed bacteriologically. Stool dark-field microscopy shows the typical 'shooting star' motility of *V. cholerae*. Rectal swab or stool cultures allow identification. Cholera is notifiable under international health regulations.

Maintenance of circulation by replacement of water and electrolytes is paramount (p. 307). Ringer-Lactate is the best fluid for intravenous replacement. Vomiting usually stops once the patient is rehydrated, and fluid should then be given orally up to 500 mL hourly. Early intervention with oral rehydration solutions that include resistant starch, based on either rice or cereal, shortens

the duration of diarrhoea and improves prognosis. Total fluid requirements may exceed 50 L over a period of 2–5 days. Accurate records are greatly facilitated by the use of a 'cholera cot', which has a reinforced hole under the patient's buttocks, beneath which a graded bucket is placed.

Three days treatment with tetracycline 250 mg 4 times daily, a single dose of doxycycline 300 mg or ciprofloxacin 1 g in adults reduces the duration of excretion of *V. cholerae* and the total volume of fluid needed for replacement.

Prevention

Strict personal hygiene is vital and drinking water should come from a clean piped supply or be boiled. Flies must be denied access to food. Parenteral vaccination with a killed suspension of *V. cholerae* provides some protection. Oral vaccines containing killed *V. cholerae* and the B subunit of cholera toxin are available but are of limited efficacy.

In epidemics, public education and control of water sources and population movement are vital. Mass single-dose vaccination and treatment with tetracycline are valuable. Disinfection of discharges and soiled clothing, and scrupulous hand-washing by medical attendants reduce the danger of spread.

Vibrio parahaemolyticus infection

This marine organism produces a disease similar to enterotoxigenic *E. coli* (see above). It is acquired from raw seafood and is very common where ingestion of such food is widespread (e.g. Japan). After an incubation period of approximately 20 hours, explosive diarrhoea, abdominal cramps and vomiting occur. Systemic symptoms of headache and fever are frequent but the illness is self-limiting after 4–7 days. Rarely, a severe septicaemic illness arises; in this case, *V. parahaemolyticus* can be isolated using specific halophilic culture.

Bacillary dysentery (shigellosis)

Shigellae are Gram-negative rods, closely related to *E. coli,* that invade the colonic mucosa. There are four main groups: *Sh. dysenteriae*, *flexneri*, *boydii* and *sonnei.* In the tropics, bacillary dysentery is usually caused by *Sh. flexneri*, whilst in the UK most cases are caused by *Sh. sonnei*. Shigellae are often resistant to multiple antibiotics, especially in tropical countries. The organism only infects humans and its spread is facilitated by its low infecting dose of around 10 organisms.

Spread may occur via contaminated food or flies, but transmission by unwashed hands after defecation is by far the most important factor. Outbreaks occur in mental hospitals, residential schools and other closed institutions, and dysentery is a constant accompaniment of wars and natural catastrophes, which bring crowding and poor sanitation in their wake. *Shigella* infection may spread rapidly amongst men who have sex with men.

Clinical features

Disease severity varies from mild *Sh. sonnei* infections that may escape detection to more severe *Sh. flexneri* infections, while those due to *Sh. dysenteriae* may be fulminating and cause death within 48 hours.

In a moderately severe illness, the patient complains of diarrhoea, colicky abdominal pain and tenesmus. Stools are small, and after a few evacuations contain blood and purulent exudate with little faecal material. Fever, dehydration and weakness occur, with tenderness over the colon. Arthritis or iritis may occasionally complicate bacillary dysentery (Reiter's syndrome, p. 1107), associated with HLA-B27.

Management and prevention

Oral rehydration therapy or, if diarrhoea is severe, intravenous replacement of water and electrolyte loss is necessary. Antibiotic therapy with ciprofloxacin (500 mg twice daily for 3 days) is effective in known shigellosis and appropriate in epidemics. The use of antidiarrhoeal medication should be avoided.

The prevention of faecal contamination of food and milk and the isolation of cases may be difficult, except in limited outbreaks. Hand-washing is very important.

Respiratory bacterial infections

Most of these infections are described in Chapter 19.

Diphtheria

Infection with *Corynebacterium diphtheriae* occurs most commonly in the upper respiratory tract and is usually spread by droplet infection. Infection may also complicate skin lesions, especially in those who misuse alcohol. The organisms remain localised at the site of infection but release of a soluble exotoxin damages the heart muscle and the nervous system.

Diphtheria has been eradicated from many parts of the world by mass vaccination using a modified exotoxin but remains important in areas where vaccination has been incomplete, e.g. in Russia and South-east Asia. The disease is notifiable in all countries of Europe and North America, and international guidelines have been issued by the WHO for the management of infection.

Clinical features

The average incubation period is 2–4 days. The disease begins insidiously with a sore throat (Box 13.49). Despite modest fever, there is usually marked tachycardia. The diagnostic feature is the 'wash-leather' elevated, greyish-green membrane on the tonsils. It has a well-defined edge, is firm and adherent, and is surrounded by a zone of inflammation. There may be swelling of the neck ('bull neck') and tender enlargement of the lymph nodes. In the mildest infections, especially in the presence of a high degree of immunity, a membrane may never appear and the throat is merely slightly inflamed.

13.49 Clinical features of diphtheria

Acute infection

- Membranous tonsillitis
- *or* Nasal infection
- *or* Laryngeal infection
- *or* Skin/wound/conjunctival infection (rare)

Complications

- Laryngeal obstruction or paralysis
- Myocarditis
- Peripheral neuropathy

With anterior nasal infection there is nasal discharge, frequently blood-stained. In laryngeal diphtheria, a husky voice and high-pitched cough signal potential respiratory obstruction requiring urgent tracheostomy. If infection spreads to the uvula, fauces and nasopharynx, the patient is gravely ill.

Death from acute circulatory failure may occur within the first 10 days. Late complications arise as a result of toxin action on the heart or nervous system. About 25% of survivors of the early toxaemia may later develop myocarditis with arrhythmias or cardiac failure. These are usually reversible, with no permanent damage other than heart block in survivors.

Neurological involvement occurs in 75% of cases. After tonsillar or pharyngeal diphtheria, it usually starts after 10 days with palatal palsy. Paralysis of accommodation often follows, manifest by difficulty in reading small print. Generalised polyneuritis with weakness and paraesthesia may follow in the next 10–14 days. Recovery from such neuritis is always ultimately complete.

Management

A clinical diagnosis of diphtheria must be notified to the public health authorities and the patient sent urgently to a specialist infectious diseases unit. Treatment should begin once appropriate swabs have been taken before waiting for microbiological confirmation.

Diphtheria antitoxin is produced from hyperimmune horse serum. It neutralises circulating toxin but has no effect on toxin already fixed to tissues, so it must be injected intramuscularly without awaiting the result of a throat swab. However, reactions to this foreign protein include a potentially lethal immediate anaphylactic reaction (p. 91) and a 'serum sickness' with fever, urticaria and joint pains, which occurs 7–12 days after injection. A careful history of previous horse serum injections or allergic reactions should be taken and a small test injection of serum should be given half an hour before the full dose in every patient. Adrenaline (epinephrine) solution must be available to deal with any immediate type of reaction (0.5–1.0 mL of 1/1000 solution IM). An antihistamine is also given. In a severely ill patient, the risk of anaphylactic shock is outweighed by the mortal danger of diphtheritic toxaemia, and up to 100 000 U of antitoxin are injected intravenously if the test dose has not given rise to symptoms. For disease of moderate severity, 16 000–40 000 U IM will suffice, and for mild cases 4000–8000 U.

Penicillin (1200 mg 4 times daily IV) or amoxicillin (500 mg 3 times daily) should be administered for 2 weeks to eliminate *C. diphtheriae.* Patients allergic to penicillin can be given erythromycin. Due to poor immunogenicity of primary infection, all sufferers should be immunised with diphtheria toxoid following recovery.

Patients must be managed in strict isolation and attended by staff with a clearly documented immunisation history until three swabs 24 hours apart are culture-negative.

Prevention

Active immunisation should be given to all children. If diphtheria occurs in a closed community, contacts should be given erythromycin, which is more effective than penicillin in eradicating the organism in carriers.

All contacts should also be immunised or given a booster dose of toxoid. Booster doses are required every 10 years to maintain immunity.

Pneumococcal infection

Strep. pneumoniae (the pneumococcus) is the leading cause of community-acquired pneumonia globally (p. 682) and one of the leading causes of infection-related mortality. Otitis media, meningitis and sinusitis are also frequently due to *Strep. pneumoniae*. Occasional patients present with bacteraemia without obvious focus. Asplenic individuals are at risk of fulminant pneumococcal disease with purpuric rash.

Increasing rates of penicillin resistance have been reported around the world for *Strep. pneumoniae*, although they remain relatively low in the UK. Strains with high-level resistance causing meningitis require treatment with glycopeptides rather than with penicillins or cephalosporins. Macrolide resistance is also increasing. Newer quinolones are also used but rates of resistance are rising.

Vaccination of infants with the protein conjugate pneumococcal vaccine decreases *Strep. pneumoniae* infection in infants and in their relatives. The polysaccharide pneumococcal vaccine is used in individuals predisposed to *Strep. pneumoniae* infection and the elderly, but only modestly reduces pneumococcal bacteraemia and does not prevent pneumonia. All asplenic individuals should receive vaccination against *Strep. pneumoniae*.

Anthrax

Anthrax is an endemic zoonosis in many countries; it causes human disease following inoculation of the spores of *Bacillus anthracis*. *B. anthracis* was the first-recognised bacterial pathogen described by Koch and became the model pathogen for 'Koch's postulates' (Box 6.1, p. 134). It is a Gram-positive organism with a central spore. The spores can survive for years in soil. Infection is commonly acquired from contact with animals, particularly herbivores. The ease of production of *B. anthracis* spores makes this infection a candidate for biological warfare or bioterrorism. *B. anthracis* produces a number of toxins which mediate the clinical features of disease.

Clinical features

These depend on the route of entry of the anthrax spores.

Cutaneous anthrax

This skin lesion is associated with occupational exposure to anthrax spores during processing of hides and bone products. It accounts for the vast majority of clinical cases. Animal infection is a serious problem in Africa, India, Pakistan and the Middle East.

Spores are inoculated into exposed skin. A single lesion develops as an irritable papule on an oedematous haemorrhagic base. This progresses to a depressed black eschar. Despite extensive oedema, pain is infrequent.

Gastrointestinal anthrax

This is associated with the ingestion of contaminated meat products. The caecum is the seat of the infection, which produces nausea, vomiting, anorexia and fever, followed in 2–3 days by severe abdominal pain and bloody diarrhoea. Toxaemia and death can develop rapidly thereafter.

Inhalational anthrax

This form of the disease is extremely rare but has been associated with bioterrorism. Without rapid and aggressive therapy at the onset of symptoms, the mortality is 50–90%. Fever, dyspnoea, cough, headache and symptoms of septicaemia develop 3–14 days following exposure. Typically, the chest X-ray shows only widening of the mediastinum and pleural effusions, which are haemorrhagic. Meningitis may occur.

Management

B. anthracis can be cultured from skin swabs from lesions. Skin lesions are readily curable with early antibiotic therapy. Treatment is with ciprofloxacin (500 mg twice daily) until penicillin susceptibility is confirmed; the regimen can then be changed to benzylpenicillin with doses up to 2.4 g IV given 6 times daily or phenoxymethylpenicillin 500–1000 mg 4 times daily administered for 10 days. The addition of an aminoglycoside may improve the outlook in severe disease. In view of concerns about concomitant inhalational exposure, particularly in the era of bioterrorism, a further 2-month course of ciprofloxacin 500 mg twice daily or doxycycline 100 mg twice daily orally is added. Prophylaxis with ciprofloxacin (500 mg twice daily) is recommended for anyone at high risk of exposure to anthrax spores.

Bacterial infections with neurological involvement

Infections affecting the CNS, including bacterial meningitis, botulism and tetanus, are described on page 1201.

Mycobacterial infections

Tuberculosis is predominantly, although by no means exclusively, a respiratory disease and is described on page 688.

Leprosy

Leprosy (Hansen's disease) is a chronic granulomatous disease affecting skin and nerves, and is caused by *Mycobacterium leprae*, a slow-growing mycobacterium which cannot be cultured in vitro. The clinical manifestations are determined by the degree of the patient's cell-mediated immunity (CMI, p. 78) towards *M. leprae* (Fig. 13.27). High levels of CMI with elimination of leprosy bacilli produces tuberculoid leprosy, whereas absent CMI results in lepromatous leprosy. The complications of leprosy are due to nerve damage, immunological reactions and bacillary infiltration. Leprosy patients are frequently stigmatised and using the word 'leper' is inappropriate.

Epidemiology and transmission

Some 4 million people have leprosy and around 750 000 new cases are detected annually. About 70% of the world's leprosy patients live in India, with the disease endemic in Brazil, Indonesia, Mozambique, Madagascar, Tanzania and Nepal.

Untreated lepromatous patients discharge bacilli from the nose. Infection occurs through the nose, followed by haematogenous spread to skin and nerve. The incubation period is 2–5 years for tuberculoid cases and 8–12 years for lepromatous cases. Leprosy incidence peaks at 10–14 years, and is more common in males and in those with close household exposure to leprosy cases.

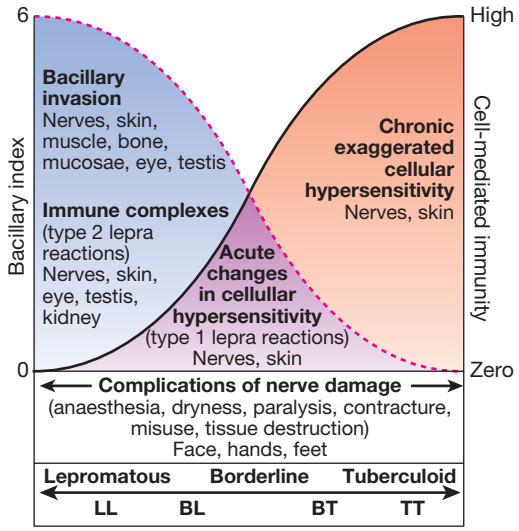

Fig. 13.27 Leprosy: mechanisms of damage and tissue affected. Mechanisms under the broken line are characteristic of disease near the lepromatous end of the spectrum, and those under the solid line are characteristic of the tuberculoid end. They overlap in the centre where, in addition, instability predisposes to type 1 lepra reactions. At the peak in the centre, neither bacillary growth nor cell-mediated immunity has the upper hand (BL = borderline lepromatous; BT = borderline tuberculoid). Based on Bryceson and Pfaltzgraff 1990 – see p. 386.

Pathogenesis

M. leprae has a predilection for infecting Schwann cells and skin macrophages. In tuberculoid leprosy, effective CMI controls bacillary multiplication ('paucibacillary') but organised epithelioid granulomas are formed. In lepromatous leprosy, there is abundant bacillary multiplication ('multibacillary'), e.g. in Schwann cells and perineurium. Between these two extremes is a continuum, varying from patients with moderate CMI (borderline tuberculoid) to patients with little cellular response (borderline lepromatous).

In addition, immunological reactions to the infection occur as the immune response develops and the antigenic stimulus from the bacilli varies, particularly in borderline patients. Delayed hypersensitivity reactions produce type 1 (reversal) reactions, while immune complexes contribute to type 2 (erythema nodosum leprosum) reactions.

HIV/leprosy co-infected patients have typical lepromatous and tuberculoid leprosy skin lesions and typical leprosy histology and granuloma formation. Surprisingly, even with low circulating CD4 counts, tuberculoid leprosy may be observed and there is not an obvious shift to lepromatous leprosy.

Clinical features

Box 13.50 gives the cardinal features of leprosy. Types of leprosy are compared in Box 13.51.

- *Skin.* The most common skin lesions are macules or plaques. Tuberculoid patients have few,

Fig. 13.28 Clinical features of leprosy. A Tuberculoid leprosy. Single lesion with a well-defined active edge and anaesthesia within the lesion. B Lepromatous leprosy. Widespread nodules and infiltration, with loss of the eyebrows. This man also has early collapse of the nose. C Borderline tuberculoid leprosy with severe nerve damage. This boy has several well-defined, hypopigmented, macular, anaesthetic lesions. He has severe nerve damage affecting both ulnar and median nerves bilaterally and has sustained severe burns to his hands. D Reversal (type 1) reactions. Erythematous, oedematous lesions.

13.50 Cardinal features of leprosy

- Skin lesions, typically anaesthetic at tuberculoid end of spectrum
- Thickened peripheral nerves
- Acid-fast bacilli on skin smears or biopsy

hypopigmented lesions (Fig. 13.28A). In lepromatous leprosy, papules, nodules or diffuse infiltration of the skin occur. The earliest lesions are ill defined; gradually, the skin becomes infiltrated and thickened. Facial skin thickening leads to the characteristic leonine facies (Fig. 13.28B).

- *Anaesthesia.* In skin lesions, the small dermal sensory and autonomic nerve fibres are damaged, causing local sensory loss and loss of sweating within that area. Anaesthesia may also occur in the distribution of a damaged large peripheral nerve. A 'glove and stocking' sensory neuropathy is also common in lepromatous leprosy.
- *Nerve damage.* Peripheral nerve trunks are affected at 'sites of predilection'. These are the ulnar (elbow), median (wrist), radial (humerus), radial cutaneous (wrist), common peroneal (knee), posterior tibial and sural nerves (ankle), facial nerve (zygomatic arch) and great auricular nerve (posterior triangle of the neck). Damage to peripheral nerve trunks produces characteristic signs with regional sensory loss and muscle dysfunction (Fig. 13.28C). All these nerves should be examined for enlargement and tenderness and tested for motor and sensory function. The CNS is not affected.
- *Eye involvement.* Blindness is a devastating complication for a patient with anaesthetic hands and feet. Eyelid closure is impaired when the facial

13.51 Clinical characteristics of the polar forms of leprosy

Clinical and tissue-specific features	Lepromatous	Tuberculoid
Skin and nerves		
Number and distribution	Widely disseminated	One or a few sites, asymmetrical
Skin lesions		
Definition		
Clarity of margin	Poor	Good
Elevation of margin	Never	Common
Colour		
Dark skin	Slight hypopigmentation	Marked hypopigmentation
Light skin	Slight erythema	Coppery or red
Surface	Smooth, shiny	Dry, scaly
Central healing	None	Common
Sweat and hair growth	Impaired late	Impaired early
Loss of sensation	Late	Early and marked
Nerve enlargement and damage	Late	Early and marked
Bacilli (bacterial index)	Many (5 or 6+)	Absent (0)
Natural history	Progressive	Self-healing
Other tissues	Upper respiratory mucosa, eye, testes, bones, muscle	None
Reactions	Immune complexes (type 2)	Cell-mediated (type 1)

nerve is affected. Damage to the trigeminal nerve causes anaesthesia of the cornea and conjunctiva. The cornea is then susceptible to trauma and ulceration.

- *Other features.* Many organs can be affected. Nasal collapse occurs secondary to bacillary destruction of the bony nasal spine. Diffuse infiltration of the testes causes testicular atrophy and the acute orchitis that occurs with type 2 reactions. This results in azoospermia and hypogonadism.

Leprosy reactions

Leprosy reactions (Box 13.52) are events superimposed on the cardinal features shown in Box 13.50.

- *Type 1 (reversal) reactions.* These occur in 30% of borderline patients (BT, BB or BL) and are delayed hypersensitivity reactions. Skin lesions become erythematous (Fig. 13.28D). Peripheral nerves become tender and painful, with sudden loss of nerve function. These reactions may occur spontaneously, after starting treatment and also after completion of multidrug therapy.
- *Type 2 (erythema nodosum leprosum, ENL) reactions.* These are partly due to immune complex deposition and occur in BL and LL patients who produce antibodies and have a high antigen load. They manifest with malaise, fever and crops of small pink nodules on the face and limbs. Iritis and episcleritis are common. Other signs are acute neuritis, lymphadenitis, orchitis, bone pain, dactylitis, arthritis and proteinuria. ENL may continue intermittently for several years.

Borderline cases

In borderline tuberculoid (BT) cases, skin lesions are more numerous than in tuberculoid (TT) cases, and there is more severe nerve damage and a risk of type 1 reactions. In borderline leprosy (BB) cases, skin lesions are numerous and vary in size, shape and distribution; annular lesions are characteristic and nerve damage is variable. In borderline lepromatous (BL) cases, there are widespread small macules in the skin and widespread nerve involvement; both type 1 and type 2 reactions occur.

Pure neural leprosy (i.e. without skin lesions) occurs principally in India and accounts for 10% of patients. There is asymmetrical involvement of peripheral nerve trunks and no visible skin lesions. On nerve biopsy, all types of leprosy have been found.

Investigations

The diagnosis is clinical, made by finding a cardinal sign of leprosy and supported by finding acid-fast bacilli in slit-skin smears or typical histology in a skin biopsy. Slit-skin smears are obtained by scraping dermal material on to a glass slide. The smears are then stained for acid-fast bacilli, the number counted per high-power field and a score derived on a logarithmic scale (0–6): the bacterial index (BI). Smears are useful for confirming the diagnosis and monitoring response to treatment. Neither serology nor PCR testing for *M. leprae* DNA is sensitive or specific enough for diagnosis.

Management

The principles of treatment are outlined in Box 13.53. All leprosy patients should be given multidrug treatment (MDT) with an approved first-line regimen (Box 13.54).

13.53 Principles of leprosy treatment

- Stop the infection with chemotherapy
- Treat reactions
- Educate the patient about leprosy
- Prevent disability
- Support the patient socially and psychologically

13.52 Reactions in leprosy

	Lepra reaction type 1 (reversal)	Lepra reaction type 2 (erythema nodosum leprosum)
Mechanism	Cell-mediated hypersensitivity	Immune complexes
Clinical features	Painful tender nerves, loss of function Swollen skin lesions New skin lesions	Tender papules and nodules; may ulcerate Painful tender nerves, loss of function Iritis, orchitis, myositis, lymphadenitis Fever, oedema
Management	Prednisolone 40 mg, reducing over 3–6 mths[1]	Moderate: prednisolone 40 mg daily Severe: thalidomide[2] or prednisolone 40–80 mg daily, reducing over 1–6 mths; local if eye involved[3]

[1]Indicated for any new impairment of nerve or eye function.
[2]Contraindicated in women who may become pregnant.
[3]1% hydrocortisone drops or ointment and 1% atropine drops.

13.54 Modified WHO-recommended multidrug therapy (MDT) regimens in leprosy

Type of leprosy[1]	Monthly supervised treatment	Daily self-administered treatment	Duration of treatment[2]
Paucibacillary	Rifampicin 600 mg	Dapsone 100 mg	6 mths
Multibacillary	Rifampicin 600 mg Clofazimine 300 mg	Clofazimine 50 mg Dapsone 100 mg	12 mths
Paucibacillary single-lesion	Ofloxacin 400 mg Rifampicin 600 mg Minocycline 100 mg		Single dose

[1]Classification uses the bacillary index (BI) in slit-skin smears or, if BI is not available, the number of skin lesions:
- paucibacillary single-lesion leprosy (one skin lesion)
- paucibacillary (2–5 skin lesions)
- multibacillary (> 5 skin lesions).

[2]Studies from India have shown that multibacillary patients with an initial BI > 4 need longer treatment, for at least 24 mths.

Rifampicin is a potent bactericidal for *M. leprae* but should always be given in combination with other antileprotics, since a single-step mutation can confer resistance. Dapsone is bacteriostatic. It commonly causes mild haemolysis and rarely anaemia. Clofazimine is a red, fat-soluble crystalline dye, weakly bactericidal for *M. leprae*. Skin discoloration (red to purple-black) and ichthyosis are troublesome side-effects, particularly on pale skins. New drugs that are bactericidal for *M. leprae* have been identified, notably the fluoroquinolones pefloxacin and ofloxacin, minocycline and clarithromycin. These agents are now established second-line drugs. Minocycline causes a grey pigmentation of skin lesions.

Although single-dose treatment is less effective than the conventional 6-month treatment for paucibacillary leprosy, it is an operationally attractive field regimen and has been recommended for use by the WHO.

Lepra reactions are treated as shown in Box 13.52. Chloroquine can also be used.

Patient education

Educating leprosy patients about their disease is vital. Patients should be reassured that, after 3 days of chemotherapy, they are not infectious and can lead a normal social life. It should be emphasised that gross deformities are not inevitable.

Patients with anaesthetic hands or feet need to take special care to avoid and treat burns and other minor injuries. Good footwear is important. Physiotherapy may be required to maintain range of movement of affected muscles and neighbouring joints.

Prognosis

Untreated, tuberculoid leprosy has a good prognosis; it may self-heal and peripheral nerve damage is limited. Lepromatous leprosy (LL) is a progressive condition with high morbidity if untreated.

After treatment, the majority of patients, especially those who have no nerve damage at the time of diagnosis, do well, with resolution of skin lesions. Borderline patients are at risk of developing type 1 reactions, which may result in devastating nerve damage.

Prevention and control

The previous strategy of centralised leprosy control campaigns has now been superseded by integrated programmes, with primary health-care workers in many countries now responsible for case detection and provision of MDT. It is not yet clear how successful this will be, especially in the time-consuming area of disability prevention.

BCG vaccination has been shown to give good but variable protection against leprosy; adding killed *M. leprae* to BCG does not enhance protection.

Rickettsial and related intracellular bacterial infections

Rickettsial fevers

The rickettsial fevers are the most common tick-borne infections. It is important to ask potentially infected patients about contact with ticks, lice or fleas. There are two main groups of rickettsial fevers: spotted fevers and typhus (Box 13.55).

Pathogenesis

The rickettsiae are intracellular Gram-negative organisms which parasitise the intestinal canal of arthropods. Infection is usually conveyed to humans through the skin from the excreta of arthropods, but the saliva of some biting vectors is infected. The organisms multiply in capillary endothelial cells, producing lesions in the skin, CNS, heart, lungs, liver, kidneys and skeletal muscles. Endothelial proliferation, associated with a perivascular reaction, may cause thrombosis and purpura. In epidemic typhus, the brain is the target organ; in scrub typhus, the cardiovascular system and lungs in particular are attacked. An eschar, a black necrotic crusted sore, is often found in tick- and mite-borne typhus (see Fig. 13.6C, p. 313). This is due to vasculitis following immunological recognition of the inoculated organism. Regional lymph nodes often enlarge.

Spotted fever group

Rocky Mountain spotted fever

Rickettsia rickettsii is transmitted by tick bites. It is widely distributed and increasing in western and south-eastern states of the USA and also in Central and South America. The incubation period is about 7 days. The rash appears on about the third or fourth day of illness, looking at first like measles, but in a few hours a typical maculopapular eruption develops. The rash spreads in 24–48 hours from wrists, forearms and ankles to the back, limbs and chest, and then to the abdomen, where it is least pronounced. Larger cutaneous and subcutaneous haemorrhages may appear in severe cases. The liver and spleen become palpable. At the extremes of life, the mortality is 2–12%.

Other spotted fevers

R. conorii (boutonneuse fever) and *R. africae* (African tick fever) cause Mediterranean and African tick typhus, which also occurs on the Indian subcontinent. The incubation period is approximately 7 days. Infected ticks may be picked up by walking on grasslands, or dogs may bring ticks into the house. Careful examination might reveal a diagnostic eschar, and the maculopapular rash on the trunk, limbs, palms and soles. There may be delirium and meningeal signs in severe infections but recovery is usual. *R. africae* can be associated with multiple eschars. Some cases, particularly those with *R. africae*, present without rash ('spotless spotted fever'). Other spotted fevers are shown in Box 13.55.

Typhus group

Scrub typhus fever

Scrub typhus is caused by *Orientia tsutsugamushi* (formerly *Rickettsia tsutsugamushi*), transmitted by mites. It occurs in the Far East, Myanmar, Pakistan, Bangladesh, India, Indonesia, the South Pacific islands and Queensland, particularly where patches of forest cleared for plantations have attracted rats and mites.

In many patients, one eschar or more develops, surrounded by an area of cellulitis (see Fig. 13.6C, p. 313) and enlargement of regional lymph nodes. The incubation period is about 9 days.

Mild or subclinical cases are common. The onset of symptoms is usually sudden, with headache (often retro-orbital), fever, malaise, weakness and cough. In severe illness, the general symptoms increase, with

13.55 Features of rickettsial infections

Disease	Organism	Reservoir	Vector	Geographical area	Rash	Gangrene	Target organs	Mortality

[1]Eschar at bite site and local lymphadenopathy. [2]Highest in adult males. [3]Except in infants, older people and the debilitated.

apathy and prostration. An erythematous maculopapular rash often appears on about the 5th–7th day and spreads to the trunk, face and limbs, including the palms and soles, with generalised painless lymphadenopathy. The rash fades by the 14th day. The temperature rises rapidly and continues as a remittent fever (i.e. the difference between maximum and minimum temperature exceeds 1°C), remaining above normal with sweating until it falls on the 12th–18th day. In severe infection, the patient is prostrate with cough, pneumonia, confusion and deafness. Cardiac failure, renal failure and haemorrhage may develop. Convalescence is often slow and tachycardia may persist for some weeks.

Epidemic (louse-borne) typhus

Epidemic typhus is caused by *R. prowazekii* and is transmitted by infected faeces of the human body louse, usually through scratching the skin. Patients suffering from epidemic typhus infect the lice, which leave when the patient is febrile. In conditions of overcrowding, the disease spreads rapidly. It is prevalent in parts of Africa, especially Ethiopia and Rwanda, and in the South American Andes and Afghanistan. Large epidemics have occurred in Europe, usually as a sequel to war. The incubation period is usually 12–14 days.

There may be a few days of malaise but the onset is more often sudden, with rigors, fever, frontal headaches, pains in the back and limbs, constipation and bronchitis. The face is flushed and cyanotic, the eyes are congested and the patient becomes confused. The rash appears on the 4th–6th day. In its early stages, it disappears on pressure but soon becomes petechial with subcutaneous mottling. It appears first on the anterior folds of the axillae, sides of the abdomen or backs of hands, then on the trunk and forearms. The neck and face are seldom affected. During the second week, symptoms increase in severity. Sores develop on the lips. The tongue becomes dry, brown, shrunken and tremulous. The spleen is palpable, the pulse feeble and the patient stuporous and delirious. The temperature falls rapidly at the end of the second week and the patient recovers gradually. In fatal cases, the patient usually dies in the second week from toxaemia, cardiac or renal failure, or pneumonia.

Endemic (flea-borne) typhus

Flea-borne or 'endemic' typhus caused by *R. typhi* is endemic worldwide. Humans are infected when the faeces or contents of a crushed flea, which has fed on an infected rat, are introduced into the skin. The incubation period is 8–14 days. The symptoms resemble those of a

mild louse-borne typhus. The rash may be scanty and transient.

Investigation of rickettsial infection

Routine blood investigations are not diagnostic but malaria must be excluded by blood film examination in most cases, and there is usually hepatitis and thrombocytopenia. Diagnosis is made on clinical grounds and response to treatment, and may be confirmed by antibody detection or PCR in specialised laboratories. Differential diagnoses include malaria, typhoid, meningococcal sepsis and leptospirosis.

Management of rickettsial fevers

The different rickettsial fevers vary greatly in severity but all respond to tetracycline 500 mg 4 times daily, doxycycline 200 mg daily or chloramphenicol 500 mg 4 times daily for 7 days. Louse-borne typhus and scrub typhus can be treated with a single dose of 200 mg doxycycline, repeated for 2–3 days to prevent relapse. Chloramphenicol- and doxycycline-resistant strains of *O. tsutsugamushi* have been reported from Thailand and patients here may need treatment with rifampicin.

Nursing care is important, especially in epidemic typhus. Sedation may be required for delirium and blood transfusion for haemorrhage. Relapsing fever and typhoid are common intercurrent infections in epidemic typhus, and pneumonia in scrub typhus. They must be sought and treated. Convalescence is usually protracted, especially in older people.

To prevent rickettsial infection, lice, fleas, ticks and mites need to be controlled with insecticides.

Q fever

Q fever occurs worldwide and is caused by the rickettsia-like organism *Coxiella burnetii*, an obligate intracellular organism that can survive in the extracellular environment. Cattle, sheep and goats are important reservoirs and the organism is transmitted by inhalation of aerosolised particles. An important characteristic of *C. burnetii* is its antigenic variation, called phase variation, due to a change of lipopolysaccharide (LPS). When isolated from animals or humans, *C. burnetii* expresses phase I antigen and is very infectious (a single bacterium is sufficient to infect a human). In culture, there is an antigenic shift to the phase II form, which is not infectious. This antigenic shift can be measured and is valuable for the differentiation of acute and chronic Q fever.

Clinical features

The incubation period is 3–4 weeks. The initial symptoms are non-specific with fever, headache and chills; in 20% of cases, a maculopapular rash occurs. Other presentations include pneumonia and hepatitis. Chronic Q fever may present with osteomyelitis, encephalitis and endocarditis.

Investigations and management

Diagnosis is usually serological and the stage of the infection can be distinguished by isotype tests and phase-specific antigens. Phase I and II IgM titres peak at 4–6 weeks. In chronic infections, IgG titres to phase I and II antigens may be raised.

Prompt treatment of acute Q fever with doxycycline reduces fever duration. Treatment of Q fever endocarditis is problematic, requiring prolonged therapy with doxycycline and rifampicin or ciprofloxacin with hydroxychloroquine; even then, organisms are not always eradicated. Valve surgery is often required (p. 629).

Bartonellosis

This group of diseases are caused by intracellular Gram-negative bacilli closely related to the rickettsiae, which have been discovered to be important causes of 'culture-negative' endocarditis. They are found in many domestic pets, such as cats, although for several the host is ill defined (Box 13.56). The principal human pathogens are *Bartonella quintana*, *B. henselae* and *B. bacilliformis*. *Bartonella* infections are associated with the following:

- *Trench fever*. This is a relapsing fever with severe leg pain and is caused by *B. quintana*. The disease is not fatal but is very debilitating.
- *Bacteraemia and endocarditis in the homeless*. Endocarditis due to *B. quintana* or *henselae* is associated with severe damage to the heart valves.
- *Cat scratch disease*. *B. henselae* causes this common benign lymphadenopathy in children and young adults. A vesicle or papule develops on the head, neck or arms after a cat scratch. The lesion resolves spontaneously but there may be regional lymphadenopathy that persists for up to 4 months before also resolving spontaneously.
- *Bacillary angiomatosis*. This is an HIV-associated disease caused by *B. quintana* or *henselae* (p. 398).
- *Oroya fever and verruga peruana* (*Carrion's disease*). This is endemic in areas of Peru. It is a biphasic disease caused by *B. bacilliformis* and is transmitted by sandflies of the genus *Phlebotomus*. Fever, haemolytic anaemia and microvascular thrombosis with end-organ ischaemia are features. It is frequently fatal if untreated.

Investigations and management

Bartonellae can be grown from the blood but this requires prolonged incubation using enriched media. Serum antibody detection is possible.

Bartonella species are susceptible to β-lactams, rifampicin, erythromycin and tetracyclines. Antibiotic use is guided by clinical need. Cat scratch disease usually

13.56 Clinical diseases caused by *Bartonella* spp.

Reservoir	Vector	Organism	Disease
Cats	Flea	*B. henselae*	**Cat scratch disease, bacillary angiomatosis, endocarditis**
Undefined	Lice	*B. quintana*	**Trench fever, bacillary angiomatosis, endocarditis**
Undefined	Sandfly	*B. bacilliformis*	**Carrion's disease: Oroya fever and verruga peruana**
Undefined	Flea	*B. rochalimae*	**Fever, rash, anaemia, splenomegaly**

resolves spontaneously but *Bartonella* endocarditis requires valve replacement and combination antibiotic therapy.

Chlamydial infections

These are listed in Box 13.57 and are also described in Chapters 15 and 19.

Trachoma

Trachoma is a chronic keratoconjunctivitis caused by *Chlamydia trachomatis*, and is the most common cause of avoidable blindness. The classic trachoma environment is dry and dirty, causing children to have eye and nose discharges. Transmission occurs through flies, on fingers and within families. In endemic areas, the disease is most common in children.

Pathology and clinical features

The onset is usually insidious. Infection may be asymptomatic, lasts for years, may be latent over long periods and may recrudesce. The conjunctiva of the upper lid is first affected with vascularisation and cellular infiltration. Early symptoms include conjunctival irritation and blepharospasm. The early follicles are characteristic (Fig. 13.29), but clinical differentiation from conjunctivitis due to other viruses may be difficult. Scarring causes inversion of the lids (entropion) so that the lashes rub against the cornea (trichiasis). The cornea becomes vascularised and opaque. The problem may not be detected until vision begins to fail.

13.57 Chlamydial infections

Organism	Disease caused
Chlamydia trachomatis	Trachoma Lymphogranuloma venereum (see Box 15.12, p. 424) Cervicitis, urethritis, proctitis (p. 422)
Chlamydia psittaci	Psittacosis (Box 19.42, p. 683)
Chlamydophila (Chlamydia) pneumoniae	Atypical pneumonia (Box 19.42, p. 683) Acute/chronic sinusitis

Fig. 13.29 Trachoma. Trachoma is characterised by hyperaemia and numerous pale follicles.

Investigations and management

Intracellular inclusions may be demonstrated in conjunctival scrapings by staining with iodine or immunofluorescence. Chlamydia may be isolated in chick embryo or cell culture.

A single dose of azithromycin (20 mg/kg) has been shown to be superior to 6 weeks of tetracycline eye ointment twice daily for individuals in mass treatment programmes. Deformity and scarring of the lids, and corneal opacities, ulceration and scarring require surgical treatment after control of local infection.

Prevention

Personal and family cleanliness should be improved. Proper care of the eyes of newborn and young children is essential. Family contacts should be examined. The WHO is promoting the SAFE strategy for trachoma control (surgery, antibiotics, facial cleanliness and environmental improvement).

PROTOZOAL INFECTIONS

Protozoa are responsible for many important infectious diseases. They can be categorised according to whether they cause systemic or local infection. Trichomoniasis is described on page 417.

Systemic protozoal infections

Malaria

Malaria in humans is caused by *Plasmodium falciparum*, *P. vivax*, *P. ovale*, *P. malariae* and the predominantly simian parasite, *P. knowlesi*. It is transmitted by the bite of female anopheline mosquitoes and occurs throughout the tropics and subtropics at altitudes below 1500 metres (Fig. 13.30). Recent estimates have put the number of episodes of clinical malaria at 515 million cases per year, with two-thirds of these occurring in sub-Saharan Africa, especially amongst children and pregnant women. Following previous WHO-sponsored campaigns focusing on prevention and effective treatment, the incidence of malaria was greatly reduced between 1950 and 1960, but since 1970 there has been resurgence. Furthermore, *P. falciparum* has now become resistant to chloroquine and sulfadoxine-pyrimethamine, initially in South-east Asia and now throughout Africa. The WHO's Millennium Development Goal 6 aims to halt the spread of the disease by 2015, and its 'Roll Back Malaria' campaign was designed to halve mortality by 2010 by utilising the 'best evidence' vector and disease control methods, such as artemisinin combination therapy (ACT).

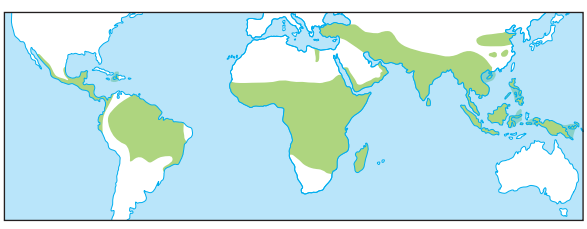

Fig. 13.30 Distribution of malaria. (For up-to-date information see the Malaria Atlas Project (MAP): www.map.ox.ac.uk)

Travellers are susceptible to malaria (p. 309). Due to increased travel, over 2000 cases are imported annually into the UK. Most are due to *P. falciparum*, usually from Africa, and of these 1% die because of late diagnosis. Immigrants returning home after visiting family and friends overseas but who have long-term residence in the UK are particularly at risk. They have lost their partial immunity and do not realise that they should be taking malaria prophylaxis. A few people living near airports in Europe have acquired malaria from accidentally imported mosquitoes.

Pathogenesis

Life cycle of the malarial parasite

The female anopheline mosquito becomes infected when it feeds on human blood containing gametocytes, the sexual forms of the malarial parasite (Figs 13.31 and 13.32). Development in the mosquito takes from 7 to 20 days, and results in sporozoites accumulating in the salivary glands and being inoculated into the human blood stream. Sporozoites disappear from human blood within half an hour and enter the liver. After some days, merozoites leave the liver and invade red blood cells, where further asexual cycles of multiplication take place, producing schizonts. Rupture of the schizont releases more merozoites into the blood and causes fever, the periodicity of which depends on the species of parasite.

P. vivax and *P. ovale* may persist in liver cells as dormant forms, hypnozoites, capable of developing into merozoites months or years later. Thus the first attack of clinical malaria may occur long after the patient has left the endemic area, and the disease may relapse after treatment if drugs that kill only the erythrocytic stage of the parasite are given.

P. falciparum and *P. malariae* have no persistent exo-erythrocytic phase but recrudescence of fever may result from multiplication of parasites in red cells which have not been eliminated by treatment and immune processes (Box 13.58).

Pathology

Red cells infected with malaria are prone to haemolysis. This is most severe with P. *falciparum*, which invades red cells of all ages but especially young cells; *P. vivax* and *P. ovale* invade reticulocytes, and *P. malariae*

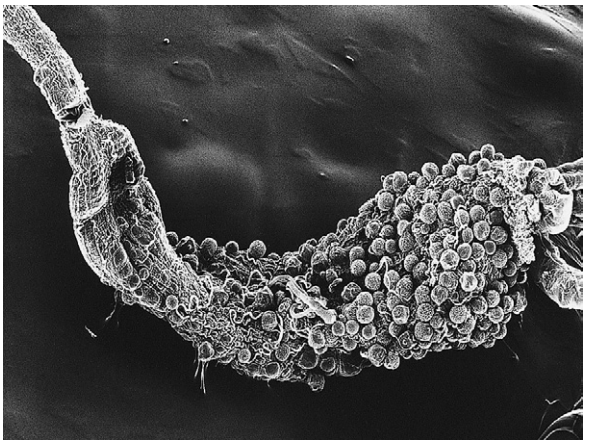

Fig. 13.31 Scanning electron micrograph of *P. falciparum* oöcysts lining an anopheline mosquito's stomach.

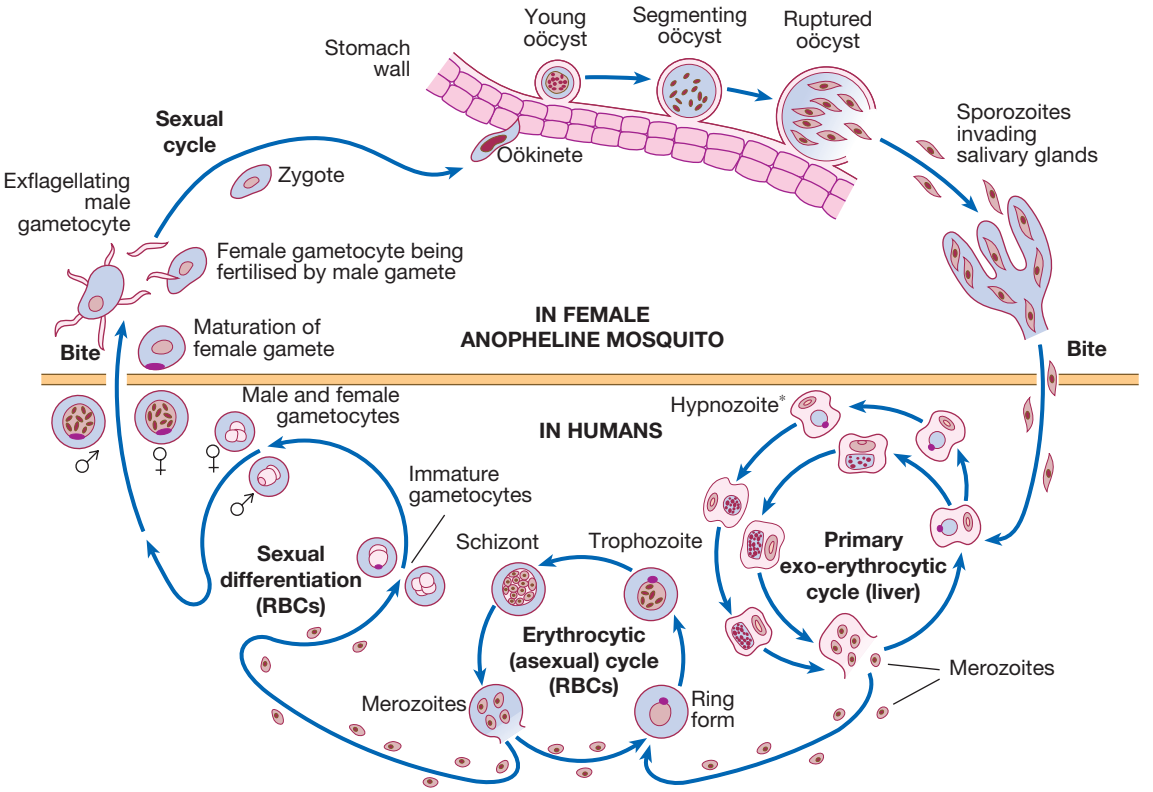

Fig. 13.32 Malarial parasites: life cycle. Hypnozoites(*) are present only in *P. vivax* and *P. ovale* infections. (RBC = red blood cell)

13.58 Relationships between life cycle of parasite and clinical features of malaria

Cycle/ feature	*P. vivax*, *P. ovale*	*P. malariae*	*P. falciparum*
Pre-patent period (minimum incubation)	8–25 days	15–30 days	8–25 days
Exo-erythrocytic cycle	Persistent as hypnozoites	Pre-erythrocytic only	Pre-erythrocytic only
Asexual cycle	48 hrs synchronous	72 hrs synchronous	< 48 hrs asynchronous
Fever periodicity	Alternate days	Every third day	None
Delayed onset	Common	Rare	Rare
Relapses	Common up to 2 yrs	Recrudescence many years later	Recrudescence up to 1 yr

normoblasts, so that infections remain lighter. Anaemia may be profound and is worsened by dyserythropoiesis, splenomegaly and depletion of folate stores.

In *P. falciparum* malaria, red cells containing trophozoites adhere to vascular endothelium in post-capillary venules in brain, kidney, liver, lungs and gut by the formation of 'knob' proteins. They also form 'rosettes' and rouleaux with uninfected red cells. The vessels become congested, resulting in widespread organ damage which is exacerbated by rupture of schizonts, liberating toxic and antigenic substances (see Fig. 13.32).

P. falciparum has influenced human evolution, with the appearance of protective mutations such as sickle-cell (HbS; p. 1032), thalassaemia (p. 1034), G6PD deficiency (p. 1029) and HLA-B53. *P. falciparum* does not grow well in red cells that contain haemoglobin F, C or especially S. Haemoglobin S heterozygotes (AS) are protected against the lethal complications of malaria. *P. vivax* cannot enter red cells that lack the Duffy blood group; therefore many West Africans and African-Americans are protected.

Clinical features

The clinical features of malaria are non-specific and the diagnosis must be suspected in anyone returning from an endemic area who has features of infection.

P. falciparum *infection*

This is the most dangerous of the malarias and patients are either 'killed or cured'. The onset is often insidious, with malaise, headache and vomiting. Cough and mild diarrhoea are also common. The fever has no particular pattern. Jaundice is common due to haemolysis and hepatic dysfunction. The liver and spleen enlarge and may become tender. Anaemia develops rapidly, as does thrombocytopenia.

A patient with *falciparum* malaria, apparently not seriously ill, may rapidly develop dangerous complications (Fig. 13.33 and Box 13.59). Cerebral malaria is manifested by confusion, seizures or coma, usually without localising signs. Children die rapidly without any special symptoms other than fever. Immunity is impaired in pregnancy and the parasite can preferentially bind to a placental protein known as chondroitin sulphate A. Abortion and intrauterine growth retardation from parasitisation of the maternal side of the placenta are frequent. Previous splenectomy increases the risk of severe malaria.

P. vivax *and* P. ovale *infection*

In many cases, the illness starts with several days of continued fever before the development of classical bouts of fever on alternate days. Fever starts with a rigor. The patient feels cold and the temperature rises to about 40°C. After half an hour to an hour, the hot or flush phase begins. It lasts several hours and gives way to profuse perspiration and a gradual fall in temperature. The cycle is repeated 48 hours later. Gradually, the spleen and liver enlarge and may become tender. Anaemia develops slowly. Relapses are frequent in the first 2 years after leaving the malarious area and infection may be acquired from blood transfusion.

P. malariae *infection*

This is usually associated with mild symptoms and bouts of fever every third day. Parasitaemia may persist for many years, with the occasional recrudescence of fever or without producing any symptoms. Chronic *P. malariae* infection causes glomerulonephritis and long-term nephrotic syndrome in children.

Investigations

Giemsa-stained thick and thin blood films should be examined whenever malaria is suspected. In the thick film, erythrocytes are lysed, releasing all blood stages of the parasite. This, as well as the fact that more blood is used in thick films, facilitates the diagnosis of low-level parasitaemia. A thin film is essential to confirm the diagnosis, to identify the species of parasite and, in *P. falciparum* infections, to quantify the parasite load (by counting the percentage of infected erythrocytes). *P. falciparum* parasites may be very scanty, especially in patients who have been partially treated. With *P. falciparum,* only ring forms are normally seen in the early stages (see Fig. 13.33); with the other species, all stages of the erythrocytic cycle may be found. Gametocytes appear after about 2 weeks, persist after treatment and are harmless, except that they are the source by which more mosquitoes become infected.

Immunochromatographic tests for malaria antigens, such as OptiMal® (which detects the *Plasmodium* lactate dehydrogenase of several species) and ParasightF® (which detects the *P. falciparum* histidine-rich protein 2), are extremely sensitive and specific for *falciparum* malaria but less so for other species. They should be used in parallel with blood film examination but are especially useful where the microscopist is less experienced in examining blood films (e.g. in the UK). The QBC Malaria Test is a fluorescence microscopy-based malaria diagnostic test which is also widely used.

DNA detection (PCR) is used mainly in research and is useful for determining whether a patient has a recrudescence of the same malaria parasite or a re-infection with a new parasite.

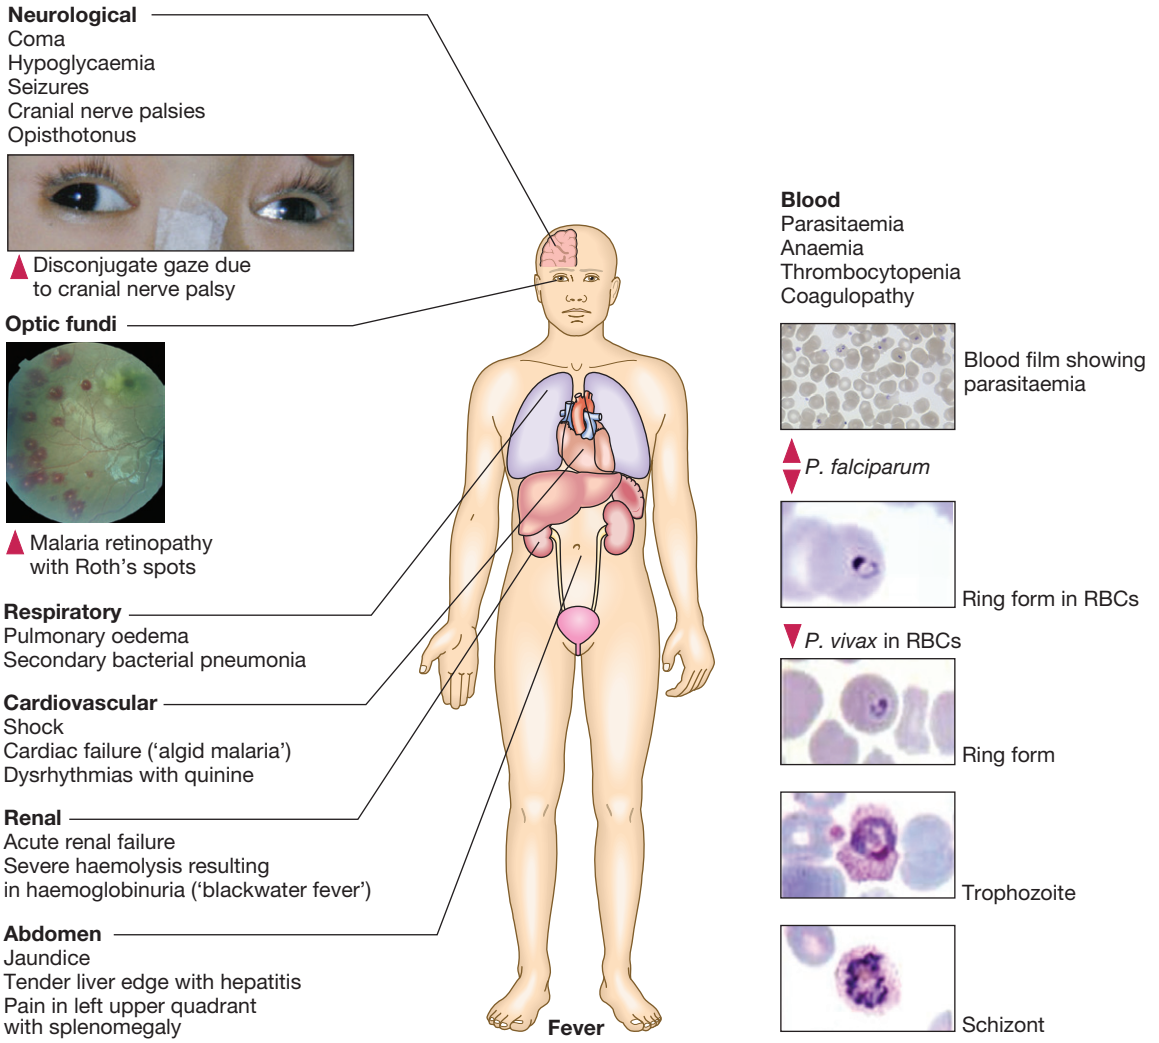

Fig. 13.33 **Features of *P. falciparum* infection.** (RBC = red blood cell)

Management

Mild P. falciparum *malaria*

Since *P. falciparum* is now resistant to chloroquine and sulfadoxine-pyrimethamine (Fansidar) almost worldwide, an artemisinin-based treatment is recommended. Co-artemether (CoArtem® or Riamet®) contains artemether and lumefantrine and is given as 4 tablets at 0, 8, 24, 36, 48 and 60 hours. Alternatives are quinine by mouth (600 mg of quinine salt 3 times daily for 5–7 days), together with or followed by either doxycycline (200 mg once daily for 7 days) or clindamycin (450 mg 3 times daily for 7 days) or atovaquone-proguanil (Malarone®, 4 tablets once daily for 3 days). Doxycycline should not be used in pregnancy and artemether should be avoided in early pregnancy.

WHO policy in Africa is moving towards always using artemisinin-based combination therapy (ACT), e.g. co-artemether or artesunate-amodiaquine. In India and other areas, artesunate (200 mg orally daily for 3 days) and mefloquine (1 g orally on day 2 and 500 mg orally on day 3) may be used. Unfortunately, artemisinin resistance has now been reported in Cambodia.

Complicated P. falciparum *malaria*

Severe malaria should be considered in any non-immune patient with a parasite count greater than 2% and is a medical emergency (see Box 13.59). Management includes early and appropriate antimalarial chemotherapy, active treatment of complications, correction of fluid, electrolyte and acid–base balance, and avoidance of harmful ancillary treatments.

The treatment of choice is intravenous artesunate given as 2.4 mg/kg IV at 0, 12 and 24 hours and then once daily for 7 days. However, as soon as the patient has recovered sufficiently to swallow tablets, oral artesunate 2 mg/kg once daily is given instead of intravenous therapy, to complete a total cumulative dose of 17–18 mg/kg. Rectal administration of artesunate is also being developed to allow administration in remote rural areas.

Quinine salt can also be used and is started with a loading dose infusion of 20 mg/kg over 4 hours, up to a maximum of 1.4 g. This is followed by maintenance doses of 10 mg/kg quinine salt given as 4-hour infusions 2–3 times daily, up to a maximum of 700 mg per dose,

13.59 Severe manifestations/complications of *falciparum* malaria and their immediate management

Coma (cerebral malaria)
- Maintain airway
- Nurse on side
- Exclude other treatable causes of coma (e.g. hypoglycaemia, bacterial meningitis)
- Avoid harmful ancillary treatments such as corticosteroids, heparin and adrenaline (epinephrine)
- Intubate if necessary

Hyperpyrexia
- Tepid sponging, fanning, cooling blanket
- Antipyretic drug (paracetamol)

Convulsions
- Maintain airway
- Treat promptly with diazepam or paraldehyde injection

Hypoglycaemia
- Measure blood glucose
- Give 50% dextrose injection followed by 10% dextrose infusion (glucagon may be ineffective)

Severe anaemia (packed cell volume < 15%)
- Transfuse fresh whole blood or packed cells if pathogen screening of donor blood is available

Acute pulmonary oedema
- Nurse at 45°, give oxygen, venesect 250 mL of blood, give diuretic, stop intravenous fluids
- Intubate and add PEEP/CPAP (p. 193) in life-threatening hypoxaemia
- Haemofilter

Acute renal failure
- Exclude pre-renal causes
- Fluid resuscitation if appropriate
- Peritoneal dialysis (haemofiltration or haemodialysis if available)

Spontaneous bleeding and coagulopathy
- Transfuse screened fresh whole blood (cryoprecipitate/fresh frozen plasma and platelets if available)
- Vitamin K injection

Metabolic acidosis
- Exclude or treat hypoglycaemia, hypovolaemia and Gram-negative septicaemia
- Fluid resuscitation
- Give oxygen

Shock ('algid malaria')
- Suspect Gram-negative septicaemia
- Take blood cultures
- Give parenteral antimicrobials
- Correct haemodynamic disturbances

Aspiration pneumonia
- Give parenteral antimicrobial drugs
- Change position
- Physiotherapy
- Give oxygen

Hyperparasitaemia
- Consider exchange or partial exchange transfusion, manual or haemophoresis (e.g. > 10% of circulating erythrocytes parasitised in non-immune patient with severe disease)

Specific therapy
- Intravenous artesunate
- Mefloquine should be avoided due to increased risk of post-malaria neurological syndrome

From WHO. Severe falciparum malaria. In: Severe and complicated malaria. 3rd edn. Trans Roy Soc Trop Med Hyg 2000; 94 (suppl. 1): S1–41.

until the patient can take drugs orally. The loading dose should *not* be given if the patient has received quinine, quinidine or mefloquine during the previous 24 hours. Patients should be monitored by ECG, with special attention to QRS duration and QT interval. Mefloquine should not be used for severe malaria since no parenteral form is available.

Exchange transfusion has not been tested in randomised controlled trials but may be beneficial for non-immune patients with persisting high parasitaemias (> 10% circulating erythrocytes).

*Management of non-*falciparum *malaria*

P. vivax, *P. ovale* and *P. malariae* infections should be treated with oral chloroquine: 600 mg chloroquine base, followed by 300 mg base in 6 hours, then 150 mg base twice daily for 2 more days. Some chloroquine resistance has been reported from Indonesia.

Late relapses can be prevented by prescribing antimalarial drugs in suppressive doses. However, 'radical cure' is now achieved in most patients with *P. vivax* or *P. ovale* malaria using a course of primaquine (15 mg daily for 14 days), which destroys the hypnozoite phase in the liver. Haemolysis may develop in those who are G6PD-deficient. Cyanosis due to the formation of methaemoglobin in the red cells is more common but not dangerous.

Prevention

Clinical attacks of malaria may be preventable with chemoprophylaxis using chloroquine, atovaquone plus proguanil (Malarone), doxycycline or mefloquine. Box 13.60 gives the recommended doses for protection of the non-immune. The risk of malaria in the area to be visited and the degree of chloroquine resistance guide the recommendations for prophylaxis. Updated recommendations are summarised at www.fitfortravel.nhs.uk. Fansidar should not be used for chemoprophylaxis, as deaths have occurred from agranulocytosis or Stevens–Johnson syndrome (p. 1302). Mefloquine is useful in areas of multiple drug resistance, such as East and Central Africa and Papua New Guinea. Experience shows it to be safe for at least 2 years, but there are several contraindications to its use (see Box 13.60).

Expert advice is required for individuals unable to tolerate the first-line agents listed or in whom they are contraindicated. Mefloquine should be started 2–3 weeks before travel to give time for assessment of

13.60 Chemoprophylaxis of malaria[1]

Antimalarial tablets	Adult prophylactic dose	Regimen
Chloroquine resistance high		
Mefloquine[2]	250 mg weekly	Started 2–3 wks before travel and continued until 4 wks after
or Doxycycline[3,4]	100 mg daily	Started 1 wk before and continued until 4 wks after travel
or Malarone[4]	1 tablet daily	From 1–2 days before travel until 1 wk after return
Chloroquine resistance absent		
Chloroquine[5] *and* proguanil	300 mg base weekly 100–200 mg daily	Started 1 wk before and continued until 4 wks after travel

[1]Choice of regimen is determined by area to be visited, length of stay, level of malaria transmission, level of drug resistance, presence of underlying disease in the traveller and concomitant medication taken.
[2]Contraindicated in the first trimester of pregnancy, lactation, cardiac conduction disorders, epilepsy, psychiatric disorders; may cause neuropsychiatric disorders.
[3]Causes photosensitisation and sunburn if high-protection sunblock is not used.
[4]Avoid in pregnancy.
[5]British preparations of chloroquine usually contain 150 mg base, French preparations 100 mg base and American preparations 300 mg base.

EBM 13.61 Prevention of malaria

Insecticide-treated bed nets (ITNs)

'Five randomised controlled clinical trials provided strong evidence that widespread use of ITNs reduces overall mortality by about one-fifth in Africa. For every 1000 children aged 1–5 years protected, approximately 5.5 lives can be saved every year. In Africa, full ITN coverage could prevent 370 000 child deaths per year.'

Electronic mosquito repellents (EMRs)

'EMRs are not effective.'

Intermittent preventive treatment in pregnancy

'Antimalarial drugs reduce antenatal parasitaemia and fever in pregnant women living in areas with endemic malaria. For women in their first or second pregnancy, this reduces the instances of severe antenatal anaemia, antenatal parasitaemia and perinatal deaths, and increases birth weight.'

Intermittent preventive treatment in children

'Antimalarial drugs reduce clinical malaria, severe anaemia and hospital admissions. Effects on mortality and on health, if prophylaxis is stopped, are unknown.'

- Gamble C, et al. (2007) PLoS Med 2007; 4(3):e107.
- Enayati A, et al. Electronic mosquito repellents for preventing mosquito bites and malaria infection. Cochrane Database of Systematic Reviews, 2007, issue 2. Art. no.: CD005434.

For further information: www.cochrane.org/cochrane-reviews

side-effects. Chloroquine should not be taken continuously as a prophylactic for more than 5 years without regular ophthalmic examination, as it may cause irreversible retinopathy. Pregnant and lactating women may take proguanil or chloroquine safely.

Prevention also involves advice about the use of high-percentage diethyltoluamide (DEET), covering up extremities when out after dark, and sleeping under permethrin-impregnated mosquito nets (Box 13.61).

Malaria control in endemic areas

There are major initiatives under way to reduce malaria in endemic areas and it is estimated that these would be cost-effective, even at a cost of $3 billion per year. Successful programmes have involved a combination of vector control, including indoor residual spraying, use of long-lasting insecticide-treated bed nets (ITNs) and intermittent preventative therapy (IPT; repeated dose of prophylactic drugs in high-risk groups, such as children and pregnant women) (see Box 13.61).

Development of a fully protective malaria vaccine is still some way off, which is not surprising, considering that natural immunity is incomplete and not long-lived. There is, however, some evidence that vaccination can reduce the incidence of severe malaria in populations. Trial vaccines are being evaluated in Africa.

Babesiosis

This is caused by a tick-borne intra-erythrocytic protozoon parasite. There are more than 100 species of *Babesia*, all of which have an animal reservoir, typically either rodents or cattle, and are transmitted to humans via the tick vector *Ixodes scapularis*. Most cases of babesiosis in the USA are due to *B. microti* and most in Europe to *B. divergens*. Patients present with fever and malaise 1–4 weeks after a tick bite. Illness may be complicated by haemolytic anaemia. Severe illness is seen in splenectomised patients. The diagnosis is made by blood-film examination. Treatment is with quinine and clindamycin.

African trypanosomiasis (sleeping sickness)

African sleeping sickness is caused by trypanosomes (Fig. 13.34) conveyed to humans by the bites of infected tsetse flies, and is unique to sub-Saharan Africa (Fig. 13.35). There has been a more than 60% decline in the incidence of sleeping sickness across Africa since 1990 due to better control measures. *Trypanosoma brucei gambiense* trypanosomiasis has a wide distribution in West and Central Africa and accounts for 90% of reported cases. *T. brucei rhodesiense* trypanosomiasis is found in parts of East and Central Africa. In West Africa, transmission is mainly at the riverside, where the fly rests in the shade of trees; no animal reservoir has been identified for *T. gambiense*. *T. rhodesiense* has a large reservoir in numerous wild animals and transmission takes place in the shade of woods bordering grasslands. Rural populations earning their livelihood from agriculture, fishing and animal husbandry are susceptible. Local

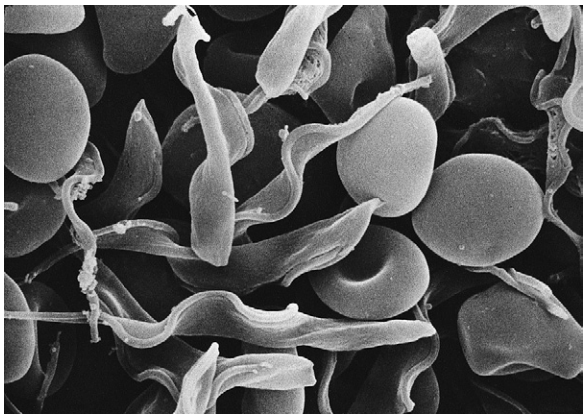

Fig. 13.34 Trypanosomiasis. Scanning electron micrograph showing trypanosomes swimming among erythrocytes.

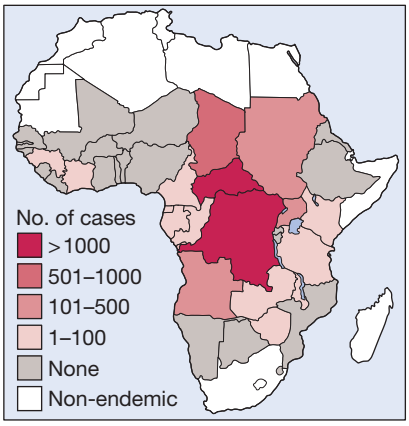

Fig. 13.35 Distribution of human African trypanosomiasis. From Simarro, et al. 2011 – see p. 386. Data are from 2009.

people and tourists visiting forests infested with tsetse flies and animal reservoirs may become infected.

Clinical features

A bite by a tsetse fly is painful and commonly becomes inflamed, but if trypanosomes are introduced, the site may again become painful and swollen about 10 days later ('trypanosomal chancre') and the regional lymph nodes enlarge ('Winterbottom's sign'). Within 2–3 weeks of infection, the trypanosomes invade the blood stream. The disease is characterised by an early haemato-lymphatic stage and a late encephalitic stage, in which the parasite crosses the blood–brain barrier and chronic encephalopathy develops.

Rhodesiense *infections*

In these infections, the disease is more acute and severe than in *gambiense* infections, so that, within days or a few weeks, the patient is usually severely ill and may have developed pleural effusions and signs of myocarditis or hepatitis. There may be a petechial rash. The patient may die before there are signs of involvement of the CNS. If the illness is less acute, drowsiness, tremors and coma develop.

Gambiense *infections*

The distinction between early and late stages may not be apparent in *gambiense* infections. The disease usually runs a slow course over months or years, with irregular bouts of fever and enlargement of lymph nodes. These are characteristically firm, discrete, rubbery and painless, and are particularly prominent in the posterior triangle of the neck. The spleen and liver may become palpable. After some months without treatment, the CNS is invaded. This is shown clinically by headache and changed behaviour, blunting of higher mental functions, insomnia by night and sleepiness by day, mental confusion and eventually tremors, pareses, wasting, coma and death.

Investigations

Trypanosomiasis should be considered in any febrile patient from an endemic area. In *rhodesiense* infections, thick and thin blood films, stained as for the detection of malaria, will reveal trypanosomes. The trypanosomes may be seen in the blood or from puncture of the primary lesion in the earliest stages of *gambiense* infections, but it is usually easier to demonstrate them by aspiration of a lymph node. Concentration methods include buffy coat microscopy and miniature anion exchange chromatography.

Due to the cyclical nature of parasitaemia, the diagnosis is often made by demonstration of antibodies using a simple, rapid screening card agglutination trypanosomiasis test (CATT), followed by parasitological confirmation. If the CNS is affected, the cell count (> 20×10^9 leucocytes per litre) and protein content of the CSF are increased and the glucose is diminished. A very high level of serum IgM or the presence of IgM in the CSF is suggestive of trypanosomiasis. Recognition of CNS involvement is critical, as failure to treat it might be fatal.

Management

Unfortunately, therapeutic options for African trypanosomiasis are limited and most of the antitrypanosomal drugs are toxic and expensive. The prognosis is good if treatment is begun early, before the brain has been invaded. At this stage, intravenous suramin, after a test dose of 100–200 mg, should be given for *rhodesiense* infections (1 g on days 1, 3, 7, 14 and 21). For *gambiense* infections, intramuscular or intravenous pentamidine 4 mg/kg for 10 days is given (Box 13.62).

13.62 Drugs used to treat human African trypanosomiasis

***Gambiense* trypanosomiasis**

Stage 1
- First-line: pentamidine
- Second-line: eflornithine or melarsoprol

Stage 2
- First-line: eflornithine
- Second-line: melarsoprol

***Rhodesiense* trypanosomiasis**

Stage 1
- First-line: suramin
- Second-line: melarsoprol

Stage 2
- First-line: melarsoprol
- Second-line: nifurtimox combined with melarsoprol

Once the nervous system is affected, treatment with melarsoprol (an arsenical) is effective for both East and West African diseases. It is used in a dose of 2–3.6 mg/kg/day IV for the first course and 3.6 mg/kg/day thereafter. Three 3-day treatment courses are given, separated by 7 days and by 10–21 days. Melarsoprol should be given with prednisolone 1 mg/kg up to 40 mg started 1–2 days before, continued during and tapered after treatment to reduce side-effects. Treatment-related mortality with melarsoprol is 4–12% due to reactive encephalopathy. For CNS infections due to *gambiense*, eflornithine (DFMO), an irreversible inhibitor of ornithine decarboxylase (100 and 150 mg/kg IV 4 times daily for 14 days for adults and children, respectively), is considered to be a safer and cost-effective option. Combinations of eflornithine (400 mg daily for 7 days) with oral nifurtimox (15 mg/kg daily for 15 days) have been shown to decrease relapses, deaths and drug toxicity.

Prevention

In endemic *gambiense* areas, various measures may be taken against tsetse flies, and field teams help to detect and treat early human infection. In *rhodesiense* areas, control is difficult.

American trypanosomiasis (Chagas' disease)

Chagas' disease occurs widely in South and Central America. The cause is *Trypanosoma cruzi*, transmitted to humans from the faeces of a reduviid (triatomine) bug, in which the trypanosomes have a cycle of development before becoming infective to humans. These bugs live in wild forests in crevices, burrows and palm trees. The *Triatoma infestans* bug has become domesticated in the Southern Cone countries (Argentina, Brazil, Chile, Paraguay and Uruguay). It lives in the mud and wattle walls and thatched roofs of simple rural houses, and emerges at night to feed and defecate on the sleeping occupants. Infected faeces are rubbed in through the conjunctiva, mucosa of mouth or nose, or abrasions of the skin. Over one hundred species of mammal, domestic, peridomestic and wild, may serve as reservoirs of infection. In some areas, blood transfusion accounts for about 5% of cases. Congenital transmission occasionally occurs.

Pathology

The trypanosomes migrate via the blood stream, develop into amastigote forms in the tissues and multiply intracellularly by binary fission. In the acute phase (primarily cell-mediated), inflammation of parasitised as well as non-parasitised cardiac muscles and capillaries occurs, resulting in acute myocarditis. In the chronic phase, focal myocardial atrophy, signs of chronic passive congestion and thromboembolic phenomena, cardiomegaly and apical cardiac aneurysm are salient findings. In the digestive form of disease, focal myositis and discontinuous lesions of the intramural myenteric plexus, predominantly in the oesophagus and colon, are seen.

Clinical features

Acute phase

Clinical manifestations of the acute phase are seen in only 1–2% of individuals who are infected before the age of 15 years. Young children (1–5 years) are most commonly affected. The entrance of *T. cruzi* through an abrasion produces a dusky-red firm swelling and enlargement of regional lymph nodes. A conjunctival lesion, although less common, is characteristic; the unilateral firm, reddish swelling of the lids may close the eye and constitutes 'Romaña's sign'. In a few patients, an acute generalised infection soon appears, with a transient morbilliform or urticarial rash, fever, lymphadenopathy and enlargement of the spleen and liver. In a small minority of patients, acute myocarditis and heart failure or neurological features, including personality changes and signs of meningoencephalitis, may be seen. The acute infection may be fatal to infants.

Chronic phase

About 50–70% of infected patients become seropositive and develop an indeterminate form when no parasitaemia is detectable. They have a normal lifespan with no symptoms, but are a natural reservoir for the disease and maintain the life cycle of parasites. After a latent period of several years, 10–30% of chronic cases develop low-grade myocarditis, and damage to conducting fibres causes a cardiomyopathy characterised by cardiac dilatation, arrhythmias, partial or complete heart block and sudden death. In nearly 10% of patients, damage to Auerbach's plexus results in dilatation of various parts of the alimentary canal, especially the colon and oesophagus, so-called 'mega' disease. Dilatation of the bile ducts and bronchi is also a recognised sequela. Autoimmune processes may be responsible for much of the damage. There are geographical variations of the basic pattern of disease. Reactivation of Chagas' disease can occur in patients with HIV if the CD4 count falls lower than 200 cells/mm^3 (p. 393); this can cause space-occupying lesions with a presentation similar to *Toxoplasma* encephalitis, encephalitis, meningoencephalitis or myocarditis.

Investigations

T. cruzi is easily detectable in a blood film in the acute illness. In chronic disease, it may be recovered in up to 50% of cases by xenodiagnosis, in which infection-free, laboratory-bred reduviid bugs are allowed to feed on the patient; subsequently, the hind gut or faeces of the bug are examined for parasites. Parasite DNA detection by PCR in the patient's blood is a highly sensitive method for documentation of infection and, in addition, can be employed in faeces of bugs used in xenodiagnosis tests to improve sensitivity. Antibody detection is also highly sensitive.

Management and prevention

Parasiticidal agents are used to treat the acute phase, congenital disease and early chronic phase (within 10 years of infection). Nifurtimox is given orally. The dose, which has to be carefully supervised to minimise toxicity while preserving parasiticidal activity, is 10 mg/kg divided into three equal doses, daily orally for 60–90 days. The paediatric dose is 15 mg/kg daily. Cure rates of 80% in acute disease are obtained. Benznidazole is an alternative, given at a dose of 5–10 mg/kg daily orally, in two divided doses for 60 days; children receive 10 mg/kg daily. Both nifurtimox and benznidazole are toxic, with adverse reaction rates of 30–55%. Specific drug treatment of the chronic form is now increasingly

favoured, but, in the cardiac or digestive 'mega' diseases, it does not reverse established tissue damage. Surgery may be needed.

Preventative measures include improving housing and destruction of reduviid bugs by spraying of houses with insecticides. Blood donors should be screened.

Toxoplasmosis

Toxoplasma gondii is an intracellular parasite. The sexual phase of the parasite's life cycle (Fig. 13.36) occurs in the small intestinal epithelium of the domestic cat. Oöcysts are shed in cat faeces and are spread to intermediate hosts (pigs, sheep and also humans) through widespread contamination of soil. Oöcysts may survive in moist conditions for weeks or months. Once they are ingested, the parasite transforms into rapidly dividing tachyzoites through cycles of asexual multiplication. This leads to the formation of microscopic tissue cysts containing bradyzoites, which persist for the lifetime of the host. Cats become infected or re-infected by ingesting tissue cysts in prey such as rodents and birds.

Human acquisition of infection occurs via oöcyst-contaminated soil, salads and vegetables, or by the ingestion or tasting of raw or undercooked meats containing tissue cysts. Sheep, pigs and rabbits are the most common meat sources. Outbreaks of toxoplasmosis have been linked to the consumption of unfiltered water. In developed countries, toxoplasmosis is the most common protozoal infection; around 22% of adults in the UK are seropositive. Most primary infections are subclinical; however, toxoplasmosis is thought to account for about 15% of heterophile antibody-negative glandular fever (p. 320). In India or Brazil, approximately 40–60% of pregnant females are seropositive for *T. gondii*. In HIV-1 infection (p. 402), toxoplasmosis is an important opportunistic infection with considerable morbidity and mortality. Generalised toxoplasmosis has been described after accidental laboratory infection with highly virulent strains.

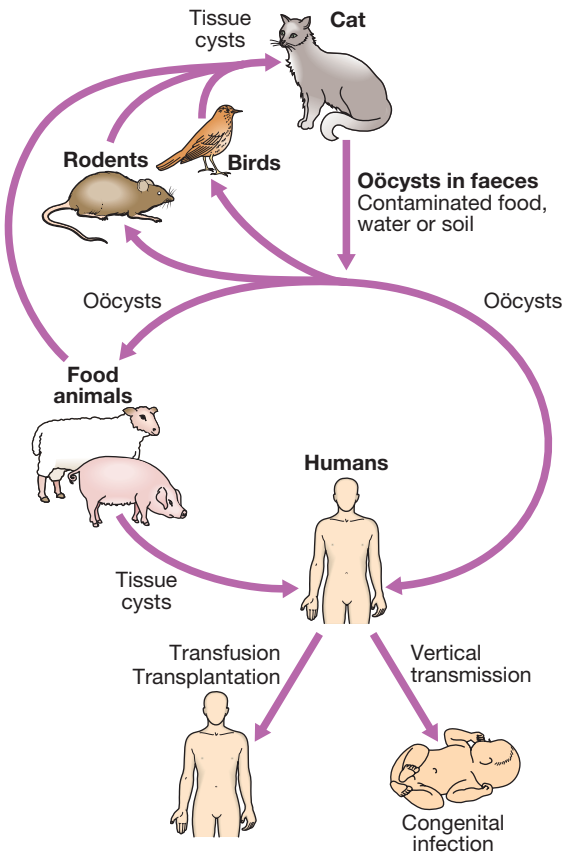

Fig. 13.36 Life cycle of *Toxoplasma gondii*.

Clinical features

In most immunocompetent individuals, including children and pregnant women, the infection goes unnoticed. In approximately 10% of patients, it causes a self-limiting illness, most common in adults aged 25–35 years. The most common presenting feature is painless lymphadenopathy, either local or generalised. In particular, the cervical nodes are involved, but mediastinal, mesenteric or retroperitoneal groups may be affected. The spleen is seldom palpable. Most patients have no systemic symptoms, but some complain of malaise, fever, fatigue, muscle pain, sore throat and headache. Complete resolution usually occurs within a few months, although symptoms and lymphadenopathy tend to fluctuate unpredictably and some patients do not recover completely for a year or more. Very infrequently, patients may develop encephalitis, myocarditis, polymyositis, pneumonitis or hepatitis. Retinochoroiditis (Fig. 13.37) is nearly always the result of congenital infection but has also been reported in acquired disease.

Congenital toxoplasmosis

Acute toxoplasmosis, mostly subclinical, affects 0.3–1% of pregnant women, with an approximately 60% transmission rate to the fetus, which rises with increasing gestation. Seropositive females infected 6 months before conception have no risk of fetal transmission. Congenital disease affects approximately 40% of infected fetuses, and is more likely and more severe with infection early in gestation (see Box 13.28, p. 314). Many fetal infections are subclinical at birth but long-term sequelae include retinochoroiditis, microcephaly and hydrocephalus.

Investigations

In contrast to immunocompromised patients, in whom the diagnosis often requires direct detection of parasites, serology is often used in immunocompetent individuals.

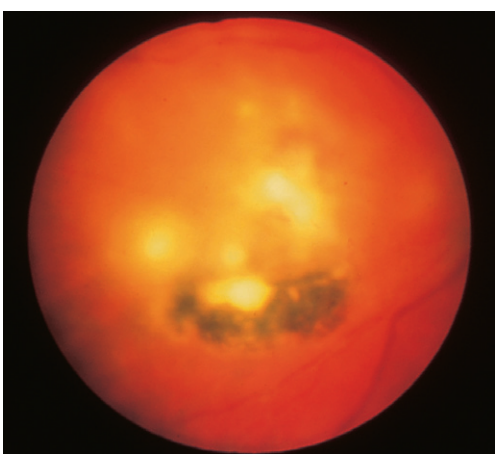

Fig. 13.37 Retinochoroiditis due to toxoplasmosis.

The Sabin–Feldman dye test (indirect fluorescent antibody test), which detects IgG antibody, is most commonly used. Recent infection is indicated by a fourfold or greater increase in titre when paired sera are tested in parallel. Peak titres of 1/1000 or more are reached within 1–2 months of the onset of infection, and the dye test then becomes an unreliable indicator of recent infection. The detection of significant levels of *Toxoplasma*-specific IgM antibody may be useful in confirming acute infection. A false-positive result or persistence of IgM antibodies for years after infection makes interpretation difficult; however, negative IgM antibodies virtually rule out acute infection.

During pregnancy, it is critical to differentiate between recent and past infection; the presence of high-avidity IgG antibodies excludes infection acquired in the preceding 3–4 months.

If necessary, the presence of *Toxoplasma* organisms in a lymph node biopsy can be sought by staining sections histochemically with *T. gondii* antiserum, or by the use of PCR to detect *Toxoplasma*-specific DNA.

Management

In immunocompetent subjects, uncomplicated toxoplasmosis is self-limiting and responds poorly to antimicrobial therapy. Treatment with pyrimethamine, sulfadiazine and folinic acid is therefore usually reserved for rare cases of severe or progressive disease, and for infection in immunocompromised patients.

In a pregnant woman with an established recent infection, spiramycin (3 g daily in divided doses) should be given until term. Once fetal infection is established, treatment with sulfadiazine and pyrimethamine plus calcium folinate is recommended (spiramycin does not cross the placental barrier). The cost/benefit of routine *Toxoplasma* screening and treatment in pregnancy is being debated in many countries. There is insufficient evidence to determine the effects on mother or baby of current antiparasitic treatment for women who seroconvert in pregnancy.

Leishmaniasis

Leishmaniasis is caused by unicellular, flagellate, intracellular protozoa belonging to the genus *Leishmania* (order Kinetoplastidae). There are 21 leishmanial species that cause several diverse clinical syndromes, which can be placed into three broad groups:

- visceral leishmaniasis (VL, kala-azar)
- cutaneous leishmaniasis (CL)
- mucosal leishmaniasis (ML).

Epidemiology and transmission

Although most clinical syndromes are caused by zoonotic transmission of parasites from animals (chiefly canine and rodent reservoirs) to humans through phlebotomine sandfly vectors (Fig. 13.38A), humans are the only known reservoir (anthroponotic) in major VL foci in the Indian subcontinent and for transmission of leishmaniasis between injection drug-users (Fig. 13.38B and C). Leishmaniasis occurs in approximately 100 countries around the world, with an estimated annual incidence of 2 million new cases (500 000 for VL and 1.5 million for CL).

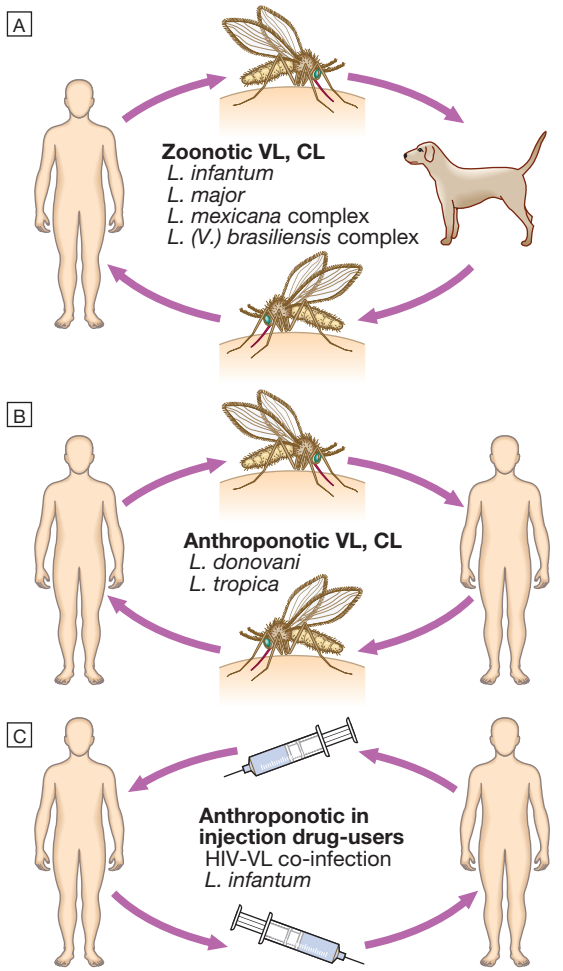

Fig. 13.38 Transmission of leishmaniasis. A Zoonotic transmission. B Anthroponotic transmission. C Anthroponotic transmission in the injection drug-user.

The life cycle of *Leishmania* is shown in Figure 13.39. Flagellar promastigotes (10–20 μm) are introduced by the feeding female sandfly. The promastigotes are taken up by neutrophils, which undergo apoptosis and are then engulfed by macrophages, in which the parasites transform into amastigotes (2–4 μm; Leishman–Donovan body). These multiply, ultimately causing lysis of the macrophages and infection of other cells. Sandflies pick up amastigotes when feeding on infected patients or animal reservoirs. In the sandfly, the parasite transforms into a flagellar promastigote, which multiplies by binary fission in the gut of the vector and migrates to the proboscis to infect a new host.

Sandflies live in hot and humid climates in the cracks and crevices of mud or straw houses and lay eggs in organic matter. People living in such conditions are more prone to acquiring the disease. Female sandflies bite during the night and preferentially feed on animals; humans are incidental hosts.

Visceral leishmaniasis (kala-azar)

VL is caused by the protozoon *Leishmania donovani* complex (comprising *L. donovani*, *L. infantum* and *L. chagasi*). India, Sudan, Bangladesh and Brazil account for 90% of cases of VL, while other affected regions include

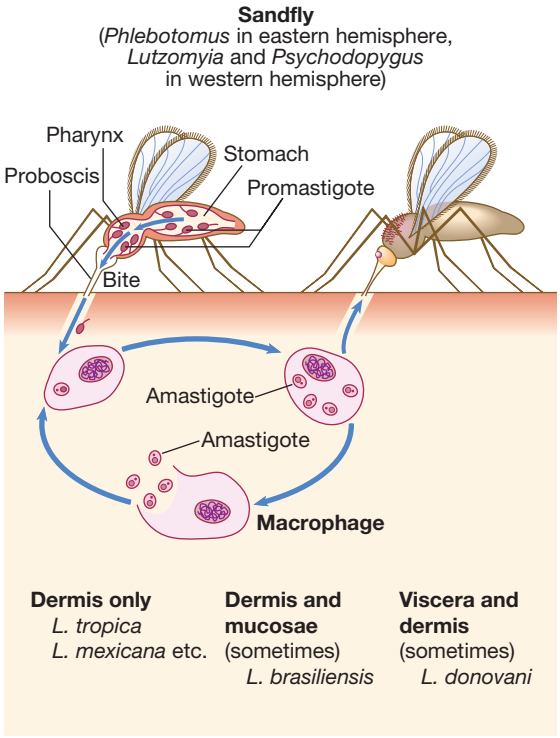

Fig. 13.39 Life cycle of *Leishmania.* From Knight 1982 – see p. 386.

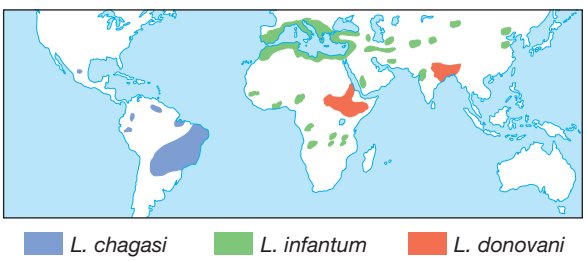

Fig. 13.40 World distribution of visceral leishmaniasis.

the Mediterranean, East Africa, China, Arabia, Israel and other South American countries (Fig. 13.40). In addition to sandfly transmission, VL has also been reported to follow blood transfusion, and disease can present unexpectedly in immunosuppressed patients – for example, after renal transplantation and in HIV infection.

The great majority of people infected remain asymptomatic. In visceral diseases, the spleen, liver, bone marrow and lymph nodes are primarily involved.

Clinical features

In the Indian subcontinent, adults and children are equally affected; elsewhere, VL is mainly a disease of small children and infants, except in adults with HIV co-infection. The incubation period ranges from weeks to months (occasionally several years).

The first sign of infection is high fever, usually accompanied by rigor and chills. Fever intensity decreases over time, and patients may become afebrile for intervening periods ranging from weeks to months. This is followed by a relapse of fever, often of lesser intensity. Splenomegaly develops quickly in the first few weeks and becomes massive as the disease progresses. Moderate hepatomegaly occurs later. Lymphadenopathy is seen in the majority of cases in Africa, the Mediterranean and South America, but is rare in the Indian subcontinent. Blackish discoloration of the skin, from which the disease derived its name, kala-azar (the Hindi word for 'black fever'), is a feature of advanced illness and is now rarely seen. Pancytopenia is a common feature. Moderate to severe anaemia develops rapidly, and can result in congestive cardiac failure and associated clinical features. Thrombocytopenia, often compounded by hepatic dysfunction, may result in bleeding from the retina, gastrointestinal tract and nose. In advanced illness, hypoalbuminaemia may manifest as pedal oedema, ascites and anasarca (gross generalised oedema and swelling).

As the disease advances, there is profound immunosuppression and secondary infections are very common. These include tuberculosis, pneumonia, severe amoebic or bacillary dysentery, gastroenteritis, herpes zoster and chickenpox. Skin infections, boils, cellulitis and scabies are common. Without adequate treatment, most patients with clinical VL die.

Investigations

Pancytopenia is the most dominant feature, with granulocytopenia and monocytosis. Polyclonal hypergammaglobulinaemia, chiefly IgG followed by IgM, and hypoalbuminaemia are seen later.

Demonstration of amastigotes (Leishman–Donovan bodies) in splenic smears is the most efficient means of diagnosis, with 98% sensitivity (Fig. 13.41); however, it carries a risk of serious haemorrhage in inexperienced hands. Safer methods, such as bone marrow or lymph node smears, are not as sensitive. Parasites may be demonstrated in buffy coat smears, especially in immunosuppressed patients. Sensitivity can be improved by culturing the aspirate material or by PCR for DNA detection and species identification, but these tests can only be performed in specialised laboratories.

Serodiagnosis, by ELISA or immunofluorescence antibody test, is employed in developed countries. In endemic regions, a highly sensitive direct agglutination test using stained promastigotes and an equally efficient rapid immunochromatographic k39 strip test have become popular. These tests remain positive for several months after cure has been achieved, so do not predict

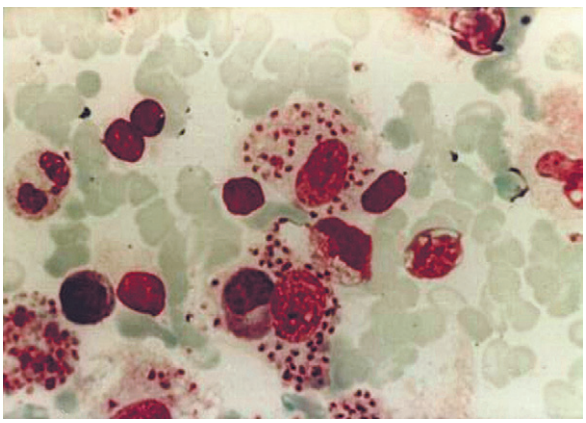

Fig. 13.41 Splenic smear showing numerous intracellular, and a few extracellular, amastigotes.

response to treatment or relapse. The vast majority of people exposed to the parasite do not develop clinical illness but may have positive serological tests thereafter. Formal gel (aldehyde) or other similar tests based on the detection of raised globulin have limited value and should not be employed for the diagnosis of VL.

Differential diagnosis

This includes malaria, typhoid, tuberculosis, schistosomiasis and many other infectious and neoplastic conditions, some of which may coexist with VL. Fever, splenomegaly, pancytopenia and non-response to antimalarial therapy may provide clues before specific laboratory diagnosis is made.

Management

Pentavalent antimonials

Antimony (Sb) compounds were the first drugs to be used for the treatment of leishmaniasis and remain the mainstay of treatment in most parts of the world. The exception is the Indian subcontinent, especially Bihar state, where almost two-thirds of cases are refractory to Sb treatment. Traditionally, pentavalent antimony is available as sodium stibogluconate (100 mg/mL) in English-speaking countries and meglumine antimoniate (85 mg/mL) in French-speaking ones. The daily dose is 20 mg/kg body weight, given either intravenously or intramuscularly for 28–30 days. Side-effects are common and include arthralgias, myalgias, raised hepatic transaminases, pancreatitis (especially in patients co-infected with HIV) and ECG changes (T wave inversion and reduced amplitude). Severe cardiotoxicity, manifest by concave ST segment elevation, prolongation of QT_c greater than 0.5 msec, and ventricular dysrhythmias, is not uncommon. The incidence of cardiotoxicity and death can be very high with improperly manufactured Sb.

Amphotericin B

Amphotericin B deoxycholate, given once daily or on alternate days at a dose of 0.75–1.00 mg/kg for 15–20 doses, is used as the first-line drug in many regions where there is a significant level of Sb unresponsiveness. It has a cure rate of nearly 100%. Infusion-related side-effects, e.g. high fever with rigor, thrombophlebitis, diarrhoea and vomiting, are extremely common. Serious adverse events, such as renal or hepatic toxicity, hypokalaemia and thrombocytopenia, are not uncommon.

Lipid formulations of amphotericin B (p. 160) are less toxic. AmBisome is approved by the US Food and Drug Administration and is first-line therapy in Europe for VL. Drug doses vary according to geographical location. In the Indian subcontinent, a total dose of 10 or 15 mg/kg, administered in a single dose or as multiple doses over several days, respectively, is considered adequate, whereas in Africa 14–18 mg, and in South America and Europe 21–24 mg, in divided doses, typically spread over 10 days, is needed for immunocompetent patients. High daily doses of the lipid formulations are well tolerated, and in one study a single dose of 10 mg/kg of AmBisome cured 96% of Indian patients. AmBisome has been made available at a preferential low price for developing countries, and greater use of this drug for treatment of VL is expected.

EBM 13.63 Combination therapy for visceral leishmaniasis

'In India, combinations of a single dose of liposomal amphotericin B (AmBisome, 5 mg/kg) with either 7 days of miltefosine or 10 days of paromomycin, or 10 days each of miltefosine and paromomycin, cured at least 97% of patients.'

'In Sudan, a combination of 17 days of antimony (Sb) with paromomycin produces a similar rate of cure (> 90%) to conventional treatment with 30 days of antimony.'

- Sundar S, et al. Lancet 2011; 377:477–486.
- Musa A, et al. PLoS NTD 2012; e1674.

Other drugs

The oral drug miltefosine, an alkyl phospholipid, has been approved in several countries for the treatment of VL. A daily dose of 50 mg (patient's body weight < 25 kg) to 100 mg (≥ 25 kg), or 2.5 mg/kg body weight for children, for 28 days cures over 90% of patients. Side-effects include mild to moderate vomiting and diarrhoea, and rarely skin allergy or renal or liver toxicity. Since it is a teratogenic drug, it cannot be used in pregnancy; female patients are advised not to become pregnant for the duration of treatment and 3 months thereafter, because of its half-life of nearly 1 week.

Paromomycin is an aminoglycoside that has undergone trials in India and Africa, and is highly effective if given intramuscularly at 11 mg/kg body weight of paromomycin base, daily for 3 weeks. No significant auditory or renal toxicity is seen. The drug has been approved in India for the treatment of VL.

Pentamidine isethionate was used to treat Sb-refractory patients with VL. However, declining efficacy and serious side-effects, such as type 1 diabetes mellitus, hypoglycaemia and hypotension, have led to it being abandoned.

Multidrug therapy of VL is likely to be used increasingly to prevent emergence of drug resistance (Box 13.63).

Response to treatment

A good response results in abatement of fever, a feeling of well-being, gradual decrease in spleen size, weight gain and recovery of blood counts. Patients should be followed regularly for a period of 6–12 months, as a small minority may experience a relapse of the disease during this period, irrespective of the treatment regimen.

HIV–visceral leishmaniasis co-infection

HIV-induced immunosuppression (Ch. 14) increases the risk of contracting VL 100–1000 times. Most cases of HIV–VL co-infection have been reported from Spain, France, Italy and Portugal. Antiretroviral therapy (ART) has led to a remarkable decline in the incidence of VL co-infection in Europe. However, numbers are increasing in Africa (mainly Ethiopia), Brazil and in the Indian subcontinent.

Although the clinical triad of fever, splenomegaly and hepatomegaly is found in the majority of co-infected patients, those with low CD4 count may have atypical clinical presentations, posing a diagnostic challenge. VL may present with gastrointestinal involvement (stomach, duodenum or colon), ascites, pleural or pericardial

effusion, or involvement of lungs, tonsil, oral mucosa or skin. Diagnostic principles remain the same as those in non-HIV patients. Parasites are numerous and easily demonstrable, even in buffy coat preparations. Sometimes amastigotes are found in unusual sites, such as bronchoalveolar lavage fluid, pleural fluid or biopsies of the gastrointestinal tract. Immunofluorescence, Western blot, ELISA and other serological tests used singly have low sensitivity. DNA detection by PCR of the blood or its buffy coat are at least 95% sensitive, and accurately track recovery and relapse.

Treatment of VL with HIV co-infection is essentially the same as in immunocompetent patients but there are some differences in outcome. Conventional amphotericin B (0.7 mg/kg/day for 28 days) may be more effective in achieving initial cure than Sb (20 mg/kg/day for 28 days). Using high-dose liposomal amphotericin B (4 mg/kg on days 1–5, 10, 17, 24, 31 and 38), a high cure rate is possible. However, these co-infected patients have a tendency to relapse within 1 year. For prevention of relapse, maintenance chemotherapy with monthly liposomal amphotericin B is useful.

Post-kala-azar dermal leishmaniasis

After treatment and apparent recovery from the visceral disease in India and Sudan, some patients develop dermatological manifestations due to local parasitic infection.

Clinical features

In India, dermatological changes occur in a small minority of patients 6 months to at least 3 years after the initial infection. They are seen as macules, papules, nodules (most frequently) and plaques, which have a predilection for the face, especially the area around the chin. The face often appears erythematous (Fig. 13.42A). Hypopigmented macules can occur over all parts of the body and are highly variable in extent and location. There are no systemic symptoms and no spontaneous healing.

In Sudan, approximately 50% of patients with VL develop post-kala-azar dermal leishmaniasis (PKDL), experiencing skin manifestations concurrently with VL or within the following 6 months. In addition to the dermatological features described above, a measles-like micropapular rash (Fig. 13.42B) may be seen all over the body. In Sudan, children are more frequently affected than in India. Spontaneous healing occurs in about three-quarters of cases within 1 year.

Investigations and management

The diagnosis is clinical, supported by demonstration of scanty parasites in lesions by slit-skin smear and culture. Immunofluorescence and immunohistochemistry may demonstrate the parasite in skin tissues. In the majority of patients, serological tests (direct agglutination test or k39 strip tests) are positive.

Treatment of PKDL is difficult. In India, Sb for 120 days, several courses of amphotericin B infusions, or miltefosine for 12 weeks is required. In Sudan, Sb for 2 months is considered adequate. In the absence of a physical handicap, most patients are reluctant to complete the treatment. PKDL patients are a human reservoir, and focal outbreaks have been linked to patients with PKDL in areas previously free of VL.

Prevention and control

Sandflies are extremely sensitive to insecticides, and vector control through insecticide spray is very important. Mosquito nets or curtains treated with insecticides will keep out the tiny sandflies. In endemic areas with zoonotic transmission, infected or stray dogs should be destroyed.

In areas with anthroponotic transmission, early diagnosis and treatment of human infections, to reduce the reservoir and control epidemics of VL, is extremely important. Serology is useful in diagnosis of suspected cases in the field. No vaccine is currently available.

Cutaneous and mucosal leishmaniasis

Cutaneous leishmaniasis

CL (oriental sore) occurs in both the Old World and the New World (the Americas). Transmission is described on page 362.

Fig. 13.42 Post-kala-azar dermal leishmaniasis. A In India, with macules, papules, nodules and plaques. From Sundar S, et al. 2006 – see p. 386. B In Sudan, with micronodular rash.

In the Old World, CL is mild. It is found around the Mediterranean basin, throughout the Middle East and Central Asia as far as Pakistan, and in sub-Saharan West Africa and Sudan (Fig. 13.43). The causative organisms for Old World zoonotic CL are *L. major*, *L. tropica* and *L. aethiopica* (Box 13.64). Anthroponotic CL is caused by *L. tropica*, and is confined to urban or suburban areas of the Old World. Afghanistan is currently the biggest focus, but infection is endemic in Pakistan, the western deserts of India, Iran, Iraq, Syria and other areas of the Middle East. In recent years, there has been an increase in the incidence of zoonotic CL in both the Old and the New World due to urbanisation and deforestation which led to peridomestic transmission (in and around human dwellings).

New World CL is a more significant disease, which may disfigure the nose, ears and mouth, and is caused by the *L. mexicana* complex (comprising *L. mexicana*, *L. amazonensis* and *L. venezuelensis*) and by the *Viannia* subgenus *L. (V.) brasiliensis* complex (comprising *L. (V.) guyanensis*, *L. (V.) panamensis*, *L. (V.) brasiliensis* and *L. (V.) peruviana*).

13.64 Types of Old World cutaneous leishmaniasis

Leishmania spp.	Host	Clinical features
L. tropica	Dogs	Slow evolution, less severe
L. major	Gerbils, desert rodents	Rapid necrosis, wet sores
L. aethiopica	Hyraxes	Solitary facial lesions with satellites

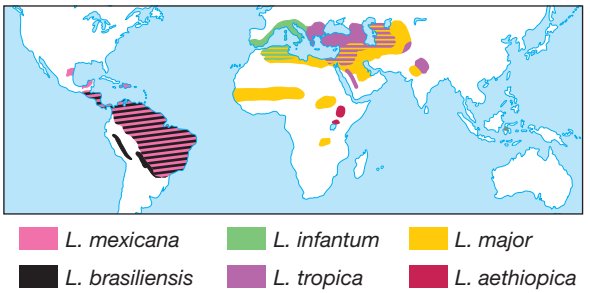

Fig. 13.43 World distribution of cutaneous leishmaniasis.

CL is commonly imported and should be considered in the differential diagnosis of an ulcerating skin lesion, especially in travellers who have visited endemic areas of the Old World or forests in Central and South America.

Pathogenesis

Inoculated parasites are taken up by dermal macrophages, in which they multiply and form a focus for lymphocytes, epithelioid cells and plasma cells. Self-healing may occur with necrosis of infected macrophages, or the lesion may become chronic with ulceration of the overlying epidermis, depending upon the aetiological pathogen.

Clinical features

The incubation period is typically 2–3 months (range 2 weeks to 5 years). In all types of CL, the common feature is development of a papule followed by ulceration of the skin with raised borders, usually at the site of the bite of the vector. Lesions, single or multiple, start as small red papules that increase gradually in size, reaching 2–10 cm in diameter. A crust forms, overlying an ulcer with a granular base (Fig. 13.44). These ulcers develop a few weeks or months after the bite. There can be satellite lesions, especially in *L. major* and occasionally in *L. tropica* infections. Regional lymphadenopathy, pain, pruritus and secondary bacterial infections may occur.

Clinically, lesions of *L. mexicana* and *L. peruviana* closely resemble those seen in the Old World, but lesions on the pinna of the ear are common, and are chronic and destructive. *L. mexicana* is responsible for chiclero ulcers, the self-healing sores of Mexico.

If immunity is good, there is usually spontaneous healing in *L. tropica*, *L. major* and *L. mexicana* lesions. In some patients with anergy to *Leishmania*, the skin lesions of *L. aethiopica*, *L. mexicana* and *L. amazonensis* infections progress to the development of diffuse CL; this is characterised by spread of the infection from the initial ulcer, usually on the face, to involve the whole body in the form of non-ulcerative nodules. Occasionally, in *L. tropica* infections, sores that have apparently healed relapse persistently (recidivans or lupoid leishmaniasis).

Mucosal leishmaniasis

The *Viannia* subgenus extends widely from the Amazon basin as far as Paraguay and Costa Rica, and is

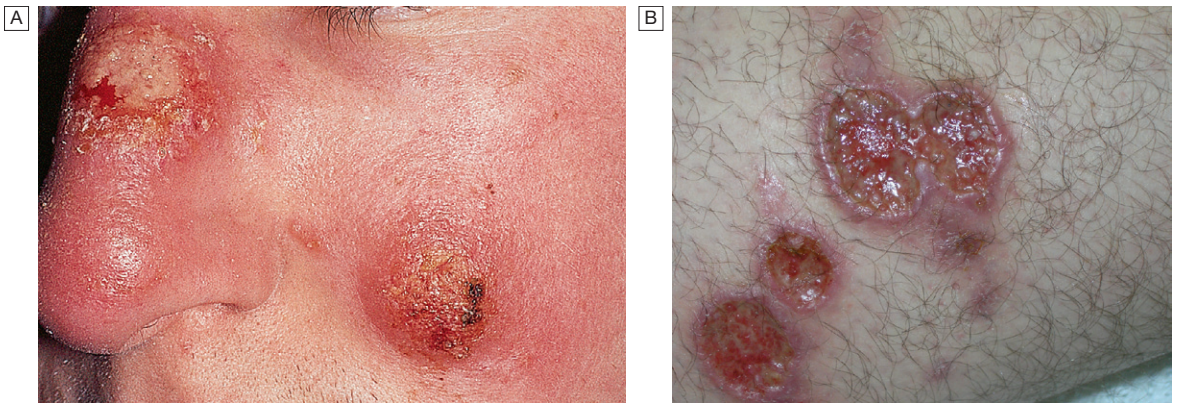

Fig. 13.44 Cutaneous leishmaniasis. **A** Papule. **B** Ulcer.

responsible for deep sores and ML. In *L. (V.) brasiliensis* complex infections, cutaneous lesions may be followed by mucosal spread of the disease simultaneously or even years later. Young men with chronic lesions are particularly at risk, and between 2% and 40% of infected persons develop 'espundia', metastatic lesions in the mucosa of the nose or mouth. This is characterised by thickening and erythema of the nasal mucosa, typically starting at the junction of the nose and upper lip. Later, ulceration develops. The lips, soft palate, fauces and larynx may also be invaded and destroyed, leading to considerable suffering and deformity. There is no spontaneous healing, and death may result from severe respiratory tract infections due to massive destruction of the pharynx.

Investigations in CL and ML

CL is often diagnosed on the basis of the lesions' clinical characteristics. However, parasitological confirmation is important because clinical manifestations may be mimicked by other infections. Amastigotes can be demonstrated on a slit-skin smear with Giemsa staining; alternatively, they can be cultured from the sores early during the infection. Parasites seem to be particularly difficult to isolate from sores caused by *L. brasiliensis*, responsible for the vast majority of cases in Brazil. Touch preparations from biopsies and histopathology usually have a low sensitivity. Culture of fine needle aspiration material has been reported to be the most sensitive method.

ML is more difficult to diagnose parasitologically. The leishmanin skin test measures delayed-type hypersensitivity to killed *Leishmania* organisms. A positive test is defined as induration of more than 5 mm 48 hours after intradermal injection. The test is positive, except in diffuse CL and during active VL. PCR is used increasingly for diagnosis and speciation, which is useful in selecting therapy.

Management of CL and ML

Small lesions may self-heal or are treated by freezing with liquid nitrogen or curettage. There is no ideal antimicrobial therapy. Treatment should be individualised on the basis of the causative organism, severity of the lesions, availability of drugs, tolerance of the patient for toxicity, and local resistance patterns.

In CL, topical application of paromomycin 15% plus methylbenzethonium chloride 12% is beneficial. Intralesional antimony (Sb: 0.2–0.8 mL/lesion) up to 2 g seems to be rapidly effective in suitable cases; it is well tolerated and economic, and is safe in patients with cardiac, liver or renal diseases.

In ML, and in CL when the lesions are multiple or in a disfiguring site, it is better to treat with parenteral Sb in a dose of 20 mg/kg/day (usually given for 20 days for CL and 28 days for ML), or with conventional or liposomal amphotericin B (see treatment of VL above). Sb is also indicated to prevent the development of mucosal disease, if there is any chance that a lesion acquired in South America is due to an *L. brasiliensis* strain. Refractory CL or ML should be treated with an amphotericin B preparation.

Other regimens may be effective. Two to four doses of pentamidine (2–4 mg/kg), administered on alternate days, are effective in New World CL caused by *L. guyanensis*. In ML, 8 injections of pentamidine (4 mg/kg on alternate days) cure the majority of patients. Ketoconazole (600 mg daily for 4 weeks) has shown some potential against *L. mexicana* infection. In Saudi Arabia, fluconazole (200 mg daily for 6 weeks) reduced healing times and cured 79% of patients with CL caused by *L. major*. In India, itraconazole (200 mg daily for 6 weeks) produced good results in CL.

Prevention of CL and ML

Personal protection against sandfly bites is important. No effective vaccine is yet available.

Gastrointestinal protozoal infections

Amoebiasis

Amoebiasis is caused by *Entamoeba histolytica*, which is spread between humans by its cysts. It is one of the leading parasitic causes of morbidity and mortality in the tropics and is occasionally acquired in other countries, such as the UK. Two non-pathogenic *Entamoeba* species (*E. dispar* and *E. moshkovskii*) are morphologically identical to *E. histolytica*, and are distinguishable only by molecular techniques, isoenzyme studies or monoclonal antibody typing. However, only *E. histolytica* causes amoebic dysentery or liver abscess. The life cycle of the amoeba is shown in Figure 13.45A.

Pathology

Cysts of *E. histolytica* are ingested in water or uncooked foods contaminated by human faeces. Infection may also be acquired through anal/oral sexual practices. In the colon, trophozoite forms emerge from the cysts. The parasite may invade the mucous membrane of the large bowel, producing lesions that are maximal in the caecum but found as far down as the anal canal. These are flask-shaped ulcers, varying greatly in size and surrounded by healthy mucosa. A localised granuloma (amoeboma), presenting as a palpable mass in the rectum or a filling defect in the colon on radiography, is a rare complication which should be differentiated from colonic carcinoma. Amoebic ulcers may cause severe haemorrhage but rarely perforate the bowel wall.

Amoebic trophozoites can emerge from the vegetative cyst from the bowel and be carried to the liver in a portal venule. They can multiply rapidly and destroy the liver parenchyma, causing an abscess (see also p. 956). The liquid contents at first have a characteristic pinkish colour, which may later change to chocolate-brown (like anchovy sauce).

Cutaneous amoebiasis, though rare, causes progressive genital, perianal or peri-abdominal surgical wound ulceration.

Clinical features

Intestinal amoebiasis – amoebic dysentery

Most amoebic infections are asymptomatic. The incubation period of amoebiasis ranges from 2 weeks to many years, followed by a chronic course with abdominal pains and two or more unformed stools a day. Offensive diarrhoea alternating with constipation, and blood or mucus in the stool, are common. There may be abdominal pain, especially right lower quadrant (which may simulate acute appendicitis). A dysenteric presentation

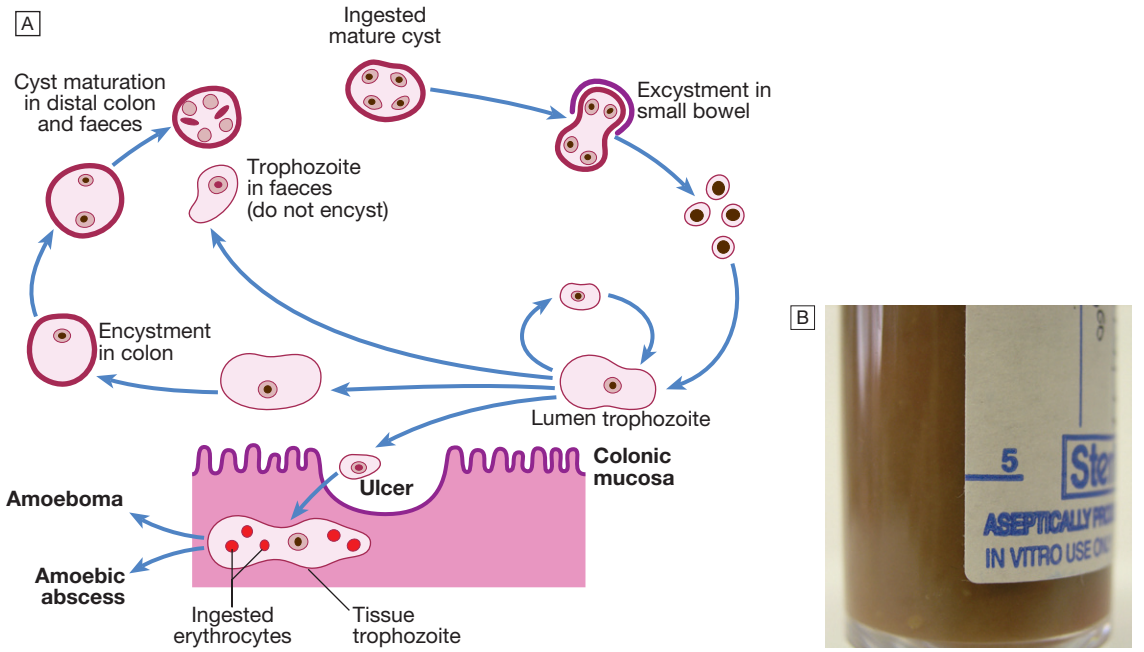

Fig. 13.45 Amoebiasis. A The life cycle of *Entamoeba histolytica.* From Knight 1982 – see p. 386. B The chocolate-brown appearance of aspirated material from an amoebic liver abscess.

with passage of blood, simulating bacillary dysentery or ulcerative colitis, occurs particularly in older people, in the puerperium and with superadded pyogenic infection of the ulcers.

Amoebic liver abscess

The abscess is usually found in the right hepatic lobe. There may not be associated diarrhoea. Early symptoms may be local discomfort only and malaise; later, a swinging temperature and sweating may develop, usually without marked systemic symptoms or associated cardiovascular signs. An enlarged, tender liver, cough and pain in the right shoulder are characteristic, but symptoms may remain vague and signs minimal. A large abscess may penetrate the diaphragm and rupture into the lung, from where its contents may be coughed up through a hepaticobronchial fistula. Rupture into the pleural or peritoneal cavity, or rupture of a left lobe abscess in the pericardial sac, is less common but more serious.

Investigations

The stool and any exudate should be examined at once under the microscope for motile trophozoites containing red blood cells. Movements cease rapidly as the stool preparation cools. Several stools may need to be examined in chronic amoebiasis before cysts are found. Sigmoidoscopy may reveal typical flask-shaped ulcers, which should be scraped and examined immediately for *E. histolytica.* In endemic areas, one-third of the population are symptomless passers of amoebic cysts.

An amoebic abscess of the liver is suspected on clinical grounds; there is often a neutrophil leucocytosis and a raised right hemidiaphragm on chest X-ray. Confirmation is by ultrasonic scanning. Aspirated pus from an amoebic abscess has the characteristic anchovy sauce or chocolate-brown appearance but only rarely contains free amoebae (Fig. 13.45B).

Serum antibodies are detectable by immunofluorescence in over 95% of patients with hepatic amoebiasis and intestinal amoeboma, but in only about 60% of dysenteric amoebiasis. DNA detection by PCR has been shown to be useful in diagnosis of *E. histolytica* infections but is not generally available.

Management

Intestinal and early hepatic amoebiasis responds quickly to oral metronidazole (800 mg 3 times daily for 5–10 days) or other long-acting nitroimidazoles like tinidazole or ornidazole (both in doses of 2 g daily for 3 days). Nitazoxanide (500 mg twice daily for 3 days) is an alternative drug. Either diloxanide furoate or paromomycin, in doses of 500 mg orally 3 times daily for 10 days after treatment, should be given to eliminate luminal cysts.

If a liver abscess is large or threatens to burst, or if the response to chemotherapy is not prompt, aspiration is required and is repeated if necessary. Rupture of an abscess into the pleural cavity, pericardial sac or peritoneal cavity necessitates immediate aspiration or surgical drainage. Small serous effusions resolve without drainage.

Prevention

Personal precautions against contracting amoebiasis consist of not eating fresh, uncooked vegetables or drinking unclean water.

Giardiasis

Infection with *Giardia lamblia* is found worldwide and is common in the tropics. It particularly affects children, tourists and immunosuppressed individuals, and is the parasite most commonly imported into the UK. In cystic form, it remains viable in water for up to 3 months and infection usually occurs by ingesting contaminated water. Its flagellar trophozoite form attaches to the duodenal and jejunal mucosa, causing inflammation.

Clinical features and investigations

After an incubation period of 1–3 weeks, there is diarrhoea, abdominal pain, weakness, anorexia, nausea and vomiting. On examination, there may be abdominal distension and tenderness.

Stools obtained at 2–3-day intervals should be examined for cysts. Duodenal or jejunal aspiration by endoscopy gives a higher diagnostic yield. The 'string test' may be used, in which one end of a piece of string is passed into the duodenum by swallowing and retrieved after an overnight fast; expressed fluid is then examined for the presence of *G. lamblia* trophozoites. A number of stool antigen detection tests are available. Jejunal biopsy specimens may show *G. lamblia* on the epithelial surface.

Management

Treatment is with a single dose of tinidazole 2 g, metronidazole 400 mg 3 times daily for 10 days, or nitazoxanide 500 mg orally twice daily for 3 days.

Cryptosporidiosis

Cryptosporidium spp. are coccidian protozoal parasites of humans and domestic animals. Infection is acquired by the faecal–oral route through contaminated water supplies. The incubation period is approximately 7–10 days and is followed by watery diarrhoea and abdominal cramps. The illness is usually self-limiting, but in immunocompromised patients, especially those with HIV, the illness can be devastating, with persistent severe diarrhoea and substantial weight loss (p. 399).

Cyclosporiasis

Cyclospora cayetanensis is a globally distributed coccidian protozoal parasite of humans. Infection is acquired by ingestion of contaminated water. The incubation period is approximately 2–11 days and is followed by acute onset of diarrhoea with abdominal cramps, which may remit and relapse. Although usually self-limiting, the illness may last as long as 6 weeks, with significant associated weight loss and malabsorption, and is more severe in immunocompromised individuals. Diagnosis is by detection of oöcysts on faecal microscopy. Treatment may be necessary in a few cases, and the agent of choice is co-trimoxazole 960 mg twice daily for 7 days.

INFECTIONS CAUSED BY HELMINTHS

Helminths (from the Greek *helmins*, meaning worm) include three groups of parasitic worm (Box 13.65), large multicellular organisms with complex tissues and organs.

Intestinal human nematodes

Diseases are caused by adult nematodes living in the human gut. There are two types:

- the hookworms, which have a soil stage in which they develop into larvae that then penetrate the host
- a group of nematodes which survive in the soil merely as eggs that have to be ingested for their life cycle to continue.

13.65 Classes of helminth that parasitise humans

Nematodes or roundworms

- Intestinal human nematodes: *Ancylostoma duodenale*, *Necator americanus*, *Strongyloides stercoralis*, *Ascaris lumbricoides*, *Enterobius vermicularis*, *Trichuris trichiura*
- Tissue-dwelling human nematodes: *Wuchereria bancrofti*, *Brugia malayi*, *Loa loa*, *Onchocerca volvulus*, *Dracunculus medinensis*, *Mansonella perstans*, *Dirofilaria immitis*
- Zoonotic nematodes: *Trichinella spiralis*

Trematodes or flukes

- Blood flukes: *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi*, *S. intercalatum*
- Lung flukes: *Paragonimus* spp.
- Hepatobiliary flukes: *Clonorchis sinensis*, *Fasciola hepatica*, *Opisthorchis felineus*
- Intestinal flukes: *Fasciolopsis buski*

Cestodes or tapeworms

- Intestinal tapeworms: *Taenia saginata*, *T. solium*, *Diphyllobothrium latum*, *Hymenolepis nana*
- Tissue-dwelling cysts or worms: *Taenia solium*, *Echinococcus granulosus*

The geographical distribution of hookworms is limited by the larval requirement for warmth and humidity. Soil-transmitted nematode infections can be prevented by avoidance of faecal soil contamination (adequate sewerage disposal) or skin contact (wearing shoes), and by strict personal hygiene.

Ancylostomiasis (hookworm)

Ancylostomiasis is caused by parasitisation with *Ancylostoma duodenale* or *Necator americanus*. The complex life cycle is shown in Figure 13.46. The adult hookworm is 1 cm long and lives in the duodenum and upper jejunum. Eggs are passed in the faeces. In warm, moist, shady soil, the larvae develop into rhabditiform and then the infective filariform stages; they then penetrate human skin and are carried to the lungs. After entering the alveoli, they ascend the bronchi, are swallowed and mature in the small intestine, reaching maturity 4–7 weeks after infection. The worms attach themselves to the mucosa of the small intestine by their buccal capsule (Fig. 13.47) and withdraw blood. The mean daily loss of blood from one *A. duodenale* is 0.15 mL and from *N. americanus* 0.03 mL.

Hookworm infection is one of the main causes of anaemia in the tropics and subtropics. *A. duodenale* is endemic in the Far East and Mediterranean coastal regions, and is also present in Africa, while *N. americanus* is endemic in West, East and Central Africa, and Central and South America, as well as in the Far East.

Clinical features

An allergic dermatitis, usually on the feet (ground itch), may be experienced at the time of infection. The passage of the larvae through the lungs in a heavy infection causes a paroxysmal cough with blood-stained sputum, associated with patchy pulmonary consolidation and eosinophilia. When the worms have reached the small intestine, vomiting and epigastric pain resembling peptic ulcer disease may occur. Sometimes, frequent loose stools are passed. The degree of iron and protein

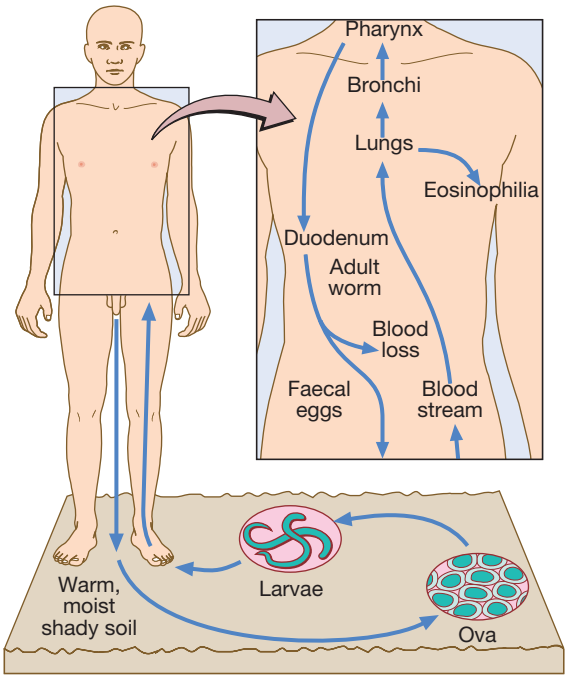

Fig. 13.46 Ancylostomiasis. Life cycle of *Ancylostoma.*

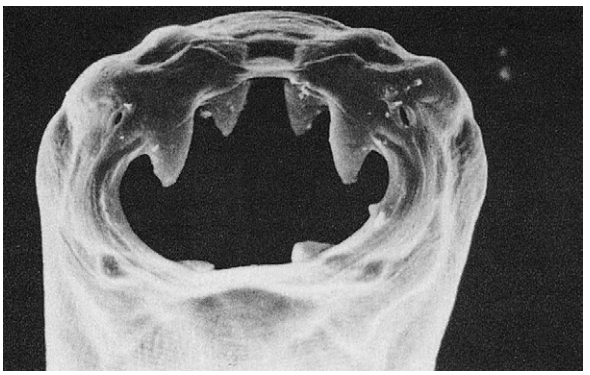

Fig. 13.47 *Ancylostoma duodenale.* Electron micrograph showing the ventral teeth. From Gibbons 1986 – see p. 386.

deficiency which develops depends not only on the load of worms but also on the nutrition of the patient and especially on the iron stores. Anaemia with high-output cardiac failure may result. The mental and physical development of children may be retarded in severe infection.

Investigations

There is eosinophilia. The characteristic ovum can be recognised in the stool. If hookworms are present in numbers sufficient to cause anaemia, faecal occult blood testing will be positive and many ova will be present.

Management

A single dose of albendazole (400 mg) is the treatment of choice. Alternatively, mebendazole 100 mg twice daily for 3 days may be used. Anaemia and heart failure associated with hookworm infection respond well to oral iron, even when severe; blood transfusion is rarely required.

Strongyloidiasis

Strongyloides stercoralis is a very small nematode (2 mm × 0.4 mm) which parasitises the mucosa of the upper part of the small intestine, often in large numbers, causing persistent eosinophilia. The eggs hatch in the bowel but only larvae are passed in the faeces. In moist soil, they moult and become the infective filariform larvae. After penetrating human skin, they undergo a development cycle similar to that of hookworms, except that the female worms burrow into the intestinal mucosa and submucosa. Some larvae in the intestine may develop into filariform larvae, which may then penetrate the mucosa or the perianal skin and lead to autoinfection and persistent infection. Patients with *Strongyloides* infection persisting for more than 35 years have been described. Strongyloidiasis occurs in the tropics and subtropics, and is especially prevalent in the Far East.

Clinical features

These are shown in Box 13.66. The classic triad of symptoms consists of abdominal pain, diarrhoea and urticaria. Cutaneous manifestations, either urticaria or larva currens (a highly characteristic pruritic, elevated, erythematous lesion advancing along the course of larval migration), are characteristic and occur in 66% of patients.

Systemic strongyloidiasis (the *Strongyloides* hyperinfection syndrome), with dissemination of larvae throughout the body, occurs in association with immune suppression (intercurrent disease, HIV and HTLV-1 infection, corticosteroid treatment). Patients present with severe, generalised abdominal pain, abdominal distension and shock. Massive larval invasion of the lungs causes cough, wheeze and dyspnoea; cerebral involvement has manifestations ranging from subtle neurological signs to coma. Gram-negative sepsis frequently complicates the picture.

Investigations

There is eosinophilia. Serology (ELISA) is helpful but definitive diagnosis depends upon finding the larvae. The faeces should be examined microscopically for motile larvae; excretion is intermittent and so repeated examinations may be necessary. Larvae can also be found in jejunal aspirate or detected using the string test (p. 369). Larvae may also be cultured from faeces.

13.66 Clinical features of strongyloidiasis

Penetration of skin by infective larvae
• Itchy rash
Presence of worms in gut
• Abdominal pain, diarrhoea, steatorrhoea, weight loss
Allergic phenomena
• Urticarial plaques and papules, wheezing, arthralgia
Autoinfection
• Transient itchy, linear, urticarial weals across abdomen and buttocks (larva currens)
Systemic (super)infection
• Diarrhoea, pneumonia, meningoencephalitis, death

Management

A course of two doses of ivermectin (200 µg/kg), administered on successive days, is effective. Alternatively, albendazole is given orally in a dose of 15 mg/kg body weight twice daily for 3 days. A second course may be required. For the *Strongyloides* hyperinfection syndrome, ivermectin is given at 200 µg/kg for 5–7 days.

Ascaris lumbricoides (roundworm)

This pale yellow nematode is 20–35 cm long. Humans are infected by eating food contaminated with mature ova. *Ascaris* larvae hatch in the duodenum, migrate through the lungs, ascend the bronchial tree, are swallowed and mature in the small intestine. This tissue migration can provoke both local and general hypersensitivity reactions, with pneumonitis, eosinophilic granulomas, bronchial asthma and urticaria.

Clinical features

Intestinal ascariasis causes symptoms ranging from occasional vague abdominal pain through to malnutrition. The large size of the adult worm and its tendency to aggregate and migrate can result in obstructive complications. Tropical and subtropical areas are endemic for ascariasis, and in these areas it causes up to 35% of all intestinal obstructions, most commonly in the terminal ileum. Obstruction can be complicated further by intussusception, volvulus, haemorrhagic infarction and perforation. Other complications include blockage of the bile or pancreatic duct and obstruction of the appendix by adult worms.

Investigations

The diagnosis is made microscopically by finding ova in the faeces. Adult worms are frequently expelled rectally or orally. Occasionally, the worms are demonstrated radiographically by a barium examination. There is eosinophilia.

Management

A single dose of albendazole (400 mg), pyrantel pamoate (11 mg/kg; maximum 1 g), ivermectin (150–200 µg/kg) or mebendazole (100 mg twice daily for 3 days) is effective for intestinal ascariasis. Patients should be warned that they might expel numerous whole, large worms. Obstruction due to ascariasis should be treated with nasogastric suction, piperazine and intravenous fluids.

Prevention

Community chemotherapy programmes have been used to reduce *Ascaris* infection. The whole community can be treated every 3 months for several years. Alternatively, schoolchildren can be targeted; treating them lowers the prevalence of ascariasis in the community.

Enterobius vermicularis (threadworm)

This helminth is common throughout the world and affects mainly children. After the ova are swallowed, development takes place in the small intestine, but the adult worms are found chiefly in the colon.

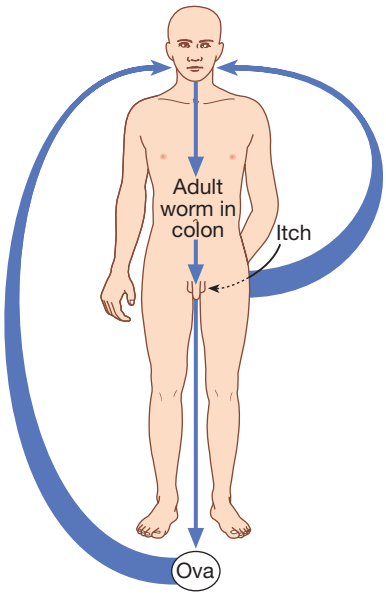

Fig. 13.48 Threadworm. Life cycle of *Enterobius vermicularis*.

Clinical features

The gravid female worm lays ova around the anus, causing intense itching, especially at night. The ova are often carried to the mouth on the fingers and so re-infection or human-to-human infection takes place (Fig. 13.48). In females, the genitalia may be involved. The adult worms may be seen moving on the buttocks or in the stool.

Investigations

Ova are detected by applying the adhesive surface of cellophane tape to the perianal skin in the morning. This is then examined on a glass slide under the microscope. A perianal swab, moistened with saline, is an alternative sampling method.

Management

A single dose of mebendazole (100 mg), albendazole (400 mg), pyrantel pamoate (11 mg/kg) or piperazine (4 g) is given and may be repeated after 2 weeks to control auto-reinfection. If infection recurs in a family, each member should be treated as above. During this period all nightclothes and bed linen are laundered. Fingernails must be kept short and hands washed carefully before meals. Subsequent therapy is reserved for those family members who develop recurrent infection.

Trichuris trichiura (whipworm)

Infections with whipworm are common all over the world under unhygienic conditions. Infection is contracted by the ingestion of earth or food contaminated with ova which have become infective after lying for 3 weeks or more in moist soil. The adult worm is 3–5 cm long and has a coiled anterior end resembling a whip. Whipworms inhabit the caecum, lower ileum, appendix, colon and anal canal. There are usually no symptoms, but intense infections in children may cause persistent diarrhoea or rectal prolapse, and growth retardation. The diagnosis is readily made by identifying ova in faeces. Treatment is with mebendazole in doses of

100 mg twice daily or albendazole 400 mg daily for 3 days for patients with light infections, and for 5–7 days for those with heavy infections.

Tissue-dwelling human nematodes

Filarial worms are tissue-dwelling nematodes. The larval stages are inoculated by biting mosquitoes or flies, each specific to a particular filarial species. The larvae develop into adult worms (2–50 cm long) which, after mating, produce millions of microfilariae (170–320 µm long) that migrate in blood or skin. The life cycle is completed when the vector takes up microfilariae while feeding on humans. In the insect, ingested microfilariae develop into infective larvae for inoculation in humans, normally the only host.

Disease is due to the host's immune response to the worms (both adult and microfilariae), particularly dying worms, and its pattern and severity vary with the site and stage of each species (Box 13.67). The worms are long-lived; microfilariae survive 2–3 years and adult worms 10–15 years. The infections are chronic and worst in individuals constantly exposed to re-infection.

Lymphatic filariasis

Infection with the filarial worms *Wuchereria bancrofti* and *Brugia malayi* is associated with clinical outcomes ranging from subclinical infection to hydrocele and elephantiasis.

W. bancrofti is transmitted by night-biting culicine or anopheline mosquitoes in most areas (Fig. 13.49). The adult worms, 4–10 cm in length, live in the lymphatics, and the females produce microfilariae which circulate in large numbers in the peripheral blood, usually at night. The infection is widespread in tropical Africa, on the North African coast, in coastal areas of Asia, Indonesia and northern Australia, the South Pacific islands, the West Indies and also in North and South America.

B. malayi usually causes less severe disease than *W. bancrofti* and is transmitted by *Mansonia* or *Anopheles* mosquitoes in Indonesia, Borneo, Malaysia, Vietnam, South China, South India and Sri Lanka.

Pathology

Several factors contribute to the pathogenesis of lymphatic filariasis. Toxins released by the adult worm cause lymphangiectasia; this dilatation of the lymphatic vessels leads to lymphatic dysfunction and the chronic clinical manifestations of lymphatic filariasis, lymphoedema and hydrocele. Death of the adult worm results in acute filarial lymphangitis. The filariae are symbiotically infected with rickettsia-like bacteria (*Wolbachia* spp.), and release of lipopolysaccharide from these bacteria contributes to inflammation. Lymphatic obstruction persists after death of the adult worm. Secondary bacterial infections cause tissue destruction. The host response to microfilariae is central to the pathogenesis of tropical pulmonary eosinophilia.

13.67 Pathogenicity of filarial infections depending on site and stage of worms

Worm species	Adult worm	Microfilariae
Wuchereria bancrofti* and *Brugia malayi	Lymphatic vessels^{+++}	Blood^{-} Pulmonary capillaries^{++}
Loa loa	Subcutaneous^{+}	Blood^{+}
Onchocerca volvulus	Subcutaneous^{+}	Skin^{+++} Eye^{+++}
Mansonella perstans	Retroperitoneal^{-}	Blood^{-}
Mansonella streptocerca	Skin^{+}	Skin^{++}

(+++ severe; ++ moderate; + mild; – rarely pathogenic)

Clinical features

Acute filarial lymphangitis presents with fever, pain, tenderness and erythema along the course of inflamed lymphatic vessels. Inflammation of the spermatic cord, epididymis and testis is common. The whole episode lasts a few days but may recur several times a year. Temporary oedema becomes more persistent and regional lymph nodes enlarge. Progressive enlargement, coarsening, corrugation, fissuring and bacterial infection of the skin and subcutaneous tissue develop gradually, causing irreversible 'elephantiasis'. The scrotum may reach an enormous size. Chyluria and chylous effusions are milky and opalescent; on standing, fat globules rise to the top.

The acute lymphatic manifestations of filariasis must be differentiated from thrombophlebitis and infection. The oedema and lymphatic obstructive changes must be distinguished from congestive cardiac failure, malignancy, trauma and idiopathic abnormalities of the lymphatic system. Silicates absorbed from volcanic soil can also cause non-filarial elephantiasis.

Tropical pulmonary eosinophilia is a complication seen mainly in India and is likely to be due to microfilariae trapped in the pulmonary capillaries and destroyed

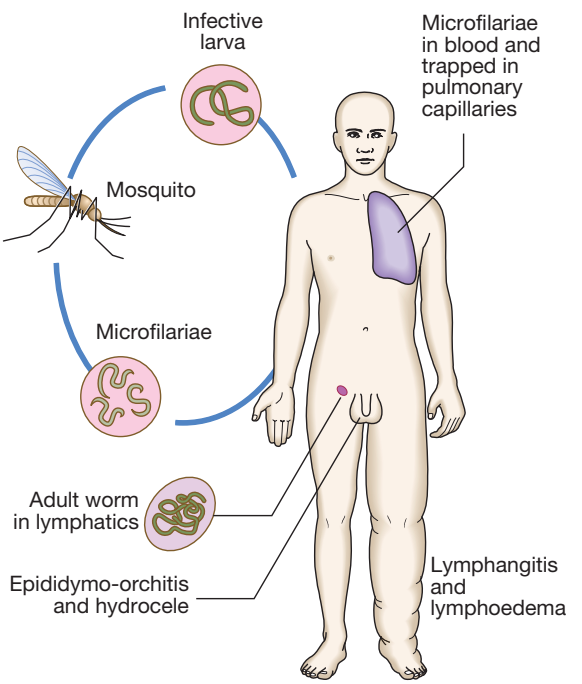

Fig. 13.49 ***Wuchereria bancrofti* and *Brugia malayi*.** Life cycle of organisms and pathogenesis of lymphatic filariasis.

by allergic inflammation. Patients present with paroxysmal cough, wheeze and fever. If untreated, this may progress to debilitating chronic interstitial lung disease.

Investigations

In the earliest stages of lymphangitis, the diagnosis is made on clinical grounds, supported by eosinophilia and sometimes by positive filarial serology. Filarial infections cause the highest eosinophil counts of all helminthic infections.

Microfilariae can be found in the peripheral blood at night, and either are seen moving in a wet blood film or are detected by microfiltration of a sample of lysed blood. They are usually present in hydrocele fluid, which may occasionally yield an adult filaria. By the time elephantiasis develops, microfilariae become difficult to find. Calcified filariae may sometimes be demonstrable by radiography. Movement of adult worms can be seen on scrotal ultrasound. PCR-based tests for detection of *W. bancrofti* and *B. malayi* DNA from blood have been developed.

Indirect fluorescence and ELISA detect antibodies in over 95% of active cases and 70% of established elephantiasis. The test becomes negative 1–2 years after cure. Serological tests cannot distinguish the different filarial infections. Highly sensitive and specific immunochromatographic card tests for detection of circulating *W. bancrofti* antigen are now commercially available; fingerprick blood taken at any time of the day can be used for these.

In tropical pulmonary eosinophilia, serology is strongly positive and IgE levels are massively elevated, but circulating microfilariae are not found. The chest X-ray shows miliary changes or mottled opacities. Pulmonary function tests show a restrictive picture.

Management

Treatment of the individual is aimed at reversing and halting disease progression. Diethylcarbamazine (DEC, 2 mg/kg orally 3 times daily for 12 days, or as a single dose) kills microfilariae and adult worms. Most adverse effects seen with DEC treatment are due to the host response to dying microfilariae, and the reaction intensity is directly proportional to the microfilarial load. The main symptoms are fever, headache, nausea, vomiting, arthralgia and prostration. These usually occur within 24–36 hours of the first dose of DEC. Antihistamines or corticosteroids may be required to control these allergic phenomena. Combining albendazole (400 mg) with ivermectin (200 µg/kg) in a single dose, with or without DEC (300 mg), is also highly effective in clearing the parasites. Treatment of *Wolbachia* with doxycycline (200 mg/day) for 4–8 weeks provides additional benefit by eliminating the bacteria; this leads to interruption of parasite embryogenesis. For tropical pulmonary eosinophilia, DEC for 14 days is the treatment of choice.

Chronic lymphatic pathology

Experience in India and Brazil shows that active management of chronic lymphatic pathology can alleviate symptoms. Patients should be taught meticulous skin care of their lymphoedematous limbs to prevent secondary bacterial and fungal infections. Tight bandaging, massage and bed rest with elevation of the affected limb may help to control the lymphoedema. Prompt diagnosis and antibiotic therapy of bacterial cellulitis are important in preventing further lymphatic damage and worsening of existing elephantiasis. Plastic surgery may be indicated in established elephantiasis. Great relief can be obtained by removal of excess tissue but recurrences are probable unless new lymphatic drainage is established. Hydroceles and chyluria can be repaired surgically.

Prevention

Treatment of the whole population in endemic areas with annual single-dose DEC (6 mg/kg), either alone or in combination with albendazole or ivermectin, can reduce filarial transmission. This mass treatment should be combined with mosquito control programmes.

Loiasis

Loiasis is caused by infection with the filaria *Loa loa*. The disease is endemic in forested and swampy parts of Western and Central Africa. The adult worms, 3–7 cm × 4 mm, chiefly parasitise the subcutaneous tissue of humans, releasing larval microfilariae into the peripheral blood in the daytime. The vector is *Chrysops*, a forest-dwelling, day-biting fly.

The host response to *Loa loa* is usually absent or mild, so that the infection may be harmless. From time to time a short-lived, inflammatory, oedematous swelling (a Calabar swelling) is produced around an adult worm. Heavy infections, especially when treated, may cause encephalitis.

Clinical features

The infection is often symptomless. The incubation period is commonly over a year but may be just 3 months. The first sign is usually a Calabar swelling, an irritating, tense, localised swelling that may be painful, especially if it is near a joint. The swelling is generally on a limb; it measures a few centimetres in diameter but sometimes is more diffuse and extensive. It usually disappears after a few days but may persist for 2 or 3 weeks. A succession of such swellings may appear at irregular intervals, often in adjacent sites. Sometimes, there is urticaria and pruritus elsewhere. Occasionally, a worm may be seen wriggling under the skin, especially that of an eyelid, and may cross the eye under the conjunctiva, taking many minutes to do so.

Investigations

Diagnosis is by demonstrating microfilariae in blood taken during the day, but they may not always be found in patients with Calabar swellings. Antifilarial antibodies are positive in 95% of patients and there is massive eosinophilia. Occasionally, a calcified worm may be seen on X-ray.

Management

DEC (see above) is curative, in a dose of 9–12 mg/kg daily, continued for 21 days. Treatment may precipitate a severe reaction in patients with a heavy microfilaraemia characterised by fever, joint and muscle pain, and encephalitis; microfilaraemic patients should be given corticosteroid cover.

Prevention

Protection is afforded by building houses away from trees and by having dwellings wire-screened. Protective

clothing and insect repellents are also useful. DEC in a dose of 5 mg/kg daily for 3 days each month is partially protective.

Onchocerciasis (river blindness)

Onchocerciasis is the result of infection by the filarial *Onchocerca volvulus*. The infection is conveyed by flies of the genus *Simulium*, which breed in rapidly flowing, well-aerated water. Adult flies inflict painful bites during the day, both inside and outside houses. While feeding, they pick up the microfilariae, which mature into the infective larva and are transmitted to a new host in subsequent bites. Humans are the only known hosts (Fig. 13.50).

Onchocerciasis is endemic in sub-Saharan Africa, Yemen and a few foci in Central and South America. It is estimated that 17.7 million people are infected, of whom 500 000 are visually impaired and 270 000 blind. Due to onchocerciasis, huge tracts of fertile land lie virtually untilled, and individuals and communities are impoverished.

Pathology

After inoculation of larvae by a bite from an infected fly, the worms mature in 2–4 months and live for up to 17 years in subcutaneous and connective tissues. At sites of trauma, over bony prominences and around joints, fibrosis may form nodules around adult worms, which otherwise cause no direct damage. Innumerable microfilariae, discharged by the female *O. volvulus*, move actively in these nodules and in the adjacent tissues, are widely distributed in the skin, and may invade the eye. Live microfilariae elicit little tissue reaction, but dead ones may cause severe allergic inflammation, leading to hyaline necrosis and loss of collagen and elastin. Death of microfilariae in the eye causes inflammation and may lead to blindness.

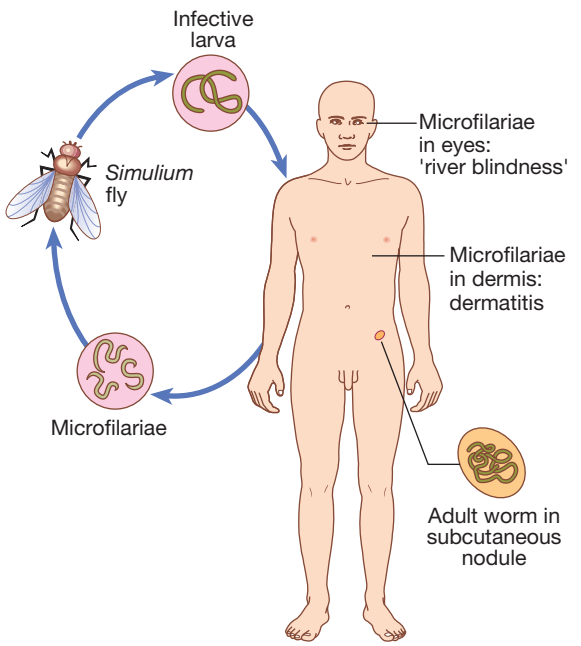

Fig. 13.50 ***Onchocerca volvulus.*** Life cycle of organism and pathogenesis of onchocerciasis.

Clinical features

The infection may remain symptomless for months or years. The first symptom is usually itching, localised to one quadrant of the body and later becoming generalised and involving the eyes. Transient oedema of part or all of a limb is an early sign, followed by papular urticaria spreading gradually from the site of infection. This is difficult to see on dark skins, in which the most common signs are papules excoriated by scratching, spotty hyperpigmentation from resolving inflammation, and more chronic changes of a rough, thickened or inelastic, wrinkled skin. Both infected and uninfected superficial lymph nodes enlarge and may hang down in folds of loose skin in the groin. Hydrocele, femoral hernias and scrotal elephantiasis can occur. Firm subcutaneous nodules of more than 1 cm in diameter (onchocercomas) occur in chronic infection.

Eye disease is most common in highly endemic areas and is associated with chronic heavy infections and nodules on the head. Early manifestations include itching, lacrimation and conjunctival injection. These cause conjunctivitis, sclerosing keratitis with pannus formation, uveitis which may lead to glaucoma and cataract, and, less commonly, choroiditis and optic neuritis. Classically, 'snowflake' deposits are seen in the edges of the cornea.

Investigations

The finding of nodules or characteristic lesions of the skin or eyes in a patient from an endemic area, associated with eosinophilia, is suggestive. Skin snips or shavings, taken with a corneoscleral punch or scalpel blade from calf, buttock and shoulder, are placed in saline under a cover slip on a microscope slide and examined after 4 hours. Microfilariae are seen wriggling free in all but the lightest infections. Slit-lamp examination may reveal microfilariae moving in the anterior chamber of the eye or trapped in the cornea. A nodule may be removed and incised, showing the coiled, thread-like adult worm.

Filarial antibodies may be detected in up to 95% of patients. Several promising rapid strip tests based on antibody or antigen detection are under clinical evaluation. When there is a strong suspicion of onchocerciasis but tests are negative, a provocative Mazzotti test, in which administration of 0.5–1.0 mg/kg of DEC exacerbates pruritus or dermatitis, strongly suggests onchocerciasis.

Management

Ivermectin, in a single dose of 100–200 µg/kg, repeated several times at 3-monthly intervals to prevent relapses, is recommended. It kills microfilariae and has minimal toxicity. In the rare event of a severe reaction causing oedema or postural hypotension, prednisolone 20–30 mg may be given daily for 2 or 3 days. Ivermectin has little macrofilaricidal effect so that, 1 year after ivermectin treatment, skin microfilarial densities regain at least 20% of pre-treatment levels; repeated treatments are required for the lifespan of the adult worm. Eradication of *Wolbachia* with doxycycline (100 mg daily for 6 weeks) prevents worm reproduction.

Prevention

Mass treatment with ivermectin is practised. It reduces morbidity in the community and slows the progression

of eye disease, but it does not clear worm infection. *Simulium* can be destroyed in its larval stage by the application of insecticide to streams. Long trousers, skirts and sleeves discourage the fly from biting.

Dracunculiasis (Guinea worm)

Infestation with the Guinea worm *Dracunculus medinensis* manifests itself when the female worm, over a metre long, emerges from the skin. Humans are infected by ingesting a small crustacean, *Cyclops*, which inhabits wells and ponds, and contains the infective larval stage of the worm. The worm was widely distributed across Africa and the Middle East, but after a successful eradication programme is now seen only in sub-Saharan Africa.

Management and prevention

Traditionally, the protruding worm is extracted by winding it out gently over several days on a matchstick. The worm must never be broken. Antibiotics for secondary infection and prophylaxis of tetanus are also required.

A global elimination campaign is based on the provision of clean drinking water and eradication of water fleas from drinking water. The latter is being achieved by simple filtration of water through a plastic mesh filter and chemical treatment of water supplies.

Other filariases

Mansonella perstans

This filarial worm is transmitted by the midges *Culicoides austeni* and *C. grahami*. It is common throughout equatorial Africa as far south as Zambia, and also in Trinidad and parts of northern and eastern South America.

M. perstans has never been proven to cause disease but it may be responsible for a persistent eosinophilia and occasional allergic manifestations. *M. perstans* is resistant to ivermectin and DEC, and the infection may persist for many years.

Dirofilaria immitis

This dog heart worm infects humans, causing skin and lung lesions. It is not uncommon in the USA, Japan and Australia.

Zoonotic nematodes

Trichinosis (trichinellosis)

Trichinella spiralis is a nematode that parasitises rats and pigs, and is only transmitted to humans if they eat partially cooked infected pork, usually as sausage or ham. Bear meat is another source. Symptoms result from invasion of intestinal submucosa by ingested larvae, which develop into adult worms, and the secondary invasion of striated muscle by fresh larvae produced by these adult worms. Outbreaks have occurred in the UK, as well as in other countries where pork is eaten.

Clinical features

The clinical features of trichinosis are determined by the larval numbers. A light infection with a few worms may be asymptomatic; a heavy infection causes nausea and diarrhoea 24–48 hours after the infected meal. A few days later, the symptoms associated with larval invasion predominate: there is fever and oedema of the face, eyelids and conjunctivae; invasion of the diaphragm may cause pain, cough and dyspnoea; and involvement of the muscles of the limbs, chest and mouth causes stiffness, pain and tenderness in affected muscles. Larval migration may cause acute myocarditis and encephalitis. An eosinophilia is usually found after the second week. An intense infection may prove fatal but those who survive recover completely.

Investigations

Commonly, a group of people who have eaten infected pork from a common source develop symptoms at about the same time. Biopsy from the deltoid or gastrocnemius muscle after the third week of symptoms may reveal encysted larvae. Serological tests are also helpful.

Management

Treatment is with albendazole (400 mg twice daily for 8–14 days) or mebendazole (200–400 mg three times daily for 3 days, followed by 400–500 mg three times daily for 10 days). Given early in the infection, this may kill newly formed adult worms in the submucosa and thus reduce the number of larvae reaching the muscles. Corticosteroids are necessary to control the serious effects of acute inflammation.

Cutaneous larva migrans

Cutaneous larva migrans (CLM) is the most common linear lesion seen in travellers (Fig. 13.51). Intensely pruritic, linear, serpiginous lesions result from the larval migration of the dog hookworm (*Ancylostoma caninum*). The track moves across the skin at a rate of 2–3 cm/day. This contrasts with the rash of *Strongyloides* (p. 370), which is fast-moving and transient. Although the larvae of dog hookworms frequently infect humans, they do not usually develop into the adult form. The most common site for CLM is the foot but elbows, breasts and buttocks may be affected. Most patients with CLM have recently visited a beach where the affected part was exposed. The diagnosis is clinical. Treatment may be

Fig. 13.51 Cutaneous larva migrans.

local with 12-hourly application of 15% thiabendazole cream, or systemic with a single dose of albendazole (400 mg) or ivermectin (150–200 µg/kg).

Trematodes (flukes)

These leaf-shaped worms are parasitic to humans and animals. Their complex life cycles may involve one or more intermediate hosts, often freshwater molluscs.

Schistosomiasis

Schistosomiasis is one of the most important causes of morbidity in the tropics. There are five species of the genus *Schistosoma* which commonly cause disease in humans: *S. haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi* and *S. intercalatum*. *S. haematobium* was discovered by Theodor Bilharz in Cairo in 1861 and the disease is sometimes called bilharzia or bilharziasis. Schistosome eggs have been found in Egyptian mummies dated 1250 BC.

The life cycle is shown in Figure 13.52A. The ovum is passed in the urine or faeces of infected individuals and gains access to fresh water, where the ciliated miracidium inside it is liberated; it enters its intermediate host, a species of freshwater snail, in which it multiplies. Large numbers of fork-tailed cercariae are then liberated into the water, where they may survive for 2–3 days. Cercariae can penetrate the skin or the mucous membrane of the mouth of humans. They transform into schistosomulae and moult as they pass through the lungs; thence they are carried by the blood stream to the liver, and so to the portal vein, where they mature. The male worm is up to 20 mm in length and the more slender cylindrical female, usually enfolded longitudinally by the male, is rather longer (Fig. 13.52B). Within 4–6 weeks of infection, they migrate to the venules draining the pelvic viscera, where the females deposit ova.

Pathology

This depends on the species and the stage of infection (Box 13.68). Most disease is due to the passage of eggs through mucosa and to the granulomatous reaction to eggs deposited in tissues. The eggs of *S. haematobium* pass mainly through the wall of the bladder, but may also involve rectum, seminal vesicles, vagina, cervix and uterine tubes. *S. mansoni* and *S. japonicum* eggs pass mainly through the wall of the lower bowel or are carried to the liver. The most serious, although rare, site of ectopic deposition of eggs is in the CNS. Granulomas are composed of macrophages, eosinophils, and epithelioid and giant cells around an ovum. Later, there is fibrosis and eggs calcify, often in sufficient numbers to become radiologically visible. Eggs of *S. haematobium* may leave the vesical plexus and be carried directly to the lung. Those of *S. mansoni* and *S. japonicum* may also reach the lungs after the development of portal hypertension and consequent portasystemic collateral circulation. In both circumstances, egg deposition in the pulmonary vasculature, and the resultant host response, can lead to the development of pulmonary hypertension.

Clinical features

Recent travellers, especially those overlanding through Africa, may present with allergic manifestations and eosinophilia; residents of schistosomiasis-endemic areas are more likely to present with chronic urinary tract pathology or portal hypertension.

During the early stages of infection, there may be itching lasting 1–2 days at the site of cercarial penetration

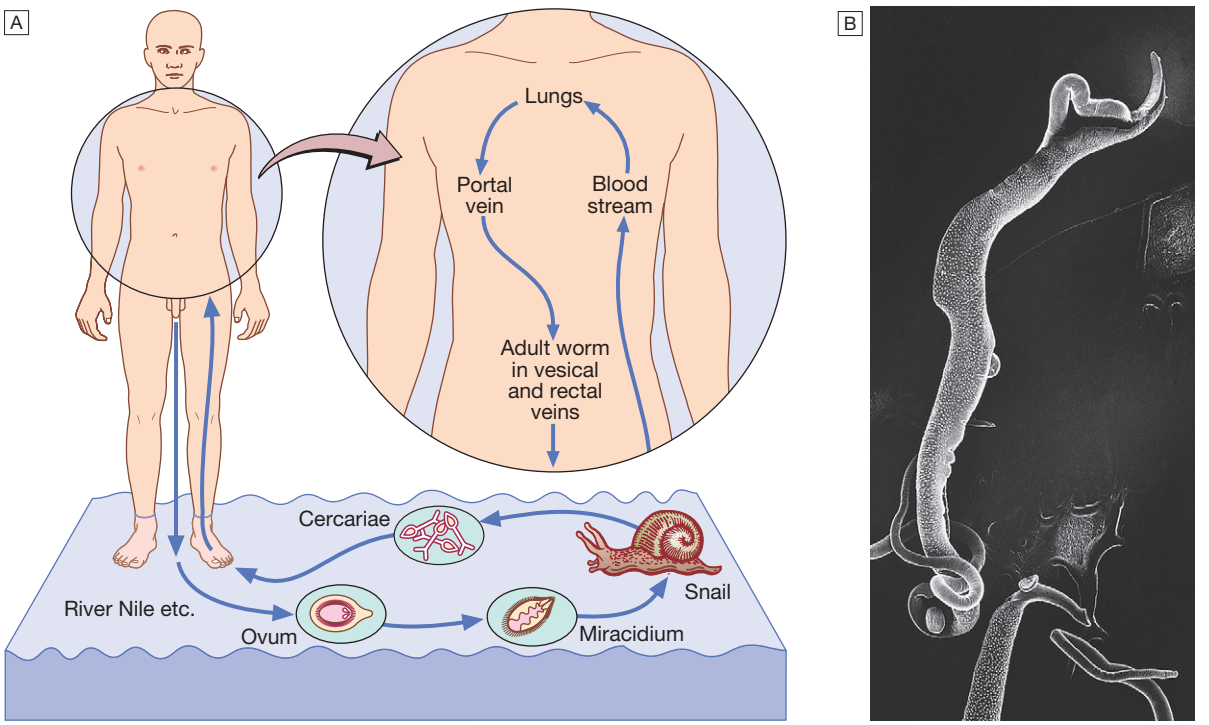

Fig. 13.52 ***Schistosoma.*** A Life cycle. B Scanning electron micrograph of adult schistosome worms, showing the larger male worm embracing the thinner female.

13.68 Pathogenesis of schistosomiasis

Time	*S. haematobium*	*S. mansoni* and *S. japonicum*
Cercarial penetration		
Days	Papular dermatitis at site of penetration	As for *S. haematobium*
Larval migration and maturation		
Weeks	Pneumonitis, myositis, hepatitis, fever, 'serum sickness', eosinophilia, seroconversion	As for *S. haematobium*
Early egg deposition		
Months	Cystitis, haematuria	Colitis, granulomatous hepatitis, acute portal hypertension
	Ectopic granulomatous lesions: skin, CNS etc. Immune complex glomerulonephritis	As for *S. haematobium*
Late egg deposition		
Years	Fibrosis and calcification of ureters, bladder: bacterial infection, calculi, hydronephrosis, carcinoma	Colonic polyposis and strictures, periportal fibrosis, portal hypertension
	Pulmonary granulomas and pulmonary hypertension	As for *S. haematobium*

('swimmer's itch'). After a symptom-free period of 3–5 weeks, acute schistosomiasis (Katayama syndrome) may present with allergic manifestations, such as urticaria, fever, muscle aches, abdominal pain, headaches, cough and sweating. On examination, hepatomegaly, splenomegaly, lymphadenopathy and pneumonia may be present. These allergic phenomena may be severe in infections with *S. mansoni* and *S. japonicum*, but are rare with *S. haematobium*. The features subside after 1–2 weeks.

Chronic schistosomiasis is due to egg deposition and occurs months to years after infection. The symptoms and signs depend upon the intensity of infection and the species of infecting schistosome (see Box 13.68).

Schistosoma haematobium

Humans are the only natural hosts of *S. haematobium*, which is highly endemic in Egypt and East Africa, and occurs throughout Africa and the Middle East (Fig. 13.53). Infection can be acquired after a brief exposure, such as swimming in freshwater lakes in Africa.

Painless terminal haematuria is usually the first and most common symptom. Frequency of micturition follows, due to bladder neck obstruction. Later, the disease may be complicated by frequent urinary tract infections, bladder or ureteric stone formation, hydronephrosis, and ultimately renal failure with a contracted calcified bladder. Pain is often felt in the iliac fossa or in the loin, and radiates to the groin. In several endemic areas, there is a strong epidemiological association of *S. haematobium* infection with squamous cell carcinoma of the bladder. Disease of the seminal vesicles may lead to haemospermia. Females may develop schistosomal papillomas of the vulva, and schistosomal lesions of the cervix may be mistaken for cancer. Intestinal symptoms may follow involvement of the bowel wall. Ectopic worms cause skin or spinal cord lesions.

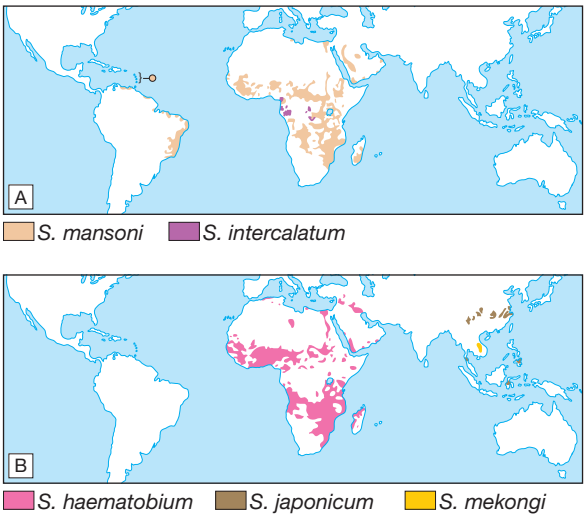

Fig. 13.53 Geographical distribution of schistosomiasis. From Cook 1995 – see p. 386.

The severity of *S. haematobium* infection varies greatly, and many with a light infection are asymptomatic. However, as adult worms can live for 20 years or more and lesions may progress, these patients should always be treated.

Schistosoma mansoni

S. mansoni is endemic throughout Africa, the Middle East, Venezuela, Brazil and the Caribbean (see Fig. 13.53).

Characteristic symptoms begin 2 months or more after infection. They may be slight, no more than malaise, or consist of abdominal pain and frequent stools which contain blood-stained mucus. With severe advanced disease, increased discomfort from rectal polyps may be experienced. The early hepatomegaly is reversible, but portal hypertension may cause massive splenomegaly, fatal haematemesis from oesophageal varices, or progressive ascites (p. 938). Liver function is initially preserved because the pathology is fibrotic rather than cirrhotic. *S. mansoni* and other schistosome infections predispose to the carriage of *Salmonella*, in part because *Salmonella* may attach to the schistosomes and in part because shared antigens on schistosomes may induce immunological tolerance to *Salmonella*.

Schistosoma japonicum, S. mekongi *and* S. intercalatum

In addition to humans, the adult worm of *S. japonicum* infects the dog, rat, field mouse, water buffalo, ox, cat, pig, horse and sheep. Although other *Schistosoma* spp. can infect species other than humans, the non-human reservoir seems to be particularly important in transmission for *S. japonicum* but not for *S. haematobium* or *S. mansoni*. *S. japonicum* is prevalent in the Yellow River and Yangtze–Jiang basins in China, where the infection is a major public health problem. It also has a focal distribution in the Philippines, Indonesia and Thailand (see Fig. 13.53). The related *S. mekongi* occurs in Laos, Thailand and Myanmar, and *S. intercalatum* in West and Central Africa.

The pathology of *S. japonicum* is similar to that of *S. mansoni*, but as this worm produces more eggs, the

lesions tend to be more extensive and widespread. The clinical features resemble those of severe infection with *S. mansoni*, with added neurological features. The small and large bowel may be affected, and hepatic fibrosis with splenic enlargement is usual. Deposition of eggs or worms in the CNS, especially in the brain or spinal cord, causes symptoms in about 5% of infections, notably epilepsy, blindness, hemiplegia or paraplegia.

Investigations

There is marked eosinophilia. Serological tests (ELISA) are useful as screening tests but remain positive after chemotherapeutic cure.

In *S. haematobium* infection, dipstick urine testing shows blood and albumin. The eggs can be found by microscopic examination of the centrifuged deposit of terminal stream urine (Fig. 13.54). Ultrasound is useful for assessing the urinary tract; bladder wall thickening, hydronephrosis and bladder calcification can be detected. Cystoscopy reveals 'sandy' patches, bleeding mucosa and later distortion.

In a heavy infection with *S. mansoni* or *S. japonicum*, the characteristic egg with its lateral spine can usually be found in the stool. When the infection is light or of long duration, a rectal biopsy can be examined. Sigmoidoscopy may show inflammation or bleeding. Biopsies should be examined for ova.

Management

The object of specific treatment is to kill the adult schistosomes and so stop egg-laying. Praziquantel (20 mg/kg orally twice daily for 1 day) is the drug of choice for all forms of schistosomiasis. The drug produces parasitological cure in 80% of treated individuals and over 90% reduction in egg counts in the remainder. Side-effects are uncommon but include nausea and abdominal pain. Praziquantel therapy in early infection reverses pathologies such as hepatomegaly and bladder wall thickening and granulomas.

Surgery may be required to deal with residual lesions such as ureteric stricture, small fibrotic urinary bladders, or granulomatous masses in the brain or spinal cord. Removal of rectal papillomas by diathermy or by other means may provide symptomatic relief.

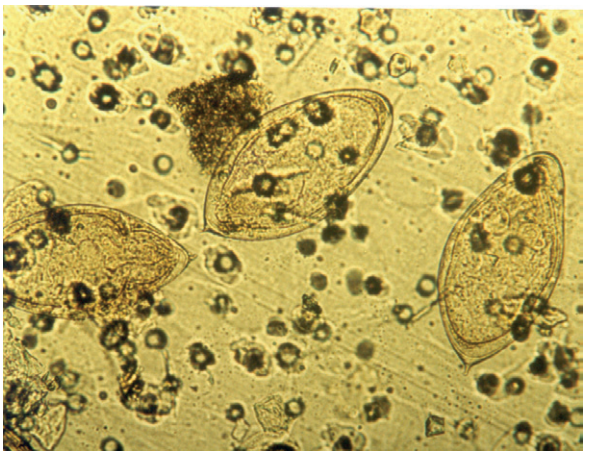

Fig. 13.54 Ova of *Schistosoma haematobium* in urine. Note the terminal spike.

Prevention

So far, no satisfactory single means of controlling schistosomiasis has been established. The life cycle is terminated if the ova in urine or faeces are not allowed to contaminate fresh water containing the snail host. The provision of latrines and of a safe water supply, however, remains a major problem in rural areas throughout the tropics. Furthermore, *S. japonicum* has so many hosts besides humans that latrines would be of little avail. Annual mass treatment of the population helps prevent *S. haematobium* and *S. mansoni* infection, but this method has so far had little success with *S. japonicum*. Targeting the intermediate host, the snail, presents many difficulties and has not, on its own, proved successful on any scale. For personal protection, contact with infected water must be avoided.

Liver flukes

Liver flukes infect at least 20 million people and remain an important public health problem in many endemic areas. They are associated with abdominal pain, hepatomegaly and relapsing cholangitis. *Clonorchis sinensis* is a major aetiological agent of bile duct cancer. The three major liver flukes have similar life cycles and pathologies, as outlined in Box 13.69.

Other flukes of medical importance include lung and intestinal flukes (see Box 13.65, p. 369).

Cestodes (tapeworms)

Cestodes are ribbon-shaped worms which inhabit the intestinal tract. They have no alimentary system and absorb nutrients through the tegumental surface. The anterior end, or scolex, has suckers for attaching to the host. From the scolex, a series of progressively developing segments arise, the proglottides, which may continue to show active movements when shed. Cross-fertilisation takes place between segments. Ova, present in large numbers in mature proglottides, remain viable for weeks, and during this period, they may be consumed by the intermediate host. Larvae liberated from the ingested ova pass into the tissues, forming larval cysticerci.

Tapeworms cause two distinct patterns of disease, either intestinal infection or systemic cysticercosis (Fig. 13.55). *Taenia saginata* (beef tapeworm), *Taenia asiatica* and *Diphyllobothrium latum* (fish tapeworm) cause only intestinal infection, following human ingestion of intermediate hosts that contain cysticerci (the larval stage of the tapeworm). *Taenia solium* causes intestinal infection if a cysticerci-containing intermediate host is ingested, and cysticercosis (systemic infection from larval migration) if ova are ingested. *Echinococcus granulosus* (dog tapeworm) does not cause human intestinal infection, but causes hydatid disease (which is analogous to cysticercosis) following ingestion of ova and subsequent larval migration.

Intestinal tapeworm

Humans acquire tapeworm by eating undercooked beef infected with the larval stage of *T. saginata*, undercooked pork containing the larval stage of *T. solium* or *T. asiatica*, or undercooked freshwater fish containing larvae of *D. latum*. Usually, only one adult tapeworm is present in the gut but up to ten have been reported. The ova of all

13.69 Diseases caused by flukes in the bile duct

Prevention	Cook fish	Cook fish	Avoid contaminated watercress
Treatment	Praziquantel 25 mg/kg 3 times daily for 2 days	As for *C. sinensis* but for 1 day only	Triclabendazole 10 mg/kg single dose; repeat treatment may be required*

*In the UK, available from the Hospital for Tropical Diseases, London.

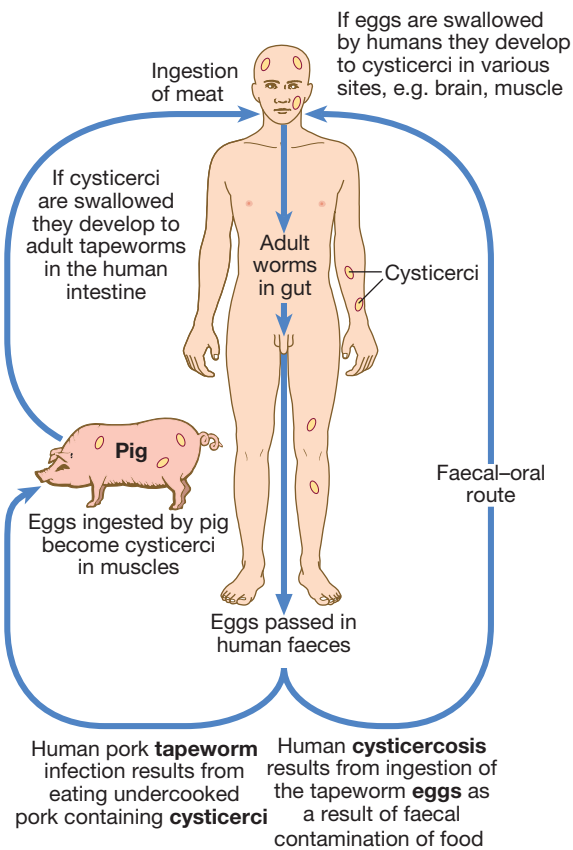

Fig. 13.55 Cysticercosis. Life cycle of *Taenia solium*.

the three *Taenia* are indistinguishable microscopically. However, examination of scolex and proglottides can differentiate: *T. solium* has a rostellum and two rows of hooklets on the scolex, and discharges multiple proglottides (3–5) attached together with lower degrees of uterine branching (approximately 10); *T. saginata* has only four suckers in its scolex, and discharges single proglottids with greater uterine branching (up to 30); *T. asiatica* has a rostellum without hooks on its scolex, and is difficult to differentiate from *T. saginata*, except that there are fewer uterine branches (16–21).

Taenia saginata

Infection with *T. saginata* occurs in all parts of the world. The adult worm may be several metres long and produces little or no intestinal upset in human beings, but knowledge of its presence, by noting segments in the faeces or on underclothing, may distress the patient. Ova may be found in the stool. Praziquantel is the drug of choice; niclosamide or nitazoxanide is an alternative. Prevention depends on efficient meat inspection and the thorough cooking of beef.

Taenia solium

T. solium, the pork tapeworm, is common in central Europe, South Africa, South America and parts of Asia. It is not as large as *T. saginata*. The adult worm is found only in humans following the eating of undercooked pork containing cysticerci. Intestinal infection is treated with praziquantel (5–10 mg/kg) or niclosamide (2 g), both as a single dose, or alternatively with nitazoxanide (500 mg twice daily for 3 days). These are followed by a mild laxative (after 1–2 hours) to prevent retrograde intestinal autoinfection. Cooking pork well prevents intestinal infection. Great care must be taken while attending a patient harbouring an adult worm to avoid ingestion of ova or segments.

Taenia asiatica

T. asiatica is a newly recognised species of *Taenia*, restricted to Asia. It is acquired by eating uncooked meat or viscera of pigs. Clinical features and treatment are similar to those of *T. saginata*.

Cysticercosis

Human cysticercosis is acquired by ingesting *T. solium* tapeworm ova, from either contaminated fingers or food (see Fig. 13.55). The larvae are liberated from eggs in the stomach, penetrate the intestinal mucosa and are carried to many parts of the body, where they develop and form cysticerci, 0.5–1 cm cysts that contain the head of a young worm. They do not grow further or migrate. Common locations are the subcutaneous tissue, skeletal muscles and brain.

Clinical features

When superficially placed, cysts can be palpated under the skin or mucosa as pea-like ovoid bodies. Here they cause few or no symptoms, and will eventually die and become calcified.

Heavy brain infections, especially in children, may cause features of encephalitis. More commonly, however, cerebral signs do not occur until the larvae die, 5–20 years later. Epilepsy, personality changes, staggering gait or signs of hydrocephalus are the most common features.

Investigations

Calcified cysts in muscles can be recognised radiologically. In the brain, however, less calcification takes place and larvae are only occasionally visible by plain X-ray; usually CT or MRI will show them. Epileptic fits starting in adult life suggest the possibility of cysticercosis if the patient has lived in or travelled to an endemic area. The subcutaneous tissue should be palpated and any nodule excised for histology. Radiological examination of the skeletal muscles may be helpful. Antibody detection is available for serodiagnosis.

Management and prevention

Albendazole, 15 mg/kg daily for a minimum of 8 days, has now become the drug of choice for parenchymal neurocysticercosis. Praziquantel is another option, 50 mg/kg in three divided doses daily for 10 days. Prednisolone, 10 mg 3 times daily, is also given for 14 days, starting 1 day before the albendazole or praziquantel. In addition, anti-epileptic drugs should be given until the reaction in the brain has subsided. Operative intervention is indicated for hydrocephalus. Studies from India and Peru suggest that most small, solitary cerebral cysts will resolve without treatment.

Echinococcus granulosus (*Taenia echinococcus*) and hydatid disease

Dogs are the definitive hosts of the tiny tapeworm *E. granulosus*. The larval stage, a hydatid cyst, normally occurs in sheep, cattle, camels and other animals that are infected from contaminated pastures or water. By handling a dog or drinking contaminated water, humans may ingest eggs (Fig. 13.56). The embryo is liberated from the ovum in the small intestine and gains access to the blood stream and thus to the liver. The resultant cyst grows very slowly, sometimes intermittently. It is composed of an enveloping fibrous pericyst, laminated hyaline membrane (ectocyst) and inner germinal layers (endocyst) which gives rise to daughter cysts, or germinating cystic brood capsule in which larvae (protoscolices) develop. Over time, some cysts may calcify and become non-viable. The disease is common in the Middle East, North and East Africa, Australia and Argentina. Foci of infection persist in the UK in rural Wales and Scotland. *E. multilocularis*, which has a cycle between foxes and voles, causes a similar but more severe

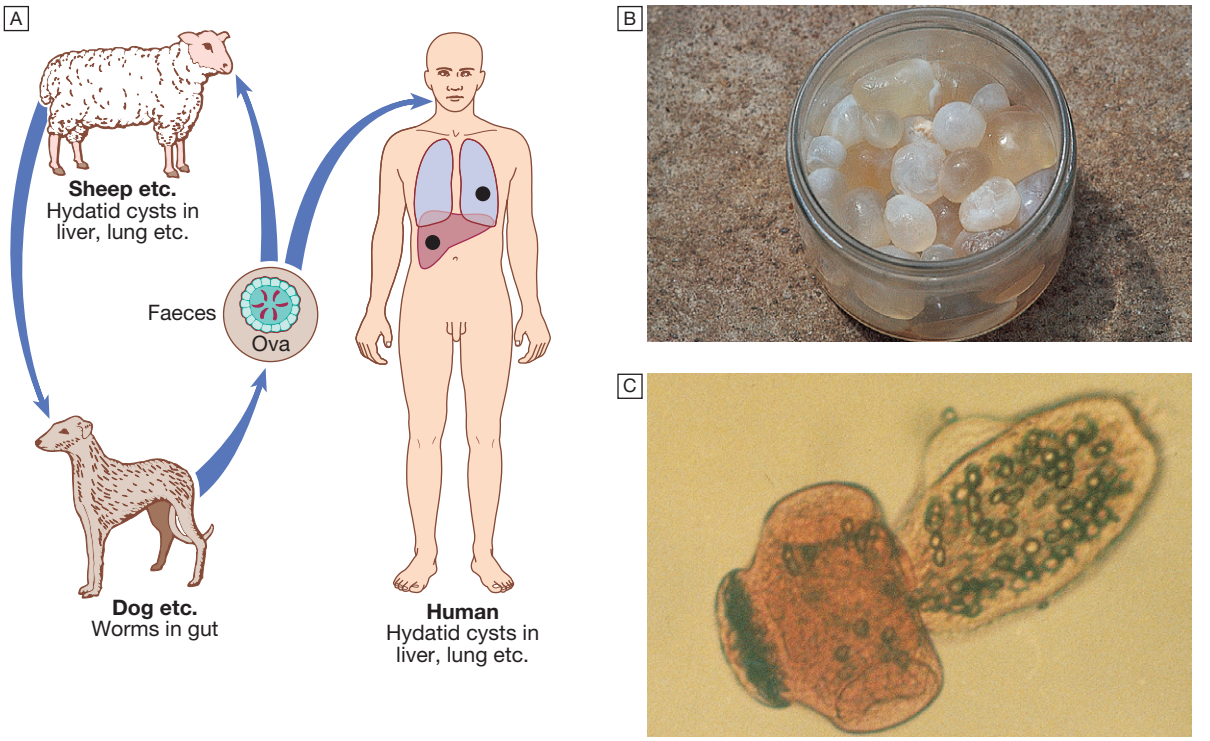

Fig. 13.56 Hydatid disease. A Life cycle of *Echinococcus granulosus*. B Daughter cysts removed at surgery. C Within the daughter cysts are the protoscolices.

infection, 'alveolar hydatid disease', which invades the liver like cancer.

Clinical features

A hydatid cyst is typically acquired in childhood and may, after growing for some years, cause pressure symptoms. These vary, depending on the organ or tissue involved. In nearly 75% of patients with hydatid disease, the right lobe of the liver is invaded and contains a single cyst (p. 956). In others, a cyst may be found in lung, bone, brain or elsewhere.

Investigations

The diagnosis depends on the clinical, radiological and ultrasound findings in a patient who has lived in close contact with dogs in an endemic area. Complement fixation and ELISA are positive in 70–90% of patients.

Management and prevention

Hydatid cysts should be excised wherever possible. Great care is taken to avoid spillage and cavities are sterilised with 0.5% silver nitrate or 2.7% sodium chloride. Albendazole (400 mg twice daily for 3 months) should also be used. The drug is now often combined with PAIR (percutaneous puncture, aspiration, injection of scolicidal agent and re-aspiration) to good effect. Praziquantel (20 mg/kg twice daily for 14 days) also kills protoscolices perioperatively.

Prevention is difficult in situations where there is a close association with dogs and sheep. Personal hygiene, satisfactory disposal of carcasses, meat inspection and deworming of dogs can greatly reduce the prevalence of disease.

Other tapeworms

There are many other cestodes whose adult or larval stages may infect humans. Sparganosis is a condition in which an immature worm develops in humans, usually subcutaneously, as a result of eating or applying to the skin the secondary or tertiary intermediate host.

ECTOPARASITES

Ectoparasites only interact with the outermost surfaces of the host; see also page 1280.

Jiggers (tungiasis)

This is widespread in tropical America and Africa, and is caused by the sand flea *Tunga penetrans*. The pregnant flea burrows into the skin around toes and produces large numbers of eggs. The burrows are intensely irritating and the whole inflammatory nodule should be removed with a sterile needle. Secondary infection of tunga lesions is common.

Myiasis

Myiasis is due to skin infestation with larvae of the South American botfly, *Dermatobia hominis*, or the African Tumbu fly, *Cordylobia anthropophaga*. The larvae develop in a subcutaneous space with a central sinus. This orifice is the air source for the larvae, and periodically the larval respiratory spiracles protrude through the sinus. Patients with myiasis feel movement within the larval burrow and can experience intermittent sharp, lancinating pains. Myiasis is diagnosed clinically and should be suspected with any furuncular lesion accompanied by pain and a crawling sensation in the skin. The larva may be suffocated by blocking the respiratory orifice with petroleum jelly and gently removing it with tweezers. Secondary infection of myiasis is remarkably infrequent and rapid healing follows removal of intact larvae.

FUNGAL INFECTIONS

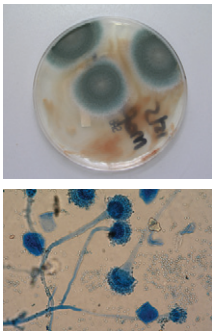
Fungal infections, or mycoses, are classified as superficial, subcutaneous or systemic (deep), depending on the degree of invasion of the host. They are also classified by the kind of fungus that causes the infection, which may be a filamentous fungus (mould) or a yeast, or may vary between these two forms, depending on the environmental conditions (dimorphic fungi; Fig. 13.57).

Superficial mycoses

Superficial cutaneous fungal infections caused by dermatophyte fungi are described in Chapter 28.

Candidiasis (thrush)

Superficial candidiasis is caused by *Candida* spp., mainly *C. albicans*. Manifestations include oropharyngeal (pp. 864 and 399) and vaginal candidiasis ('thrush'), intertrigo and chronic paronychia. Superficial candidiasis often follows antibiotic therapy. Intertrigo is characterised by inflammation in skin folds with surrounding 'satellite lesions'. Chronic paronychia is associated with frequent wetting of the hands. Superficial candidiasis is treated mainly with topical azoles (p. 159), oral azoles being reserved for refractory or recurrent disease. Severe oropharyngeal and oesophageal candidiasis is a consequence of CD4+ T lymphocyte depletion/dysfunction, as in HIV infection (p. 399). Recurrent vaginal or penile candidiasis may be a manifestation of diabetes mellitus. Rarely, mutations in the autoimmune regulator gene, *AIRE*, cause a syndrome of chronic mucocutaneous candidiasis (p. 796).

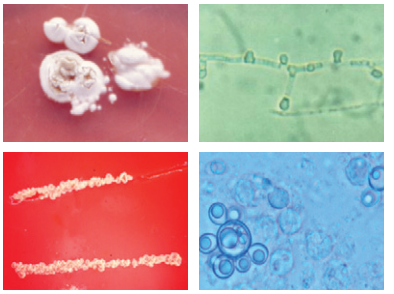


Subcutaneous mycoses

Chromoblastomycosis

Chromoblastomycosis is a predominantly tropical or subtropical fungal disease caused by environmental dematiaceous (dark-pigmented) fungi, most commonly *Fonsecaea pedrosoi*. Other causes include *F. compacta, Cladophialophora carrionii* and *Phialophora verrucosa*. The disease is a cutaneous/subcutaneous mycosis acquired by traumatic inoculation. Consequently, the most commonly affected areas are the foot, ankle and lower leg. Lesions may start several months after the initial injury, and medical attention is often sought several years later. The initial lesion is a papule. Further papules develop, and coalesce to form irregular plaques. Nodular lesions may produce a characteristic 'cauliflower' appearance.

Diagnosis is by histopathological examination of infected material, which shows dematiaceous, rounded, thick-walled 'sclerotic bodies' with septa at right angles



Filamentous fungi (moulds)

Characterised by the production of elongated, cylindrical, often septate cells (hyphae) and conidia (spores)

Examples:
- *Aspergillus* spp. (*A. fumigatus* shown here)
- *Fusarium* spp.
- Dermatophyte fungi (*Tricophyton* spp., *Microsporum* spp. etc.)
- Mucorales

Dimorphic fungi

Exist in filamentous (top) or yeast (bottom) form, depending on environmental conditions

Examples:
- *Histoplasma capsulatum*, *Coccidioides immitis*, *Paracoccidioides brasiliensis* (shown here), *Blastomyces dermatidis*
- *Sporothrix schenkii*
- *Penicillium marneffei*
- *Malassezia* spp.

Yeasts

Characterised by the production of oval or round cells, which reproduce by binary fission (budding)

Examples:
- *Candida* spp.*
- *Cryptococcus* spp. *(C. neoformans* shown here)

Fig. 13.57 Classification of medically important fungi. Fungal classification is based on simple morphological characteristics. *Pneumocystis jirovecii* (*carinii*) is morphologically distinct from other fungi and does not fit into this classification. *Although *Candida albicans* exists in a number of forms, including filamentous (hyphae and pseudohyphae), it is generally encountered in its yeast form, so is classified in this category.

to each other. The aetiological agent is confirmed by culture. Many therapeutic approaches have been explored, including antifungal agents, cryosurgery and surgical excision, alone or in combination, but the optimal therapy is unknown. Of the antifungal agents, itraconazole and terbinafine are considered to be the most effective. However, posaconazole has also been used with a good outcome.

Mycetoma

Mycetoma is a chronic suppurative infection of the deep soft tissues and bones, most commonly of the limbs but also of the abdominal or chest wall or head. It is caused by either aerobic or anaerobic branching Gram-positive bacilli, *Actinomycetales* (actinomycetoma – 60%, p. 135), or by true fungi, Eumycetes (eumycetoma – 40%). Many fungi cause eumycetomas, the most common being *Madurella mycetomatis*, *M. grisea*, *Leptosphaeria senegalensis* and *Scedosporium apiospermum*. Actinomycetomas are caused by *Actinomadura*, *Nocardia* and *Streptomyces* spp. Both groups produce characteristically coloured grains, the colour depending on the organism (black grains – eumycetoma, red and yellow grains – actinomycetoma, white grains – either). The disease occurs mostly in the tropics and subtropics.

Clinical features

The disease is acquired by inoculation (e.g. from a thorn) and most commonly affects the foot (Madura foot). Mycetoma begins as a painless swelling at the implantation site, which becomes chronic and progressive, grows and spreads steadily within the soft tissues, eventually extending into bone. Nodules develop under the epidermis and these rupture, revealing sinuses through which grains (fungal colonies) may be discharged. Sinuses heal with scarring, while fresh sinuses appear elsewhere. Deeper tissue invasion and bone involvement are less rapid and extensive in eumycetoma than actinomycetoma. There is little pain and usually no fever or lymphadenopathy, but there is progressive disability.

Investigations

Diagnosis is confirmed by demonstration of fungal grains in pus, and/or histopathological examination of tissue. Culture is necessary for species identification and susceptibility testing. Serological tests are not available.

Management

Eumycetoma is usually treated with a combination of surgery and antifungal therapy. Antifungal susceptibility testing, if available, is recommended, although clinical outcome does not necessarily correspond to in vitro test results. Itraconazole and ketoconazole (both 200–400 mg/day) are used most commonly. Success has also been reported with terbinafine monotherapy, and refractory cases have responded to both voriconazole and posaconazole. Amphotericin B is not generally considered effective. Therapy is continued for 6–12 months or longer. In extreme cases, amputation may be required. Management of actinomycetoma is described on page 341.

Phaeohyphomycosis

Phaeohyphomycoses are a heterogenous group of fungal diseases caused by a large number (more than 70) of dematiaceous fungi. In phaeohyphomycosis, the tissue form of the fungus is predominantly mycelial (filamentous), as opposed to eumycetoma (grain) or chromoblastomycosis (sclerotic body). Disease may be superficial,

subcutaneous or deep. The most serious manifestation is cerebral phaeohyphomycosis, which presents with a ring-enhancing, space-occupying cerebral lesion. Optimal therapy for this condition has not been established, but treatment usually consists of neurosurgical intervention and antifungal (usually triazole) therapy. Causative agents are *Cladophialophora bantiana*, *Fonsecaea* spp. and *Rhinocladiella mackenziei*, which occurs in the Middle East and is usually fatal.

Sporotrichosis

Sporotrichosis is caused by *Sporothrix schenckii*, a dimorphic fungal saprophyte of plants in tropical and subtropical regions. Disease is caused by dermal inoculation of the fungus, usually from a thorn (occasionally from a cat scratch). In fixed cutaneous sporotrichosis, a subcutaneous nodule develops at the site of infection and subsequently ulcerates, with a purulent discharge. The disease may then spread along the cutaneous lymphatic channels, resulting in multiple cutaneous nodules along their route, which ulcerate and discharge (lymphocutaneous sporotrichosis). Rarer forms of disease are seen: for example, in patients with cutaneous disease presenting with arthritis. Later, draining sinuses may form. Pulmonary sporotrichosis occurs as a result of inhalation of the conidia, and manifests itself as chronic cavitary fibronodular disease with haemoptysis and constitutional symptoms. Disseminated disease may occur, especially in patients with HIV.

Investigations

Typical yeast forms detected on histology of the biopsy confirm the diagnosis but are rarely seen; the fungus can be grown from the specimen in culture. A latex agglutination test is available to detect *S. schenkii* antibodies in serum.

Management

Cutaneous and lymphocutaneous disease is treated with oral itraconazole (200–400 mg daily, prescribed as the oral solution, which has better bio-availability than the capsule formulation) for 3–6 months. Alternative agents include a saturated solution of potassium iodide (SSKI, given orally), initiated with 5 drops and increased to 40–50 drops 3 times daily, or terbinafine (500 mg twice daily). Localised hyperthermia may be used in pregnancy (to avoid azole use). Osteoarticular disease requires a longer course of therapy (at least 12 months). Severe or life-threatening disease is treated with amphotericin B (lipid formulation preferred).

Systemic mycoses

Aspergillosis

Aspergillosis is an opportunistic systemic mycosis, which affects predominantly the respiratory tract. It is described on page 697.

Candidiasis

Systemic candidiasis is an opportunistic mycosis caused by *Candida* spp. The most common cause is C. *albicans*. Other agents include *C. dubliniensis*, *C. glabrata*, *C. krusei*, *C. parapsilosis* and *C. tropicalis*. Species distribution varies geographically. *Candida* species identification often enables prediction of susceptibility to fluconazole: *C. krusei* is universally resistant, many *C. glabrata* isolates have reduced susceptibility or are resistant, and other species are mostly susceptible. Candidiasis is usually an endogenous disease that originates from oropharyngeal, genitourinary or skin colonisation, although nosocomial spread has been reported.

Syndromes of systemic candidiasis

Acute disseminated candidiasis

This usually presents as candidaemia (isolation of *Candida* spp. from the blood). The main predisposing factor is the presence of a central venous catheter. Other major factors include recent abdominal surgery, total parenteral nutrition (TPN), recent antibiotic therapy and localised *Candida* colonisation. Up to 40% of cases will have ophthalmic involvement, with characteristic retinal 'cotton wool' exudates. As this is a sight-threatening condition, candidaemic patients should be assessed by detailed ophthalmoscopy. Skin lesions (non-tender pink/red nodules) may be seen. Although predominantly a disease of intensive care and surgical patients, acute disseminated candidiasis and/or *Candida* endophthalmitis is seen occasionally in injection drug-users, thought to be due to candidal contamination of citric acid or lemon juice used to dissolve heroin.

Chronic disseminated candidiasis (hepatosplenic candidiasis)

In this condition, a neutropenic patient has a persistent fever, despite antibacterial therapy. The fever persists, even though there is neutrophil recovery, and is associated with the development of abdominal pain, raised alkaline phosphatase and multiple lesions in abdominal organs (e.g. liver, spleen and/or kidneys) on radiological imaging. Chronic disseminated candidiasis is a form of immune reconstitution syndrome (p. 138) in patients recovering from neutropenia and usually lasts for several months, despite appropriate therapy.

Other manifestations

Renal tract candidiasis, osteomyelitis, septic arthritis, peritonitis, meningitis and endocarditis are all well recognised, and are usually sequelae of acute disseminated disease. Diagnosis and treatment of these conditions require specialist mycological advice.

Management

Blood cultures positive for *Candida* spp. must never be ignored. Acute disseminated candidiasis is treated with antifungal therapy, removal of any in-dwelling central venous catheter (whether known to be the source of infection or not) and removal of any known source. Current evidence suggests that candidaemia should be treated initially with an echinocandin (p. 160), with subsequent adjustment (usually to IV or oral fluconazole) guided by clinical response, species identification and susceptibility testing. Treatment should continue for a minimum of 14 days. Other appropriate therapies include voriconazole and amphotericin B formulations.

Chronic disseminated candidiasis requires prolonged treatment over several months with fluconazole or other agents, depending on species and clinical response. The duration of the condition may be reduced by adjuvant therapy with systemic corticosteroids.

Cryptococcosis

Cryptococcosis is a systemic mycosis caused by two environmental yeast species, *Cr. neoformans* and *Cr. gattii*. *Cr. neoformans* is distributed worldwide and is primarily an opportunistic pathogen, most commonly associated with HIV infection. *Cr. gattii* is a primary pathogen with a widespread distribution that includes Australasia, Africa, Canada (Vancouver Island) and the north-western USA.

Cryptococcosis is acquired by inhalation of yeasts. These may disseminate to any organ, most commonly the CNS and skin. The manifestations of *Cr. neoformans* are most severe in immunocompromised individuals. Conversely, *Cr. gattii* causes severe disease most often in immunocompetent hosts. Disseminated cryptococcosis (sepsis with cryptococci present in the blood stream or at multiple sites) is largely restricted to immunocompromised patients. CNS manifestations of cryptococcosis include meningitis (p. 403) and cryptococcoma (Fig. 13.58), the latter more likely with *Cr. gattii* infection. Manifestations of pulmonary cryptococcosis range from severe pneumonia (in immunocompromised patients) to asymptomatic disease with single or multiple pulmonary nodules, sometimes exhibiting cavitation (in immunocompetent patients). Cryptococcal nodules may mimic other causes of lung pathology, such as tuberculosis or malignancy, and diagnosis is often made by histopathology and/or culture.

Treatment of severe cryptococcosis is the same as for cryptococcal meningitis (p. 403). Mild pulmonary disease is usually treated with fluconazole, although, for asymptomatic nodules, resection of the lesions is likely to be sufficient. Relevant guidelines (e.g. www.idsociety.org) should be consulted.

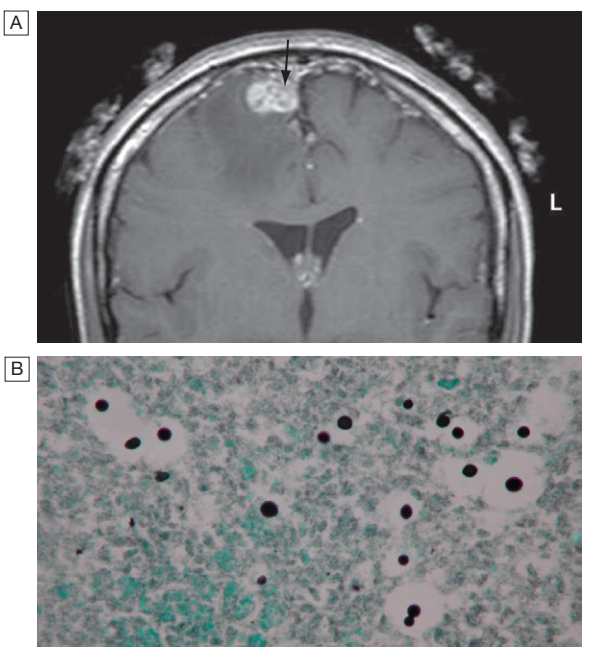


Fig. 13.58 Cryptococcal disease. A 23-year-old HIV-positive male developed headache and left-sided weakness. **A** MRI scan of the brain showed a space-occupying lesion (arrow) with surrounding oedema. **B** Histopathological examination of the lesion stained with Grocott's silver stain showed encapsulated yeasts. *Cryptococcus neoformans* was cultured.

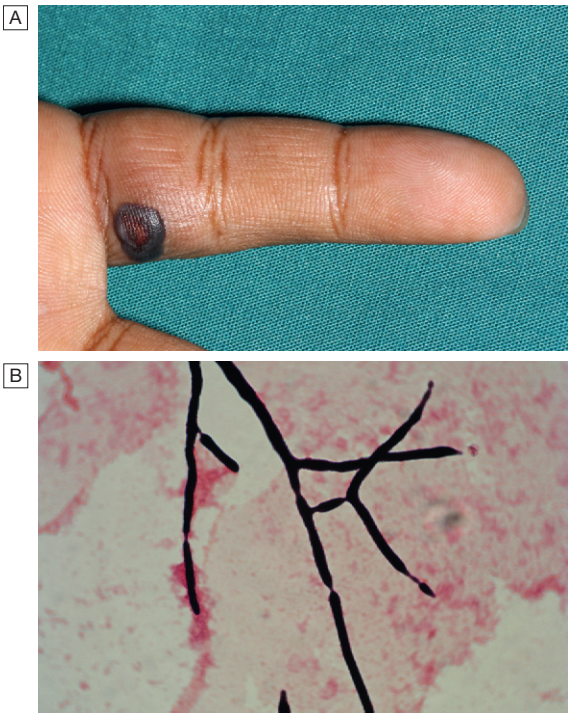

Fig. 13.59 *Fusarium* infection. A patient presented with fever and skin nodules after developing neutropenia secondary to haematopoietic stem cell transplantation and chemotherapy for relapsed leukaemia. *Fusarium solani* was cultured from skin lesions and blood cultures. **A** Tender, erythematous papules/nodules on upper arm. **B** Gram stain of *Fusarium* in blood culture medium.

Fusariosis

Fusarium spp. cause disseminated disease in patients with profound or prolonged neutropenia. The disease presents with antibiotic-resistant fever and evidence of dissemination (e.g. skin nodules, endophthalmitis, septic arthritis, pulmonary disease; Fig. 13.59). In contrast to *Aspergillus* spp., *Fusarium* spp. is often recovered from blood cultures. Treatment is challenging because of resistance to several antifungal agents. Voriconazole, posaconazole and lipid-formulated amphotericin B are the most commonly used antifungal agents.

Mucormycosis

Mucormycosis is a severe but uncommon opportunistic systemic mycosis caused by a number of 'mucoraceous' moulds, most commonly *Lichtheimia* (formerly *Absidia*) spp., *Rhizomucor* spp., *Mucor* spp. and *Rhizopus* spp. Disease patterns include rhinocerebral/craniofacial, pulmonary, cutaneous and systemic disease. All are characterised by the rapid development of severe tissue necrosis, which is almost always fatal if left untreated. The most common predisposing factors are profound immunosuppression from neutropenia and/or haematopoietic stem cell transplantation, uncontrolled diabetes mellitus, iron chelation therapy with desferrioxamine and severe burns.

Definitive diagnosis is by culture, but histopathological confirmation is required as the fungi may be environmental contaminants. Treatment requires a combination of antifungal therapy and surgical débridement, with correction of predisposing factor(s) if

possible. High-dose lipid-formulated amphotericin B is used most commonly. Posaconazole is active against many mucoraceous moulds in vitro and may be used as a second-line agent or as oral 'step-down' therapy.

Penicillium marneffei infection

P. marneffei is a thermally dimorphic pathogen (filamentous in environmental conditions and yeast at body temperature), which causes disease in South-east Asia, mainly in association with HIV infection (although immunocompetent patients may also be infected). Acquisition is most likely to be by inhalation of environmental spores, with primary lung infection followed by haematogenous dissemination. A generalised papular rash, which progresses to widespread necrosis and ulceration, is a characteristic feature. Skin lesions may resemble those of molluscum contagiosum. Diagnosis is by histopathology and/or culture of respiratory secretions, blood or any infected clinical material (e.g. skin lesions, bone marrow, biopsies). Recommended treatment is with an amphotericin B formulation followed by itraconazole (in severe infection), or with itraconazole alone.

Histoplasmosis

Histoplasmosis is a primary systemic mycosis caused by the dimorphic fungus *Histoplasma capsulatum*. *H. capsulatum* var. *capsulatum* is endemic to east-central USA (especially the Mississippi and Ohio river valleys), parts of Canada, Latin America, the Caribbean, East and South-east Asia, and Africa. It occurs sporadically in Australia and India, and is very rare in Europe. *H. capsulatum* var. *duboisii* is found in West Africa and Madagascar. Genetic analysis suggests that *H. capsulatum* may, in fact, be made up of several different species, and its taxonomy is under review.

Habitat

The primary reservoir of *H. capsulatum* is soil enriched by bird and bat droppings, in which the fungus remains viable for many years. Infection is by inhalation of dust from such soil. Natural infections are found in bats, which represent a secondary reservoir of infection (via bat faeces). Histoplasmosis is a specific hazard for explorers of caves and people who clear out bird (including chicken) roosts.

Pathology

The organism is inhaled in the form of conidia (spores) or hyphal fragments and transforms to the yeast phase during infection. Conidia or yeasts are phagocytosed by alveolar macrophages and neutrophils, and this may be followed by haematogenous dissemination to any organ. Subsequent development of a T-lymphocyte response brings the infection under control, resulting in a latent state in most exposed individuals.

Clinical features

Disease severity depends on the quantity of spores inhaled and the immune status of the host. In most cases, infection is asymptomatic. Pulmonary symptoms are the most common disease presentation, with fever, non-productive cough and an influenza-like illness. Erythema nodosum, myalgia and joint pain are common, and chest radiography may reveal a pneumonitis with hilar or mediastinal lymphadenopathy.

Patients with pre-existing lung disease, such as chronic obstructive pulmonary disease (COPD) or emphysema, may develop chronic pulmonary histoplasmosis. The predominant features of this condition, which may easily be mistaken for tuberculosis, are fever, cough, dyspnoea, weight loss and night sweats. Radiological findings include fibrosis, nodules, cavitation and hilar/mediastinal lymphadenopathy.

Disease caused by *H. capsulatum* var. *duboisii* presents more commonly with papulonodular and ulcerating lesions of the skin and underlying subcutaneous tissue and bone (sometimes referred to as 'African histoplasmosis'). Multiple lesions of the ribs are common and the bones of the limbs may be affected. Lung involvement is relatively rare. Radiological examination may show rounded foci of bone destruction, sometimes associated with abscess formation. Other disease patterns include a visceral form with liver and splenic invasion, and disseminated disease.

Acute disseminated histoplasmosis is seen in association with immunocompromise, including HIV infection. Features include fever, pancytopenia, hepatosplenomegaly, lymphadenopathy and often a papular skin eruption. Chronic disseminated disease presents with fever, anorexia and weight loss. Cutaneous and mucosal lesions, lymphadenopathy, hepatosplenomegaly and meningitis may also develop.

Investigations

In areas where the disease occurs, histoplasmosis should be suspected in every undiagnosed infection in which there are pulmonary signs, enlarged lymph nodes, hepatosplenomegaly or characteristic cutaneous/bony lesions. Radiological examination in long-standing cases may show calcified lesions in the lungs, spleen or other organs. In the more acute phases of the disease, single or multiple soft pulmonary shadows with enlarged tracheobronchial nodes are seen on chest X-ray.

Laboratory diagnosis is by direct detection (histopathology or antigen detection), culture and serology; although antigen detection is the most effective method, it is not widely available. Antibody is detected by complement fixation testing or immunodiffusion; the pattern of antibody production is complex and the results require specialist interpretation. *Histoplasma* antigen may be detectable in blood or urine. Culture is definitive but slow (up to 12 weeks). Histopathology may show characteristic intracellular yeasts. Diagnosis of subcutaneous or bony infection is mainly by histopathological examination and/or culture.

Management

Mild pulmonary disease does not require treatment. However, if prolonged, it may be treated with itraconazole. More severe pulmonary disease is treated with an amphotericin B formulation for 2 weeks, followed by itraconazole for 12 weeks, with methylprednisolone added for the first 2 weeks of therapy if there is hypoxia or ARDS. Chronic pulmonary histoplasmosis is treated with itraconazole (prescribed as the oral solution) for 12–24 months, and disseminated histoplasmosis with an amphotericin B formulation followed by itraconazole. Lipid formulations of amphotericin B are preferred, but their use is subject to availability. Treatment should be guided by current evidence-based guidelines (e.g.

Infectious Diseases Society of America practice guidelines: www.idsociety.org). In subcutaneous and bone infection, patterns of remission and relapse are more common than cure. A solitary bony lesion may require local surgical treatment only.

Coccidioidomycosis

This is a primary systemic mycosis caused by the dimorphic fungi *Coccidioides immitis* and *C. posadasii*, found in the south-western USA, and Central and South America. The disease is acquired by inhalation of conidia (arthrospores). In 60% of cases it is asymptomatic, but in the remainder it affects the lungs, lymph nodes and skin. Rarely (in approximately 0.5%), it may spread haematogenously to bones, adrenal glands, meninges and other organs.

Pulmonary coccidioidomycosis has two forms: primary and progressive. If symptomatic, primary coccidioidomycosis presents with cough, fever, chest pain, dyspnoea and (commonly) arthritis and a rash (erythema multiforme). Progressive disease presents with systemic upset (e.g. fever, weight loss, anorexia) and features of lobar pneumonia, and may resemble tuberculosis.

Coccidioides meningitis (which may be associated with CSF eosinophils) is the most severe disease manifestation; it is fatal if untreated, and requires life-long suppressive therapy with antifungal azoles.

Investigations and management

Diagnosis is by direct detection (histopathological examination of infected tissue), culture of infected tissue or fluids, or antibody detection. IgM may be detected after 1–3 weeks of disease by precipitin tests. IgG appears later and is detected with the complement fixation test. Change in IgG titre may be used to monitor clinical progress.

Treatment depends on specific disease manifestations, and ranges from regular clinical re-assessment without antifungal therapy (in mild pulmonary, asymptomatic cavitary or single nodular disease) to high-dose treatment with an antifungal azole, which may be continued indefinitely (e.g. in meningitis). Amphotericin B is used in diffuse pneumonia, disseminated disease and, intrathecally, in meningitis. Posaconazole has been used successfully in refractory disease.

Paracoccidioidomycosis

This is a primary systemic mycosis caused by inhalation of the dimorphic fungus *Paracoccidioides brasiliensis*, which is restricted to South America. The disease affects the lungs, mucous membranes (painful destructive ulceration in 50% of cases), skin, lymph nodes and adrenal glands (hypoadrenalism). Diagnosis is by microscopy and culture of lesions, and antibody detection. Oral itraconazole solution (200 mg/day) has demonstrated 98% efficacy and is currently the treatment of choice (mean duration 6 months). Ketoconazole, fluconazole and voriconazole have also been used, as have long (2–3-year) courses of sulphonamides. Amphotericin B may be used in severe or refractory disease, followed by an azole or sulphonamide.

Blastomycosis

Blastomyces dermatitidis is a dimorphic fungus endemic to restricted parts of North America, mainly around the Mississippi and Ohio rivers. Very occasionally, it is reported from Africa. The disease usually presents as a chronic pneumonia similar to pulmonary tuberculosis. Bones, skin and the genitourinary tract may also be affected. Diagnosis is by culture of the organism or identification of the characteristic yeast form in a clinical specimen. Antibody detection is rarely helpful. Treatment is with amphotericin B (severe disease) or itraconazole.

CLINICAL EXAMINATION IN HIV DISEASE

HIV clinical staging classifications

World Health Organization (WHO) clinical stage (used in low- and middle-income countries)	Centers for Disease Control (CDC) clinical categories (used in high-income countries)
Stage 1 Asymptomatic Persistent generalised lymphadenopathy	**Category A** Primary HIV infection Asymptomatic Persistent generalised lymphadenopathy
Stage 2 Unexplained moderate weight loss (< 10% of body weight) Recurrent upper respiratory tract infections Herpes zoster Angular cheilitis Recurrent oral ulceration Papular pruritic eruptions Seborrhoeic dermatitis Fungal nail infections	**Category B** Bacillary angiomatosis Candidiasis, oropharyngeal (thrush) Candidiasis, vulvovaginal; persistent, frequent or poorly responsive to therapy Cervical dysplasia (moderate or severe)/cervical carcinoma in situ Constitutional symptoms, such as fever (38.5°C) or diarrhoea lasting > 1 mth Oral hairy leucoplakia Herpes zoster, involving two distinct episodes or more than one dermatome Idiopathic thrombocytopenic purpura Listeriosis Pelvic inflammatory disease, particularly if complicated by tubo-ovarian abscess Peripheral neuropathy
Stage 3 Unexplained severe weight loss (> 10% of body weight) Unexplained chronic diarrhoea for > 1 mth Unexplained persistent fever (> 37.5°C for > 1 mth) Persistent oral candidiasis Oral hairy leucoplakia Pulmonary tuberculosis Severe bacterial infections Acute necrotising ulcerative stomatitis, gingivitis or periodontitis Unexplained anaemia (< 80 g/L (8 g/dL)), neutropenia (< 0.5×10^9/L) and/or chronic thrombocytopenia (< 50×10^9/L)	
Stage 4 Symptomatic HIV-associated nephropathy* Symptomatic HIV-associated cardiomyopathy* Leishmaniasis, atypical disseminated*	**Category C** Candidiasis of oesophagus, trachea, bronchi or lungs Cervical carcinoma – invasive Cryptococcosis – extrapulmonary Cryptosporidiosis, chronic (> 1 mth) Cytomegalovirus disease (outside liver, spleen and nodes) Herpes simplex chronic (> 1 mth) ulcers or visceral HIV encephalopathy HIV wasting syndrome Isosporiasis, chronic (> 1 mth) Kaposi's sarcoma Lymphoma (cerebral or B-cell non-Hodgkin) Mycobacterial infection, non-tuberculous, extrapulmonary or disseminated Mycosis – disseminated endemic (coccidiodomycosis or histoplasmosis) *Pneumocystis* pneumonia Pneumonia, recurrent bacterial Progressive multifocal leucoencephalopathy Toxoplasmosis – cerebral Tuberculosis – extrapulmonary (CDC includes pulmonary) Septicaemia, recurrent (including non-typhoidal *Salmonella*) (CDC only includes *Salmonella*)

*These conditions are in WHO stage 4 but not in CDC category C.

EPIDEMIOLOGY

The acquired immunodeficiency syndrome (AIDS) was first recognised in 1981, although the earliest documented case of HIV infection has been traced to a blood sample from the Democratic Republic of Congo in 1959. AIDS is caused by the human immunodeficiency virus (HIV), which progressively impairs cellular immunity. The origin of HIV is a zoonotic infection with simian immunodeficiency viruses (SIV) from African primates, probably first infecting local hunters. SIVs do not cause disease in their natural primate hosts. HIV-1 was transmitted from chimpanzees and HIV-2 from sooty mangabey monkeys. HIV-1 is the cause of the global HIV pandemic, while HIV-2, which causes a similar illness to HIV-1 but progresses more slowly and is less transmissible, is restricted mainly to western Africa. It has been estimated from mutation rates of SIV and HIV that both HIV-1 and HIV-2 first infected humans about 100 years ago.

There are three groups of HIV-1 representing three separate transmission events from chimpanzees: M ('major', worldwide distribution), O ('outlier') and N ('non-major and non-outlier'). Groups O and N are restricted to West Africa. Group M consists of nine subtypes: A–D, F–H, J and K (subtypes E and I were subsequently shown to be recombinants of other subtypes). Globally, subtype C (Africa and India) accounts for half of strains and appears to be more readily transmitted. Subtype B predominates in Western Europe, the Americas and Australia. In Europe, the prevalence of non-B subtypes is increasing because of migrants (predominantly from Africa). Subtypes A and D are associated with slower and faster disease progression respectively.

Global epidemic and regional patterns

In 2011 it was estimated that there were 34.2 million people living with HIV/AIDS, 2.5 million new infections and 1.7 million deaths (Fig. 14.1). Globally, new infections have declined by 20% over the last 10 years. Not all regions have experienced reductions in new infections and the dominant modes of transmission also vary regionally (Box 14.1). Expanding access to combination antiretroviral therapy (ART) has resulted in a 24% decline in global AIDS-related deaths since the peak in 2005. The improved life expectancy on ART has resulted in an increase in the number of people living with HIV. Despite these encouraging epidemiological data, HIV remains an important cause of death globally and has caused over 30 million deaths since the epidemic started. HIV has had a devastating effect in sub-Saharan Africa, particularly in southern African where average life expectancy of the general population fell to below 40 years.

Modes of transmission

HIV is transmitted by sexual contact, by exposure to blood (e.g. injection drug use, occupational exposure in

14.1 Regional HIV incidence and transmission, 2001–2011

Region	HIV incidence	Dominant transmission
Sub-Saharan Africa	Decreasing	Heterosexual
South, South-east and East Asia	Decreasing	IDU, heterosexual
Oceania	Decreasing	Heterosexual
Caribbean	Decreasing	Heterosexual
Latin America	Stable	MSM
North America	Stable	MSM
Western and Central Europe	Stable	MSM
Eastern Europe and Central Asia	Increasing	IDU
Middle East and North Africa	Increasing	IDU, MSM

(IDU = intravenous drug users; MSM = men who have sex with men)

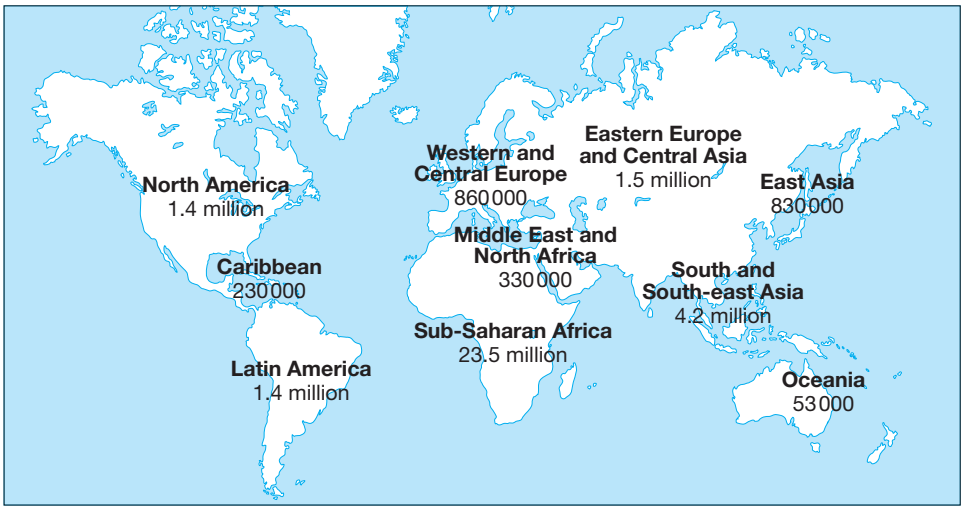

Fig. 14.1 Worldwide distribution of HIV infection in 2011.

health-care workers) and blood products, or to infants of HIV-infected mothers (who may be infected in utero, perinatally or via breastfeeding). Worldwide, the major route of transmission is heterosexual. The risk of contracting HIV after exposure to infected body fluid is dependent on the integrity of the exposed site, the type and volume of fluid, and the level of viraemia in the source person. The approximate transmission risk after exposure is given in Box 14.2. Factors that increase the risk of transmission are listed in Box 14.3.

A high proportion of patients with haemophilia in high-income countries had been infected through contaminated blood products by the time HIV antibody screening was adopted in 1985. Routine screening of blood and blood products for HIV infection using antibody and antigen tests (or polymerase chain reaction, PCR) has virtually eliminated this as a mode of transmission. However, the World Health Organization (WHO) estimates that, because of the lack of adequate screening facilities in resource-poor countries, 5–10% of blood transfusions globally are with HIV-infected blood.

14.2 Risk of HIV transmission after single exposure to an HIV-infected source

HIV exposure	Approximate risk
Sexual	
Vaginal intercourse: female to male	0.05%
Vaginal intercourse: male to female	0.1%
Anal intercourse: insertive	0.05%
Anal intercourse: receptive	0.5%
Oral intercourse: insertive	0.005%
Oral intercourse: receptive	0.01%
Blood exposure	
Blood transfusion	90%
Intravenous drug users sharing needles	0.67%
Percutaneous needle stick injury	0.3%
Mucous membrane splash	0.09%
Mother to child	
Vaginal delivery	15%
Breastfeeding (per month)	0.5%

14.3 Factors increasing the risk of transmission of HIV

Common to all transmission categories

- High viral load

Sexual transmission

- STIs, especially genital ulcers
- Cervical ectopy
- Rectal or vaginal lacerations
- Menstruation
- Uncircumcised male partner
- Depot intramuscular progesterone contraceptive use

Injection drug use transmission

- Sharing equipment
- Linked commercial sex
- Intravenous use
- Concomitant cocaine use
- Incarceration

Occupational transmission

- Deep injury
- Visible blood on device
- Needle was in a blood vessel

Vertical transmission

- Older gestational age
- Prolonged rupture of membranes

(STIs = sexually transmitted infections)

VIROLOGY AND IMMUNOLOGY

HIV is an enveloped ribonucleic acid (RNA) retrovirus from the lentivirus family. After mucosal exposure, HIV is transported to the lymph nodes via dendritic cells, where infection becomes established. This is followed by viraemia and dissemination to lymphoid organs, which are the main sites of viral replication.

Each mature virion has a lipid membrane lined by a matrix protein that is studded with glycoprotein (gp) 120 and gp41 spikes. The inner cone-shaped protein core (p24) houses two copies of the single-stranded RNA genome and viral enzymes. The HIV genome consists of three characteristic retroviral genes – *gag* (encodes a polyprotein that is processed into structural proteins, including p24), *pol* (codes for the enzymes reverse transcriptase, integrase and protease) and *env* (codes for envelope proteins gp120 and gp41) – as well as six regulatory genes (*vif*, *vpr*, *vpu*, *nef*, *tat* and *rev*).

HIV can only infect cells bearing the CD4 receptor; these are T-helper lymphocytes, monocyte–macrophages, dendritic cells, and microglial cells in the central nervous system (CNS). Entry into the cell commences with binding of gp120 to the CD4 receptor (stage 1, Fig. 14.2), which results in a conformational change in gp120 that permits binding to one of two chemokine co-receptors (CXCR4 or CCR5: stage 2). The chemokine co-receptor CCR5 is utilised during initial infection, but later on the virus may adapt to use CXCR4. Individuals who are homozygous for the CCR5 delta 32 mutation do not express CCR5 on CD4 cells and are immune to HIV infection. Chemokine receptor binding is followed by membrane fusion and cellular entry involving gp41 (stage 3). After penetrating the cell and uncoating, a deoxyribonucleic acid (DNA) copy is transcribed from the RNA genome by the reverse transcriptase (RT) enzyme (stage 4) that is carried by the infecting virion. Reverse transcription is an error-prone process and multiple mutations arise with ongoing replication, which results in considerable viral genetic heterogeneity. Viral DNA is transported into the nucleus and integrated within the host cell genome by the integrase enzyme (stage 5). Integrated virus is known as proviral DNA and persists for the life of the cell. Cells infected with proviral HIV DNA produce new virions only if they undergo cellular activation, resulting in the transcription of viral messenger RNA (mRNA) copies (stage 6), which are then translated into viral peptide chains (stage 7). The precursor polyproteins are then cleaved by the viral protease enzyme to form new viral structural proteins and enzymes (stage 8). These then migrate to the cell surface and are assembled using the host cellular apparatus to produce infectious viral particles, which bud from the cell surface, incorporating the host cell membrane into the viral envelope (stage 9). The mature virion then infects other CD4 cells and the process is repeated. CD4 lymphocytes that are replicating HIV have a very short

Stage	Steps in replication	Drug targets
1	Attachment to CD4 receptor	
2	Binding to co-receptor CCR5 or CXCR4	CCR5/CXCR4 receptor inhibitors
3	Fusion	Fusion inhibitors
4	Reverse transcription	Nucleoside and non-nucleoside reverse transcriptase inhibitors
5	Integration	Integrase inhibitors
6	Transcription	
7	Translation	
8	Cleavage of polypeptides and assembly	Protease inhibitors
9	Viral release	

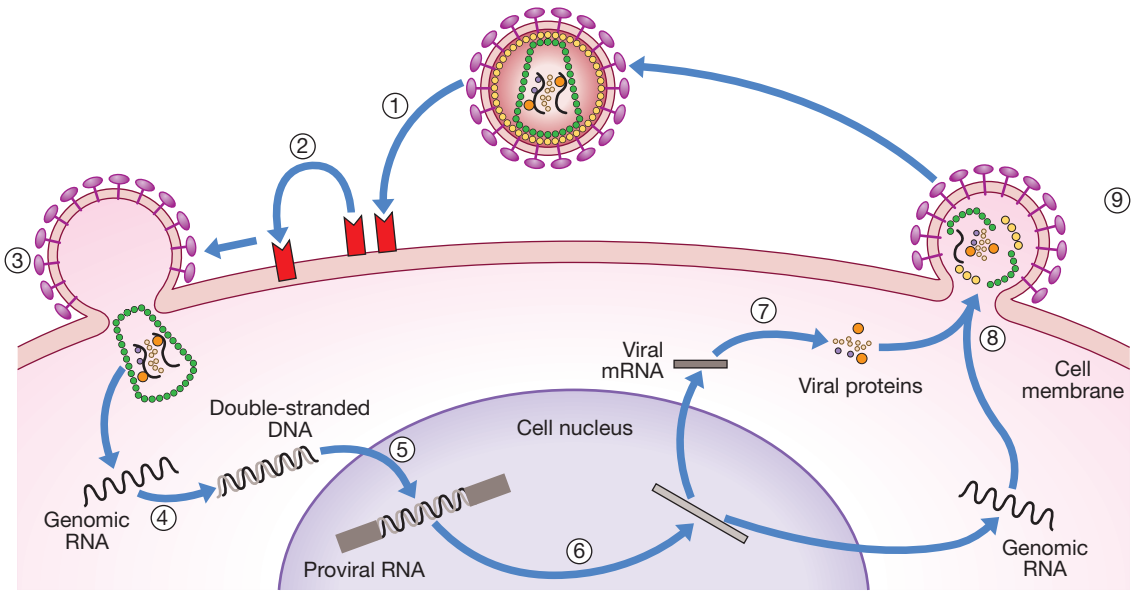

Fig. 14.2 Life cycle of HIV.

survival time of about 1 day. It has been estimated that in asymptomatic HIV-infected people, more than 10^{10} virions are produced and 10^9 CD4 lymphocytes destroyed each day.

A small percentage of T-helper lymphocytes enter a post-integration latent phase. Latently infected cells are important as sanctuary sites from antiretroviral drugs, which only act on replicating virus. Current ART is unable to eradicate HIV infection due to the persistence of proviral DNA in long-lived latent CD4 cells. Novel HIV eradication strategies are being devised to target latently infected cells.

The host immune response to HIV infection is both humoral, with the development of antibodies to a wide range of antigens, and cellular, with a dramatic expansion of HIV-specific CD8 cytotoxic T lymphocytes, resulting in a CD8 lymphocytosis and reversal of the usual CD4:CD8 ratio. CD8 cytotoxic T lymphocytes kill activated CD4 cells that are replicating HIV, but not latently infected CD4 cells. HIV evades destruction despite this vigorous immune response in part because the highly conserved regions of gp120 and gp41 that are necessary for viral attachment and entry are covered by highly variable protein loops that change over time as a result of mutations selected for by the immune response. The initial peak of viraemia in primary infection settles to a plateau phase of persistent chronic viraemia. With time, there is gradual attrition of the T-helper lymphocyte population and, as these cells are pivotal in orchestrating the immune response, the patient becomes susceptible to opportunistic diseases. The predominant opportunist infections in HIV-infected people are the consequences of impaired cell-mediated rather than antibody-mediated immunity (e.g. mycobacteria, herpesviruses). However, there is also a B lymphocyte defect with impaired antibody production to new antigens and dysregulated antibody production with a polyclonal increase in gamma globulins, resulting in an increased risk of infection with encapsulated bacteria, notably *Streptococcus pneumoniae*.

DIAGNOSIS AND INVESTIGATIONS

Diagnosing HIV infection

Globally, the trend is towards universal HIV testing, rather than testing patients at high risk or those with manifestations of HIV infection only. However, in the UK, testing is still targeted (Box 14.4). HIV is diagnosed by detecting host antibodies either by using rapid point-of-care tests or in the laboratory, where enzyme-linked immunosorbent assay (ELISA) tests are usually done. Most tests detect antibodies to both HIV-1 and HIV-2. A positive antibody test from two different immunoassays is sufficient to confirm infection. Western blot assays can also be used to confirm infection, but they are expensive

14.4 HIV testing in the UK

Settings where recommended to all

- Genitourinary medicine or sexual health clinics
- Antenatal services
- Termination of pregnancy services
- Drug dependency programmes
- Services for those with hepatitis B, hepatitis C, tuberculosis and lymphoma

Patients routinely offered and recommended testing

- All those presenting with a possible primary HIV infection or where HIV enters the differential diagnosis
- All with an STI
- All sexual partners of an HIV-positive individual
- All MSM and female sexual contacts of MSM
- All with a history of injecting drug use
- All from a country of high HIV prevalence
- All who report sexual contact abroad or in the UK with individuals from a country of high HIV prevalence (> 1%)

Settings where testing should be considered, in areas where HIV prevalence in the local population is > 2 in 1000 population

- All registering with a general practice
- All general medical admissions

Groups in whom testing is routinely performed

- Blood donors
- Dialysis patients
- Organ transplant donors and recipients

14.5 How to carry out pre-test counselling

- Discuss meaning of positive and negative test results
- Realise importance of maintaining confidentiality
- Identify person to whom positive result could be disclosed
- Explore knowledge and explain natural history of HIV
- Discuss transmission and risk reduction
- Assess coping strategy
- Explain test procedure
- Obtain informed consent

and sometimes yield indeterminate results. Screening tests often include a test for p24 antigen in addition to antibodies, in order to detect patients with primary infection before the antibody response occurs. Nucleic acid amplification tests (usually PCR) to detect HIV-RNA are used to diagnose infections in infants of HIV-infected mothers, who carry maternal antibodies to HIV for up to 15 months irrespective of whether they are infected, and to diagnose primary infection before antibodies have developed. (PCR is more sensitive than p24 antigen detection, but p24 is more widely available.)

The purpose of HIV testing is not simply to identify infected individuals, but also to educate people about prevention and transmission of the virus. Counselling is essential both before HIV testing and after the result is obtained (Boxes 14.5 and 14.6). There are major advantages to using rapid point-of-care HIV tests in that pre- and post-test counselling can be done at the same visit. Counselling should always be given in the client's home language.

14.6 How to carry out post-test counselling

Test result negative

- Discuss transmission and need for behaviour modification
- Advise second test 3 mths after last exposure

Test result positive

- Explain meaning of result
- Organise medical follow-up
- Assess coping strategy
- Stress importance of disclosure
- Explain value of antiretroviral therapy
- Provide written information and useful Internet resources
- Discuss confidentiality issues
- Organise emotional and practical support (provide names/phone numbers)
- Facilitate notification of sexual partners

14.7 Baseline investigations

- CD4 count
- Viral load
- Hepatitis B surface antigen
- Hepatitis C antibody (injection drug users)
- Liver function tests
- Full blood count
- Urinalysis and serum creatinine
- Syphilis serology
- Cervical smear in women
- Serum cryptococcal antigen (if CD4 < 100)
- Tuberculin skin test
- STI screen

A number of baseline investigations should be done at the initial medical evaluation (Box 14.7). The extent of these investigations will depend on the resources available.

Viral load and CD4 counts

CD4 counts

CD4 lymphocyte counts are usually determined by flow cytometry, but cheaper methods have been developed for low-income countries. The CD4 count is the most clinically useful laboratory indicator of the degree of immune suppression and is used, together with clinical staging, in decisions to start ART and prophylaxis against opportunistic infections, and in the differential diagnosis of clinical problems.

The CD4 count varies by up to 20% from day to day and is also transiently reduced by intercurrent infections. Due to this variability, major therapeutic decisions should not be taken on the basis of a single count. This is particularly important when ART is being initiated in patients who do not fulfil the clinical criteria to start ART. The percentage of lymphocytes that are CD4+, rather than the absolute count, is routinely used in paediatrics, as the normal CD4 counts in infants and young children are much higher. In adults, the CD4 percentage is occasionally useful when evaluating significant reductions in an individual's CD4 count, which may be associated with transient lymphopenia due to intercurrent infection or pregnancy. In this case, the CD4 percentage will be unchanged.

The normal CD4 count is > 500 cells/mm^3. The rate of decline in CD4 count is highly variable. People with CD4 counts between 200 and 500 cells/mm^3 have a low risk of developing major opportunistic infections. Morbidity due to inflammatory dermatoses, herpes zoster, oral candidiasis, tuberculosis, bacterial pneumonia and HIV-related immune disorders (e.g. immune thrombocytopenia) becomes increasingly common as CD4 counts decline. Once the count is below 200 cells/mm^3, there is severe immune suppression and a high risk of AIDS-defining conditions. It is important to note that patients can be asymptomatic despite very low CD4 counts and that major opportunistic diseases occasionally present with high CD4 counts.

The CD4 count should be performed every 3–6 months in patients not yet eligible for ART and is usually done at similar intervals in patients on ART, together with measurement of the viral load.

Viral load

The level of viraemia is measured by quantitative PCR of HIV-RNA, known as the viral load. Determining the viral load is important for monitoring responses to ART (p. 407) and also has some prognostic value before starting ART. However, many low-income countries are unable to afford viral load measurements. People with high viral loads (e.g. > 100 000 copies/mL) experience more rapid declines in CD4 count, while those with low viral loads (< 1000 copies/mL) usually have slow or even no decline in CD4 counts. There is little point in repeated measurements of viral load before starting ART, as viral loads remain at a relatively stable plateau after primary infection (Fig. 14.3).

Transient increases in viral load occur with intercurrent infections and immunisations, so the test should be done at least 2 weeks afterwards. Viral load results vary because of assay variability and fluctuations within patients. Only changes in viral load of more than 0.5 $\log_{10}$ copies/mL are considered clinically significant. The same laboratory and viral load test manufacturer should be used for follow-up tests in individual patients if possible.

NATURAL HISTORY AND STAGING OF HIV

Clinical staging of patients should be done at the initial medical examination, as it provides prognostic information and is a key criterion for initiating ART and prophylaxis against opportunistic infections. Two clinical staging systems are used internationally (p. 389). In both systems, patients are staged according to the most severe manifestation and do not improve their classification. For example, a patient who is asymptomatic following a major opportunistic disease (AIDS) remains at stage 4 or category C of the WHO and CDC systems respectively, and never reverts to earlier stages. Finally, patients do not always progress steadily through all stages and may present with AIDS, having previously been asymptomatic.

Primary infection

Primary infection is symptomatic in more than 50% of cases, but the diagnosis is often missed. The incubation period is usually 2–4 weeks after exposure. The duration of symptoms is variable, but is seldom longer than 2 weeks. The clinical manifestations (Box 14.8) resemble a glandular fever-type illness, but the presence of maculo-papular rash or mucosal ulceration strongly suggests primary HIV infection rather than the other viral causes of glandular fever (p. 320). In infectious mononucleosis due to other viruses, rashes generally only occur if aminopenicillins are given. Atypical lymphocytosis occurs less frequently than in Epstein–Barr virus (EBV) infection. Transient lymphopenia, including CD4 lymphocytes, is found in most cases (see Fig. 14.3), which may result in opportunistic infections, notably oropharyngeal candidiasis. Major opportunistic infections like *Pneumocystis jirovecii* pneumonia (PJP) may rarely occur. Thrombocytopenia and moderate elevation of liver enzymes are commonly present. The differential diagnosis of primary HIV includes acute EBV, primary cytomegalovirus (CMV) infection, rubella, primary toxoplasmosis and secondary syphilis.

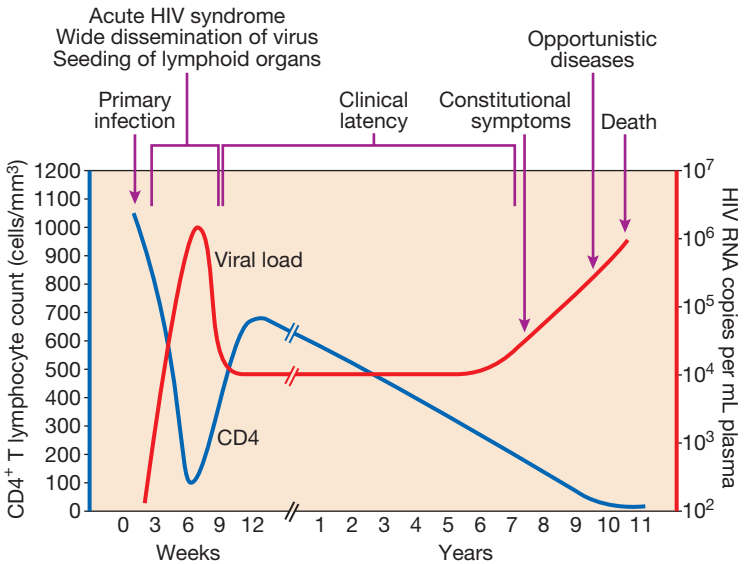

Fig. 14.3 Virological and immunological progression of untreated HIV infection.

14.8 Clinical features of primary infection

- Fever
- Maculo-papular rash
- Pharyngitis
- Lymphadenopathy
- Myalgia/arthralgia
- Diarrhoea
- Headache
- Oral and genital ulceration
- Meningo-encephalitis
- Bell's palsy

Early diagnosis is made by detecting HIV-RNA on PCR or p24 antigenaemia. The appearance of specific anti-HIV antibodies in serum (seroconversion) occurs 2–12 weeks after the development of symptoms. The window period during which antibody tests may be false-negative is prolonged when post-exposure prophylaxis has been used.

Asymptomatic infection

A prolonged period of clinical latency follows primary infection, during which infected individuals are asymptomatic. Persistent generalised lymphadenopathy with nodes typically < 2 cm diameter is a common finding. Eventually the lymph nodes regress, with destruction of node architecture as disease advances.

Viraemia peaks during primary infection and then drops as the immune response develops, to reach a plateau about 3 months later. The level of viraemia post-seroconversion is a predictor of the rate of decline in CD4 counts, which is highly variable and explained in part by genetic factors affecting the immune response. The median time from infection to the development of AIDS in adults is about 9 years (see Fig. 14.3). A small proportion of untreated HIV-infected people are long-term non-progressors with CD4 counts in the reference range for 10 years or more. Some long-term non-progressors have undetectable viral loads and are known as 'elite controllers'.

Minor HIV-associated disorders

A wide range of disorders indicating some impairment of cellular immunity occur in most patients before they develop AIDS (CDC category B or WHO stages 2 and 3). Careful examination of the mouth is important when patients are being followed up, as oral candidiasis and oral hairy leucoplakia are common and important conditions that require initiation of ART and prophylaxis against opportunistic infections, irrespective of the CD4 count.

Acquired immunodeficiency syndrome

AIDS is defined by the development of specified opportunistic infections, cancers and severe manifestations of HIV itself (p. 389). CDC category C is the most widely used definition of AIDS. WHO updated its classification more recently and added a few conditions of similar prognosis to its stage 4 disease. Box 14.9 outlines the correlation between CD4 count and HIV-related diseases.

14.9 CD4 count and risk of common HIV-associated diseases

< 500 cells/mm^3

- Tuberculosis
- Bacterial pneumonia
- Herpes zoster
- Oropharyngeal candidiasis
- Non-typhoid salmonellosis
- Kaposi's sarcoma
- Non-Hodgkin lymphoma
- HIV-associated idiopathic thrombocytopenic purpura

< 200 cells/mm^3

- *Pneumocystis jirovecii* pneumonia
- Chronic herpes simplex ulcers
- Oesophageal candidiasis
- *Isospora belli* diarrhoea
- HIV wasting syndrome
- HIV-associated dementia
- Peripheral neuropathy
- Endemic mycoses

< 100 cells/mm^3

- Cerebral toxoplasmosis
- Cryptococcal meningitis
- Cryptosporidiosis and microsporidiosis
- Primary CNS lymphoma
- Cytomegalovirus
- Disseminated *Mycobacterium avium* complex (MAC)
- Progressive multifocal leucoencephalopathy

PRESENTING PROBLEMS IN HIV INFECTION

HIV itself is associated with a wide variety of clinical manifestations, and opportunistic diseases add many more. All body systems can be affected by HIV. The CD4 count is useful in differential diagnosis (see Box 14.9): opportunistic diseases that may present at higher CD4 counts become increasingly common as CD4 counts decline, so the CD4 count helps to rule out certain disorders. For example, in a patient with a pulmonary infiltrate and a CD4 count of 350 cells/mm^3, pulmonary tuberculosis is a likely diagnosis and *Pneumocystis* infection is very unlikely, but if the patient's CD4 count is 50 cells/mm^3, both *Pneumocystis* and tuberculosis are likely.

Globally, tuberculosis is the most common cause of morbidity and mortality in HIV-infected patients. Tuberculosis should be considered in the differential diagnosis of most presenting problems in patients from communities where tuberculosis is common.

Lymphadenopathy

Persistent generalised lymphadenopathy due to HIV is described above under asymptomatic infection. Lymphadenopathy may also be due to malignancy (Kaposi's sarcoma or lymphoma) or infections, especially tuberculosis, which is an extremely common cause in low- and middle-income countries. Rapid enlargement of a node, asymmetric enlargement or lymphadenopathy associated with constitutional symptoms (even if the nodes are symmetrical) warrants further investigation. Tuberculous lymph nodes often undergo extensive caseous necrosis, causing them to become fluctuant, and inexperienced clinicians often inappropriately perform incision and drainage. Lymphoma typically presents with large nodes that are not fluctuant. Lymph node needle aspiration (using a wide-bore needle such as 19G) should be undertaken for microscopy. One slide should be air-dried and sent for staining for acid-fast bacilli, which has about a 70% yield in tuberculosis. The other slide should be fixed and sent for cytology. If caseous liquid is

aspirated, this should be sent for mycobacterial culture. If needle aspiration is unhelpful, or if lymphoma or Kaposi's sarcoma is suspected, excision biopsy should be performed.

Weight loss

Weight loss is a very common finding in advanced HIV infection. The HIV wasting syndrome is an AIDS-defining condition and is defined as weight loss of more than 10% of body weight, plus either unexplained chronic diarrhoea (lasting > 1 month) or chronic weakness and unexplained prolonged fever (lasting > 1 month). This is a diagnosis of exclusion. If the weight loss is rapid (more than 1 kg a month), then major opportunistic infections or cancers become more likely. Painful oral conditions and nausea from drugs contribute by limiting intake. Depression is very common and can cause significant weight loss. Measurement of C-reactive protein is helpful in the work-up of weight loss, as this is markedly raised with most opportunistic diseases but not with HIV itself. Erythrocyte sedimentation rate (ESR) is elevated by HIV infection and is therefore not useful. The presence of fever or diarrhoea is helpful in the differential diagnosis (Fig. 14.4).

Fever

Fever is a very common presenting feature. Common causes of prolonged fever with weight loss are listed in Figure 14.4. Non-typhoid *Salmonella* bacteraemia, which commonly presents with fever in low-income countries, presents without diarrhoea in about 50% of patients. Pyrexia of unknown origin (PUO) in HIV infection is defined as temperature over 38°C with no cause found after 4 weeks in outpatients or 3 days in inpatients, and initial investigations such as chest X-rays, urinalysis and blood cultures will have failed to identify the cause. HIV itself can present with prolonged fever, but this is a diagnosis of exclusion, as a treatable cause will be found in most patients. Abdominal imaging, preferably by computed tomography (CT), should be requested. Abdominal nodes (especially if they are hypodense in the centre) or splenic microabscesses strongly suggest tuberculosis. Mycobacterial (or 'lytic') blood cultures, which can also detect fungi, should be performed. Bone marrow aspirate and trephine biopsy are helpful if the full blood count shows cytopenias. Liver biopsy may be helpful if the liver enzymes are elevated, but is invasive and seldom necessary. Mycobacterial and fungal stains and cultures should be done on all biopsies. Chest X-rays should be repeated after about a week, as micronodular or interstitial infiltrates may have become apparent (see p. 401 for differential diagnosis).

Tuberculosis is by far the most common cause of PUO in low- and middle-income countries, and in these settings an early trial of empiric therapy is warranted after cultures have been sent. In high-income countries, disseminated *Mycobacterium avium* complex (MAC) infection is an important cause of PUO, often with diarrhoea and splenomegaly. Disseminated endemic mycoses (histoplasmosis, coccidiodomycosis and penicilliosis) present with PUO, often with papular skin eruptions. Skin biopsy for histology and fungal culture is often diagnostic.

Mucocutaneous disease

The skin and mouth must be carefully examined, as mucocutaneous manifestations are extremely common in HIV and many prognostically important conditions can be diagnosed by simple inspection. The differential diagnosis of dermatological conditions is simplified by categorising disorders according to the lesion type (Box 14.10). Some common dermatological diseases, notably psoriasis, are exacerbated by HIV. The risk of drug

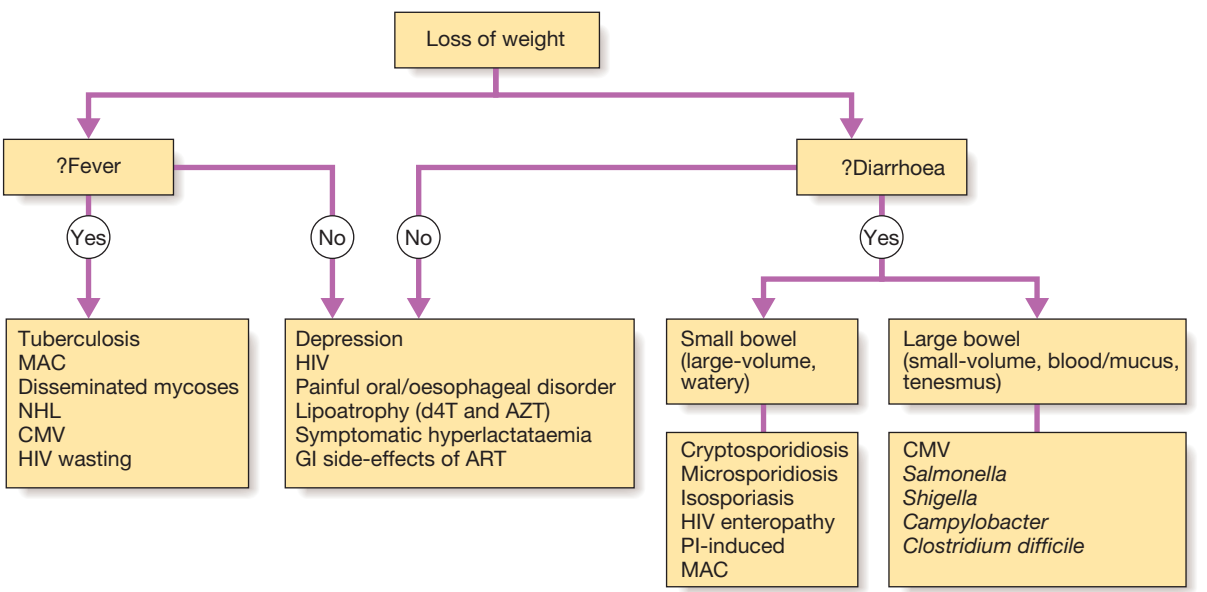

Fig. 14.4 Presentation and differential diagnosis of weight loss. (AZT = zidovudine; CMV = cytomegalovirus; d4T = stavudine; KS = Kaposi's sarcoma; MAC = *Mycobacterium avium* complex; NHL = non-Hodgkin lymphoma; PI = protease inhibitor)

14.10 Differential diagnosis of skin conditions by lesion type

Scaly rashes	
• Seborrhoeic dermatitis	• Dry skin/icthyosis
• Psoriasis* (exacerbated by HIV)	• Norwegian scabies*
• Tinea corporis*	• Drug rashes*
Pruritic papules	
• Pruritic papular eruption ('itchy red bump disease')	• Eosinophilic folliculitis
	• Scabies*
Papules and nodules (non-pruritic)	
• Molluscum contagiosum*	• Warts*
• Secondary syphilis	• Disseminated endemic mycoses (histoplasmosis, coccidiodomycosis and penicilliosis)
• Kaposi's sarcoma	
• Bacillary angiomatosis	
• Cryptococcosis	
Blisters	
• Herpes simplex	• Drug rashes (especially toxic epidermal necrolysis)
• Herpes zoster	
• Fixed drug eruptions	
Mucocutaneous ulcers	
• Ecthyma	• Histoplasmosis
• Herpes simplex	• Drug rashes (Stevens–Johnson syndrome)
• Aphthous ulcers (minor and major)	
Hyperpigmentation	
• Post-inflammatory (especially pruritic papular eruption)	• Zidovudine
	• Emtricitabine (palms and soles)

*See Chapter 28 for more information.

rashes is greatly increased in HIV-infected patients. Skin biopsy should be taken, and sent for histology and culture for mycobacteria and fungi in patients with unusual rashes or if there are constitutional symptoms coinciding with the development of the rash.

Seborrhoeic dermatitis

Seborrhoeic dermatitis is very common in HIV. The severity increases as the CD4 count falls. It presents as scaly red patches, typically in the nasolabial folds and in hairy areas. Fungal infections are thought to play a role in the pathogenesis of this condition. It responds well to a combined topical antifungal and steroid. Selenium sulphide shampoo is helpful for scalp involvement.

Herpes simplex infections

Recurrences of herpes simplex infection are very common and primarily affect the nasolabial and anogenital areas (Fig. 14.5). As immune suppression worsens, the ulcers take longer to heal and become more extensive. Ulcers that persist for more than 4 weeks are AIDS-defining. The diagnosis is clinical, but PCR of vesicle fluid or from ulcer swabs may be diagnostic with unusual presentations. Response to a course of aciclovir or a related drug is good, but relapses are common. Frequent relapses that persist despite ART should be treated with aciclovir 400 mg twice daily for 6–12 months.

Fig. 14.5 Severe mucocutaneous herpes simplex. Chronic anogenital or perioral ulcers are very common in advanced HIV infection.

Herpes zoster

This usually presents with a pathognomonic vesicular rash on an erythematous base in a dermatomal distribution (p. 318). The median CD4 count at the first episode of zoster is 350 cells/mm^3. In patients with advanced disease, the rash may be multidermatomal and recurrent episodes may occur. Disseminated zoster is rare. In HIV-infected patients, zoster is generally more extensive, has a longer duration, and there is a higher risk of developing post-herpetic neuralgia. High doses of aciclovir or its congeners should be given for all cases with active disease, irrespective of the time since the onset of the rash. Post-herpetic neuralgia is difficult to manage. Analgesic adjuvants, e.g. amitriptyline and pregabalin, should be commenced in all patients with prolonged pain. Topical capsaicin has modest efficacy.

Kaposi's sarcoma

Kaposi's sarcoma (KS) is a spindle-cell tumour of lympho-endothelial origin. All forms of KS are due to sexually transmitted human herpesvirus 8, also known as KS-associated herpesvirus. KS occurs in four patterns:

- classic KS: rare, indolent and restricted largely to elderly Mediterranean or Jewish men
- endemic KS: occurs in sub-Saharan Africa, is more aggressive, presents at earlier ages than classic KS, and affects men more than women
- KS in patients on immunosuppressant drugs: usually transplant recipients, who experience disseminated disease
- AIDS-associated KS.

In Africa, the male:female ratio of AIDS-associated KS is much lower than is seen with endemic KS, but men are still more affected than women despite the fact that the seroprevalence of human herpesvirus 8 is the same in both sexes.

AIDS-associated KS is always a multicentric disease. Early mucocutaneous lesions are macular and may be difficult to diagnose. Subsequently, lesions become papular or nodular, and may ulcerate. KS lesions typically have a red–purple colour (Fig. 14.6 and p. 388), but may become hyperpigmented, especially in dark-skinned patients. As the disease progresses, the skin

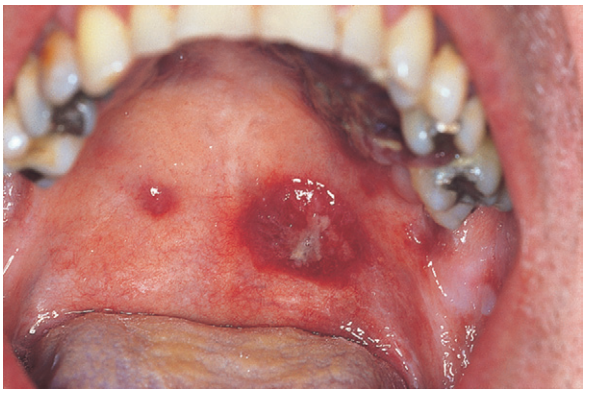

Fig. 14.6 Oral Kaposi's sarcoma. A full examination is important to detect disease that may affect the palate, gums, fauces or tongue.

lesions become more numerous and larger. Lymphoedema is common, as lymphatic vessels are infiltrated. KS also commonly spreads to lymph nodes and viscerally, especially to the lungs and gastrointestinal tract. Visceral disease occasionally occurs in the absence of mucocutaneous involvement. B symptoms of fever, night sweats and weight loss may occur.

KS may respond to ART. Chemotherapy should be reserved for those patients who fail to remit on ART, or given together with ART if there are poor prognostic features such as visceral involvement, oedema, ulcerated lesions and B symptoms.

Bacillary angiomatosis

Bacillary angiomatosis is a bacterial infection caused by *Bartonella henselae* or *B. quintana*. Skin lesions range from solitary superficial red–purple lesions resembling Kaposi's sarcoma or pyogenic granuloma, to multiple subcutaneous nodules or plaques. Lesions are painful and may bleed or ulcerate. The infection may become disseminated with fevers, lymphadenopathy and hepatosplenomegaly. Diagnosis is made by biopsy of a lesion and Warthin–Starry silver staining, which reveals aggregates of bacilli. Treatment with doxycycline or azithromycin is effective.

Papular pruritic eruption

Papular pruritic eruption ('itchy red bump disease') is an intensely itchy, symmetrical rash affecting the trunk and extremities. It thought to be due to an allergic reaction to insect bites. In sub-Saharan Africa, it is the most common skin manifestation of HIV. Post-inflammatory hyperpigmentation is common. Topical steroids, emollients and antihistamines are useful but response is variable. Measures to reduce insect bites are logical, but difficult to implement in low-income settings.

Drug rashes

Cutaneous hypersensitivity to drugs is said to occur 100 times more frequently in HIV infection. The most common type is an erythematous maculo-papular rash, which may be scaly. The drugs most commonly associated with rashes are sulphonamides and non-nucleoside reverse transcriptase inhibitors (NNRTIs – see below). Severe, life-threatening features of drug rashes include blistering (when this affects more than 30% of surface area it is known as toxic epidermal necrolysis), involvement of mucous membranes (Stevens–Johnson syndrome, pp. 1264 and 1302), or systemic involvement with fever or organ dysfunction (especially hepatitis, which is often delayed for a few days after the rash develops). Because sulphonamides are important in the treatment and prophylaxis of opportunistic infections, rechallenge or desensitisation is often attempted in patients who have previously experienced rashes, provided the reaction was not life-threatening. Details of rashes caused by ART are given below.

Oral conditions

Oropharyngeal candidiasis is very common. It is nearly always caused by *C. albicans* (p. 381), but other azole-resistant *Candida* species may be selected for if there have been repeated courses of azole drugs. Pseudomembranous candidiasis is the most common manifestation, with white patches on the buccal mucosa (p. 388) that can be scraped off to reveal a red raw surface. Erythematous candidiasis is more difficult to diagnose and presents with a reddened mucosa and a smooth shiny tongue. Angular cheilitis due to *Candida* is a common manifestation. Topical antifungals are usually effective. Antifungal lozenges and gentian violet are both more effective than antifungal solutions. Systemic azole therapy, usually fluconazole, should be given if topical therapy fails or if there are oesophageal symptoms.

Oral hairy leucoplakia (p. 388) appears as corrugated white plaques running vertically on the side of the tongue, and is virtually pathognomonic of HIV disease. It is usually asymptomatic and is due to EBV. If high doses of aciclovir or a related drug are given for varicella zoster virus infections, the lesions may temporarily regress.

Oral ulcers are common. Herpetiform oral ulcers occur in primary infection. Herpes simplex typically affects the nasolabial area, but may cause oral ulcers. In early disease, minor aphthous ulcers are common. In advanced disease, giant aphthous ulcers occur. These destroy tissue, are painful and need to be differentiated from herpes simplex and CMV ulcers by biopsy. They respond to systemic steroids. Histoplasmosis (p. 385) is an uncommon cause of oral ulcers, usually associated with constitutional symptoms. Finally, superficial oral ulcers may occur as part of the Stevens–Johnson syndrome, usually caused by sulphonamides or NNRTIs.

KS often involves the mouth, especially the hard palate (see above and Fig. 14.6). Nodular oral lesions are associated with a worse prognosis.

Gingivitis is very common. Good oral hygiene and regular dental checkups are important. Acute necrotising ulcerative gingivitis and periostitis (p. 388) can result in loss of teeth; they should be treated with a course of metronidazole and a dental referral should be made.

Nail disorders

Fungal infections (onychomycosis, p. 1280) are very common and often involve multiple nails. Blue discoloration of nails is common and may be due to HIV or to the antiretroviral drug zidovudine.

Gastrointestinal disease

Oesophageal diseases

Oesophageal candidiasis (Fig. 14.7) is the most common cause of pain on swallowing (odynophagia), dysphagia and regurgitation. Concomitant oral candidiasis is present in about 70% of patients. Systemic azole therapy, e.g. fluconazole 200 mg daily for 14 days, is usually curative, but relapses are common. Patients whose oesophageal symptoms fail to respond to azoles should be investigated with oesophagoscopy. Major aphthous ulceration and CMV ulcers are the most likely causes and need to be differentiated by biopsy. Occasionally, herpes simplex oesophagitis or obstructive KS is responsible.

Diarrhoea

Chronic diarrhoea is a very common presenting problem in patients with advanced HIV, especially in areas where there is no access to safe water. It is a major cause of wasting. The differential diagnosis of diarrhoea depends on whether the presentation is with large- or small-bowel symptoms (see Fig. 14.4, p. 396). The presentation and aetiology of acute diarrhoea are similar to those in HIV-uninfected patients.

Large-bowel diarrhoea

Acute diarrhoea caused by the bacterial enteric pathogens *Campylobacter*, *Shigella* and *Salmonella* occurs more frequently than in HIV-uninfected people and the illness is more severe. Bacteraemia is much more common, notably due to non-typhoid *Salmonella*. Diarrhoea caused by *Clostridium difficile* should be considered if there has been prior exposure to antibiotics, as is often the case in patients with symptomatic HIV.

CMV colitis presents with chronic large-bowel symptoms and fever in patients with CD4 counts below 100 cells/mm^3. On colonoscopy, ulcers are seen, mostly involving the left side of the colon. Biopsy of ulcers shows typical 'owl's-eye' inclusion bodies.

Small-bowel diarrhoea

Chronic small-bowel diarrhoea may be due to HIV enteropathy, but this is a diagnosis of exclusion. It typically presents with chronic watery diarrhoea and wasting without fever. Infection with one of three unicellular organisms is responsible for most cases: cryptosporidiosis, microsporidiosis and isosporiasis (Box 14.11). All three are intracellular parasites that invade enterocytes. If the diagnosis is not made by stool microscopy on at least two specimens, a duodenal biopsy should be performed (Fig. 14.8). Electron microscopy is essential for speciation of microsporidia.

14.11 Common causes of chronic watery diarrhoea

	Cryptosporidiosis	Microsporidiosis	Isosporiasis
Organism	Protozoan	Fungus	Protozoan
Species	*Cryptosporidium parvum* *C. hominis*	*Encephalitozoon bieneusi* *E. intestinalis*, etc.	*Isospora belli*
Animal host	Multiple	Multiple	No
Distribution	Global	Global	Tropics
Stool examination	Acid-fast stain	Trichrome stain PCR	Acid-fast stain
Specific treatment	No established therapy	Albendazole (some species)	Co-trimoxazole

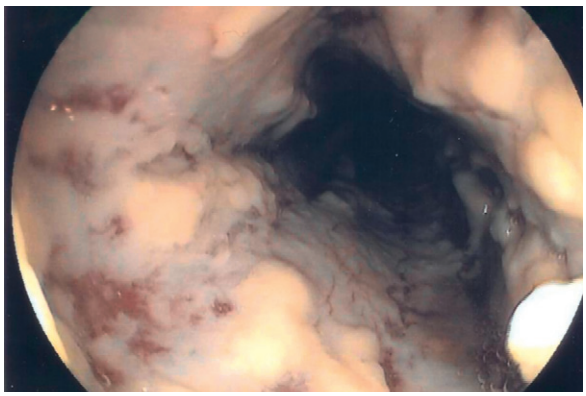

Fig. 14.7 Oesophageal candidiasis. Endoscopy showing typical pseudomembranous candidiasis.

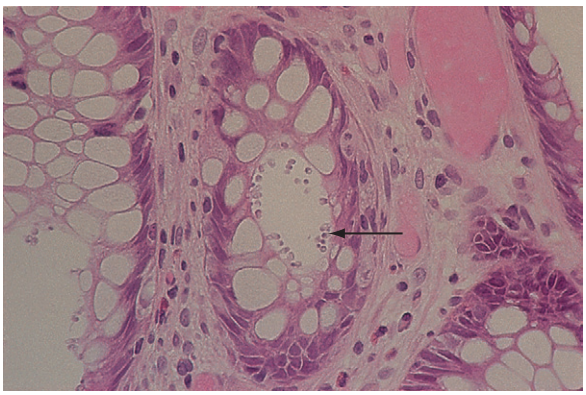

Fig. 14.8 Cryptosporidiosis. Duodenal biopsy may be necessary to confirm cryptosporidiosis or microsporidiosis. Arrow indicates an öocyst.

About 40% of patients with disseminated MAC infections have watery diarrhoea. Unlike in cryptosporidiosis, microsporidiosis and isosporiasis, fever is a prominent feature of MAC infection. Intestinal tuberculosis typically involves the ileocaecal area and may present with fever and diarrhoea, but the diarrhoea is seldom profuse.

Hepatobiliary disease

Chronic viral hepatitis

Hepatitis B and/or C (HBV and HCV) co-infection is common in HIV-infected people due to shared risk factors for transmission. The natural history of both HBV and HCV is altered by HIV co-infection. In the ART era, chronic liver disease from viral hepatitis has emerged as a major cause of morbidity and mortality. HBV and HCV are further described on pages 950 and 954.

Hepatitis B

HBV infection is common in several groups of people at risk of HIV infection: residents of low- and middle-income countries, injection drug users, haemophiliacs and MSM. HIV co-infection increases HBV viraemia, is associated with less elevation of transaminase (presumably due to immune suppression), and increases the risk of liver fibrosis and hepatoma. Several NRTIs (lamivudine, emtricitabine and tenofovir) are also effective against HBV. HBV status should be checked at baseline in all HIV-infected patients. Treatment with anti-HBV drugs should be considered for all patients who have active HBV replication (HBeAg-positive or HBV DNA > 2000 U/mL) and/or evidence of inflammation or fibrosis on liver biopsy. This is best achieved by starting an ART regimen that includes tenofovir with either lamivudine or emtricitabine. Interferon is seldom used, but may be considered in patients with CD4 counts above 500 cells/mm^3. A flare of hepatitis may be associated with improved immune function after starting ART or discontinuing antiretrovirals that have anti-HBV activity. There is an increased risk of antiretroviral hepatotoxicity.

Hepatitis C

HCV infection is extremely common in injection drug users and haemophiliacs. HIV co-infection increases HCV viraemia and increases the risk of liver fibrosis and hepatoma. Treatment for HCV should preferably be deferred in patients with low CD4 counts until the CD4 count has risen to 350 cells/mm^3 or more. As with HBV, a flare of hepatitis may be associated with improved immune function after starting ART, and there is an increased risk of antiretroviral hepatotoxicity. Response to anti-HCV therapy is similar to that seen in HIV-uninfected people, but there is more toxicity and there are important drug–drug interactions between several antiretrovirals and both ribavirin and the newer HCV protease inhibitors.

HIV cholangiopathy

HIV cholangiopathy, a form of secondary sclerosing cholangitis (p. 965), is seen in patients with severe immune suppression. In some patients, co-existing intestinal infection with CMV, cryptosporidiosis or microsporidiosis is present, but it is uncertain if these organisms play an aetiological role. Papillary stenosis is common and is amenable to cautery via endoscopic retrograde cholangiopancreatography (ERCP), which provides symptomatic relief. Acalculous cholecystitis is a common complication of cholangiopathy. ART may improve the condition.

Respiratory disease

Pulmonary disease is very common and is the major reason for hospital admission. More than 90% of patients who are admitted for respiratory diseases will have either bacterial pneumonia, pulmonary tuberculosis or *Pneumocystis jirovecii* pneumonia (PJP). PJP is more common in high-income countries, while tuberculosis is more common in low- and middle-income countries. An approach to the differential diagnosis of all three conditions is given in Box 14.12.

Pneumocystis jirovecii pneumonia

The key presenting feature of PJP is progressive dyspnoea. Dry cough and fever are common. The chest X-ray typically shows a bilateral interstitial infiltrate spreading out from the hilar regions (Fig. 14.9), but may be normal initially. High-resolution CT scan is more sensitive than chest X-ray, usually showing typical 'ground-glass' interstitial infiltrates. Pneumatocoeles may occur and may rupture, resulting in a pneumothorax. The diagnosis is made with silver stains, PCR or immunofluorescence of broncho-alveolar lavage or induced sputum. Treatment is with high-dose co-trimoxazole, together with adjunctive steroids if the patient is hypoxic.

Pulmonary tuberculosis

Tuberculosis is the most common cause of admission in countries with a high tuberculosis incidence. Pulmonary tuberculosis in patients with mild immune suppression typically presents as in HIV-uninfected patients, with a chronic illness and apical pulmonary cavities (p. 688). However, in patients with CD4 counts below 200 cells/mm^3, there are four important differences in the clinical presentation of pulmonary tuberculosis.

14.12 Characteristic features of bacterial pneumonia, PJP and pulmonary TB

	Bacterial pneumonia	PJP	Pulmonary TB
Duration	Acute	Subacute	Variable
Dyspnoea	Common	Prominent	Occasional
White cell count	Increased	Normal	Variable
Chest X-ray			
Infiltrate	Consolidation	Interstitial	Variable
Bilateral infiltrate	Occasional	Yes	Common
Effusion	Occasional	No	Common
Nodes	Uncommon	No	Common
C-reactive protein	Markedly increased	Variable	Increased

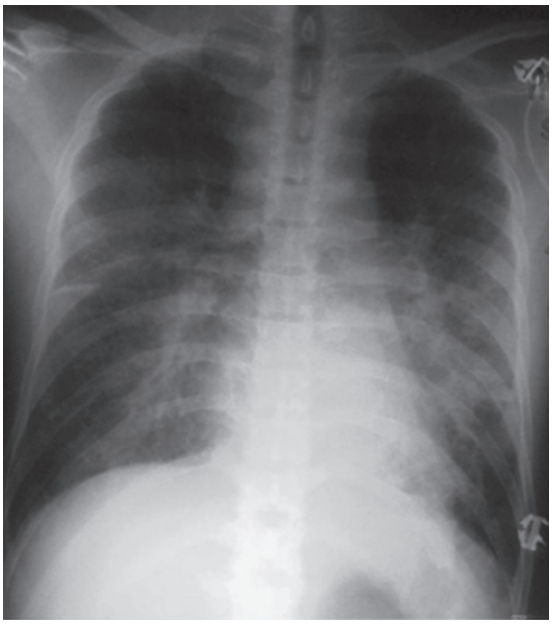

Fig. 14.9 *Pneumocystis* pneumonia: typical chest X-ray appearance. Note the interstitial bilateral infiltrate.

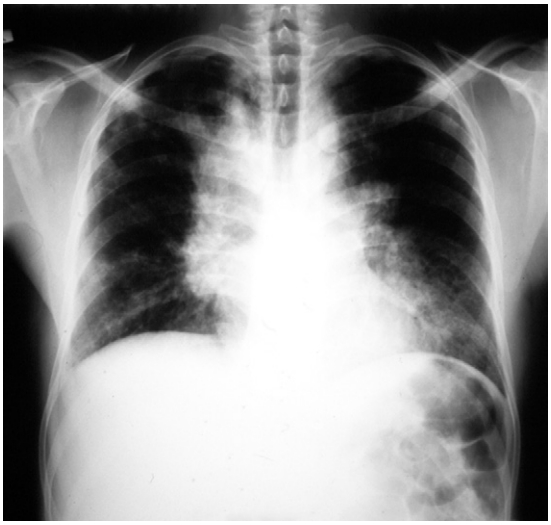

Fig. 14.10 Chest X-ray of pulmonary tuberculosis in advanced HIV infection. Lower-zone infiltrates and hilar or mediastinal nodes in a patient with a CD4 count of less than 200 cells/mm^3.

- Tuberculosis progresses more rapidly, with a subacute or even acute presentation. Therefore the diagnosis needs to be made and therapy commenced promptly. A trial of empirical therapy is often started while awaiting the results of mycobacterial cultures.
- The chest X-ray appearance alters: cavities are rarely seen, pulmonary infiltrates are no longer predominantly in apical areas, and pleural effusions and hilar or mediastinal lymphadenopathy are common (Fig. 14.10). A normal chest X-ray is not unusual in symptomatic patients with tuberculosis confirmed on sputum culture. These atypical findings can result in delayed or missed diagnosis.
- Sputum smears, which are positive in most HIV-uninfected adults with pulmonary tuberculosis, are negative in more than half of patients. The main reason for this is the absence of pulmonary cavities.
- Many patients have disseminated tuberculosis, sometimes with a classic miliary pattern on chest X-ray, but more commonly presenting with pulmonary and extrapulmonary tuberculosis. The most common sites of concomitant extrapulmonary tuberculosis are the pleura and lymph nodes. Acid-fast bacilli are more often found on wide-needle aspirate of nodes than on sputum (p. 395). Pleural aspirate showing a lymphocytic exudate suggests tuberculosis as a likely cause and pleural biopsy will usually confirm the diagnosis.

Tuberculosis in HIV-infected patients responds well to standard short-course therapy (p. 693).

Bacterial pneumonia

The incidence of bacterial pneumonia is increased about 100-fold by HIV infection. The severity, likelihood of bacteraemia, risk of recurrent pneumonia, and mortality are all increased compared with HIV-uninfected patients. The aetiology is similar to that of community-acquired pneumonia in HIV-uninfected patients with co-morbidity: *S. pneumoniae* is the commonest, followed by *Haemophilus influenzae*, enterobacteriaceae (e.g. *Klebsiella pneumoniae*) and *Staphylococcus aureus*. The prevalence of atypical bacteria in HIV-infected patients with pneumonia is probably similar to that in the general population, but the data are limited. Treatment is with a broad-spectrum β-lactam (e.g. ceftriaxone, amoxicillin–clavulanate), with the addition of a macrolide if the pneumonia is severe.

Uncommon bacteria causing pneumonia include *Pseudomonas aeruginosa, Nocardia* (which mimics tuberculosis) and *Rhodococcus equi* (which can cause pulmonary cavities).

Miscellaneous causes of pulmonary infiltrates

Pulmonary cryptococcosis may present as a component of disseminated disease or be limited to the lungs. The chest X-ray appearances are variable. Cryptococcomas occur less commonly than in HIV-uninfected people. The commonest radiographic pattern seen in HIV infection is patchy consolidation, often with small areas of cavitation resembling tuberculosis. Pleural involvement is rare. The endemic mycoses (histoplasmosis, coccidioidomycosis and penicilliosis) often also cause non-specific pulmonary infiltrates.

Lymphoid interstitial pneumonitis is a slowly progressive disorder with a diffuse reticulonodular infiltrate. It is caused by a benign polyclonal lymphocytic interstitial infiltrate and is part of the diffuse infiltrative lymphocytosis syndrome (DILS – see p. 404). Patients may have other features of DILS, notably parotidomegaly.

Kaposi's sarcoma often spreads to the lungs. Typical chest X-ray appearances are large, irregular nodules, linear reticular pattern and pleural effusions. Bronchoscopy is diagnostic.

Nervous system and eye disease

The central and peripheral nervous systems are commonly involved in HIV, either as a direct consequence of HIV infection or due to opportunistic diseases. Presentations are outlined in Figure 14.11.

Cognitive impairment

HIV-associated neurocognitive disorders

HIV is a neurotropic virus and invades the CNS early during infection. Meningo-encephalitis may occur at seroconversion. About 50% of HIV-infected people have abnormal neuropsychiatric testing, the proportion increasing with declining CD4 counts. The term HIV-associated neurocognitive disorders (HAND) describes a spectrum of disorders: asymptomatic neurocognitive impairment (which is the most common), minor neurocognitive disorder and HIV-associated dementia (also called HIV encephalopathy). Dementia occurs in late disease and is a subcortical dementia characterised by impairment of executive function, psychomotor retardation and impaired memory. There is no diagnostic test for HIV-associated dementia. CT or magnetic resonance imaging (MRI) shows diffuse cerebral atrophy out of keeping with age. It is important to exclude depression, cryptococcal meningitis and neurosyphilis. ART usually improves HIV-associated dementia, but milder forms of HAND often persist.

Progressive multifocal leucoencephalopathy

Progressive multifocal leucoencephalopathy (PML) is a progressive disease that presents with stroke-like episodes and cognitive impairment. Vision is often impaired due to involvement of the occipital cortex. PML is caused by the JC virus. A combination of characteristic appearances on MRI (Fig. 14.12) and detection of JC virus DNA in the cerebrospinal fluid (CSF) by PCR is diagnostic. No specific treatment exists and prognosis remains poor despite ART.

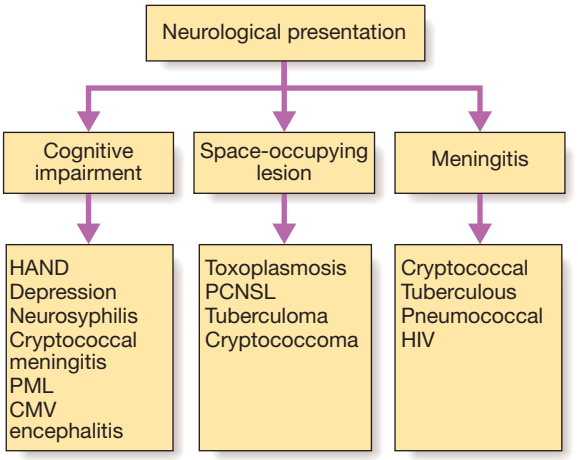

Fig. 14.11 Presentation and differential diagnosis of HIV-related neurological disorders. (CMV = cytomegalovirus; HAND = HIV-associated neurocognitive disorder; PCNSL = primary CNS lymphoma; PML = progressive multifocal leucoencephalopathy; TB = tuberculosis)

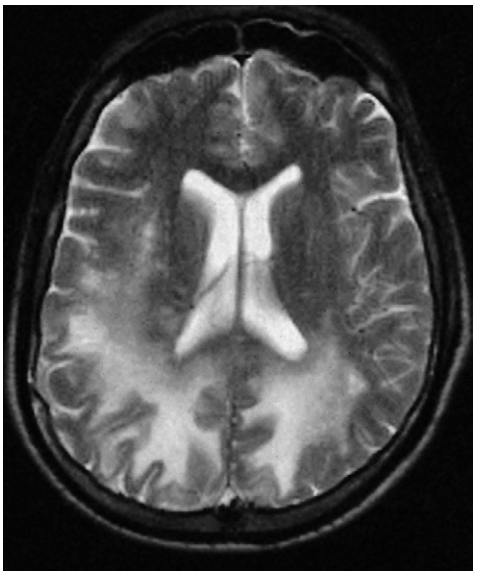

Fig. 14.12 Progressive multifocal leucoencephalopathy. Non-enhancing white-matter lesions without surrounding oedema are seen.

CMV encephalitis

This presents with behavioural disturbance, cognitive impairment and a reduced level of consciousness. Focal signs may also occur. Detection of CMV DNA in the CSF supports the diagnosis. Response to anti-CMV therapy is poor.

Space-occupying lesions

Space-occupying lesions in AIDS patients typically present over days to weeks. The most common cause is toxoplasmosis. As toxoplasmosis responds rapidly to therapy, a trial of anti-toxoplasmosis therapy should be given to all patients presenting with space-occupying lesions while the results of diagnostic tests are being awaited.

Cerebral toxoplasmosis

Cerebral toxoplasmosis is caused by reactivation of residual *Toxoplasma gondii* cysts from past infection, which results in the development of space-occupying lesions. The characteristic findings on imaging are multiple space-occupying lesions with ring enhancement on contrast and surrounding oedema (Fig. 14.13). *Toxoplasma* serology shows evidence of previous exposure (positive immunoglobulin (Ig)G antibodies). The standard therapy for toxoplasmosis is sulfadiazine with pyrimethamine, together with folinic acid, to reduce the risk of bone marrow suppression. However, co-trimoxazole has been shown to be as effective and less toxic, and is also more widely available. Response to a trial of therapy is usually diagnostic, with clinical improvement in 1–2 weeks and shrinkage of lesions on imaging in 2–4 weeks. Definitive diagnosis is by brain biopsy but this is seldom necessary.

Primary CNS lymphoma (PCNSL)

Primary CNS lymphomas (PCNSLs) are high-grade B-cell lymphomas associated with EBV infection. Characteristically, imaging demonstrates a single,

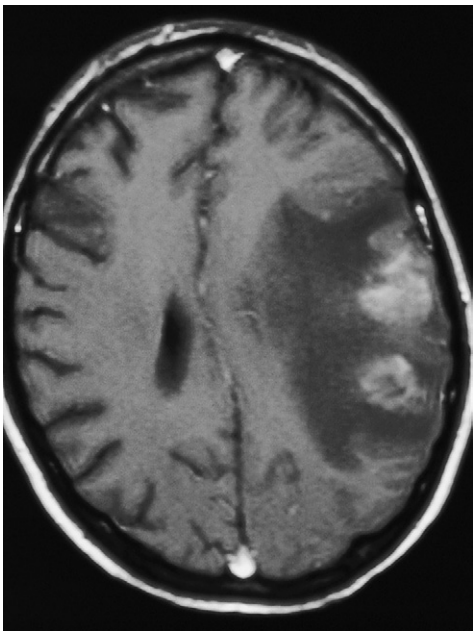

Fig. 14.13 Cerebral toxoplasmosis. Multiple ring-enhancing lesions with surrounding oedema are characteristic.

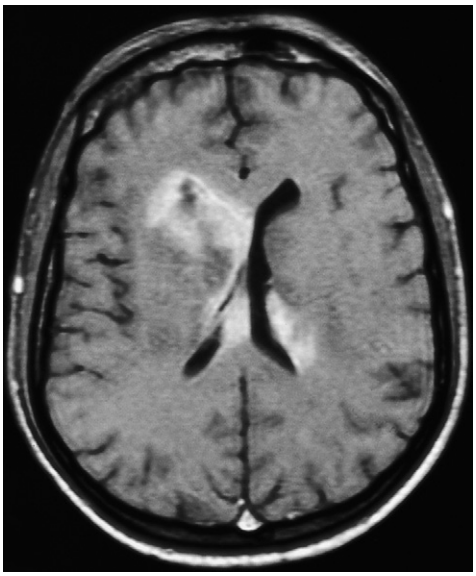

Fig. 14.14 Primary CNS lymphoma. A single enhancing periventricular lesion with moderate oedema is typical.

homogeneously enhancing, periventricular lesion with surrounding oedema (Fig. 14.14). If it is considered safe to perform a lumbar puncture, PCR for EBV DNA in the CSF has a high sensitivity and specificity for PCNSL. Brain biopsy is definitive, but carries a risk of morbidity and may be non-diagnostic in up to one-third. The prognosis is very poor.

Tuberculoma

Lesions resemble toxoplasmosis on imaging, except that oedema tends to be less marked and single lesions occur more commonly. There may be evidence of tuberculosis elsewhere. The CSF may show features consistent with tuberculous meningitis. Response to antituberculosis therapy is slow and paradoxical expansion of lesions despite therapy is not uncommon.

Stroke

There is a higher incidence of stroke in patients with HIV disease. Atherosclerosis is accelerated by HIV-associated inflammation and by some antiretroviral drugs. HIV vasculopathy with occlusion can cause a stroke. The aetiology is thought to be a vasculitis. It is important to exclude tuberculous meningitis and meningovascular syphilis in all patients who present with a stroke.

Meningitis

Cryptococcal meningitis

Cryptococcus neoformans is the most common cause of meningitis in AIDS patients. Patients usually present subacutely with headache, vomiting and mild confusion. Neck stiffness is present in less than half. CSF pleocytosis is often mild or even absent, and protein and glucose concentrations are variable. It is important to request CSF cryptococcal antigen tests in all HIV-infected patients undergoing lumbar puncture, as this test has a sensitivity and specificity of almost 100%. Treatment is with amphotericin B (plus flucytosine if available) for 2 weeks, followed by fluconazole. Raised intracranial pressure is common and should be treated with repeated therapeutic lumbar punctures, removing sufficient CSF to reduce pressure to less than 20 cmH_2O. (Most experts would be reluctant to withdraw more than 30 mL at a time.)

Tuberculous meningitis

The presentation and CSF findings of tuberculous meningitis are similar to those in HIV-uninfected patients (p. 1201), except that concomitant tuberculosis at other sites is more common in HIV infection.

Peripheral nerve disease

HIV infection causes axonal degeneration, resulting in a sensorimotor peripheral neuropathy in about one-third of AIDS patients. The incidence is increased with lower CD4 counts, older age and increased height. Sensory symptoms predominate. Treatment involves foot care, analgesia and analgesic adjuvants. ART has minimal effect on halting or reversing the process. The NRTIs stavudine and didanosine can cause drug-induced peripheral neuropathy, which is typically more painful and more rapidly progressive than HIV neuropathy. It may remit if the offending drug is withdrawn early.

Acute inflammatory demyelinating polyneuropathy is an uncommon manifestation, usually occurring in primary infection. It resembles Guillain–Barré syndrome (p. 1224), except that CSF pleocytosis is more prominent. Mononeuritis may also occur, commonly involving the facial nerve.

Myelopathy and radiculopathy

Globally, the most common cause of myelopathy in HIV infection is cord compression from tuberculous spondylitis. Vacuolar myelopathy is seen in advanced disease and is due to HIV. It presents with a slowly progressive

paraparesis with no sensory level. MRI of the spine is normal, but is an important investigation to exclude other causes. Most patients have concomitant HIV-associated dementia.

CMV polyradiculitis presents with painful legs, progressive flaccid paraparesis, saddle anaesthesia, absent reflexes and sphincter dysfunction. CSF shows a neutrophil pleocytosis (which is unusual for a viral infection), and the detection of CMV DNA by PCR confirms the diagnosis. Despite treatment with ganciclovir or valganciclovir, functional recovery is poor.

Psychiatric disease

Significant psychiatric morbidity is very common and is a major risk factor for poor adherence. Reactive depression is the most common disorder. Diagnosis is often difficult, as many patients have concomitant HAND. Substance misuse is common in many groups of people at risk of HIV. Some forms of ART can cause psychiatric adverse effects and these are detailed on page 409.

Retinopathy

CMV retinitis presents with painless, progressive visual loss in patients with severe immune suppression. On fundoscopy the vitreous is clear. Haemorrhages and exudates are seen in the retina (p. 388), often with sheathing of vessels ('frosted branch angiitis'). The disease usually starts unilaterally, but progressive bilateral involvement occurs in most untreated patients. Diagnosis is usually clinical, but if there is doubt, demonstrating CMV DNA by PCR of vitreous fluid is diagnostic. Treatment with ganciclovir or valganciclovir stops progression of the disease, but vision does not recover. Some patients may develop immune recovery uveitis in response to ART, with intraocular inflammation, macular oedema and cataract formation that requires prompt treatment with oral and intraocular corticosteroids to prevent visual loss.

Three other conditions may mimic CMV retinitis. Like CMV, they all occur in patients with CD4 counts below 100 cells/mm^3. Ocular toxoplasmosis typically presents with a vitritis and retinitis without retinal haemorrhages. HIV retinopathy is a microangiopathy that causes cotton wool spots, which are not sight-threatening. Varicella zoster virus can cause rapidly progressive outer retinal necrosis.

Rheumatological disease

The immune dysregulation associated with HIV infection may result in autoantibody formation, usually in low titres. Mild arthralgias and a fibromyalgia-like syndrome are common in HIV-infected people.

Arthritis

HIV can cause a seronegative arthritis, which resembles rheumatoid arthritis. A more benign oligoarthritis may also occur. Reactive arthritis and Reiter's syndrome are more severe in HIV infection (Ch. 25).

Diffuse infiltrative lymphocytosis syndrome

Diffuse infiltrative lymphocytosis syndrome (DILS) is a benign disorder involving polyclonal CD8 lymphocytic infiltration of tissues, which has some features in common with Sjögren's syndrome (p. 1114). It is linked to human leucocyte antigen (HLA)-DRB1. Most patients have a CD8 lymphocytosis. DILS usually presents in patients with mild immune suppression. The most common manifestation is bilateral parotid gland enlargement; the glands are often massive, with lymphoepithelial cysts on histology (Fig. 14.15). Other salivary glands may also be enlarged. Sicca symptoms are common but usually mild. Lymphocytic interstitial pneumonitis is the most common manifestation outside the salivary glands. Generalised lymphadenopathy with nodes, larger than those seen with persistent generalised lymphadenopathy of HIV, may occur. Hepatitis, mononeuritis, polyarthritis and polymyositis may also occur. The manifestations outside the salivary glands usually respond to steroids. The parotid glands are treated for cosmetic reasons but surgery is best avoided. Aspiration of parotid cysts and instillation of a sclerosant are of some benefit. Low-dose irradiation has also been used successfully. DILS may regress on ART but response is variable.

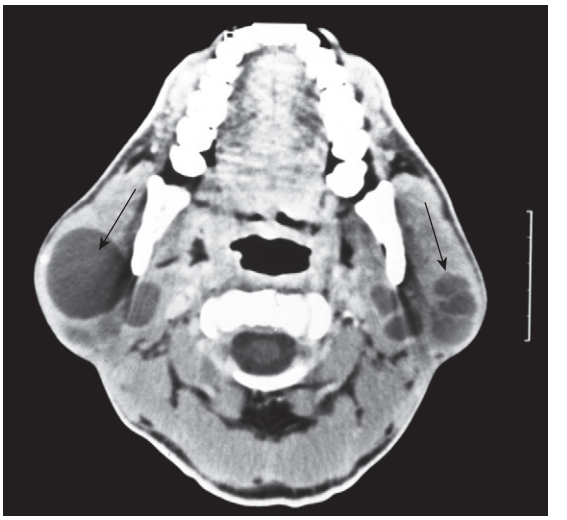

Fig. 14.15 CT scan of parotid glands showing multiple cysts (arrows) in a patient with the diffuse infiltrative lymphocytosis syndrome.

Haematological abnormalities

Disorders of all three major cell lines may occur in HIV. In advanced disease, haematopoiesis is impaired due to the direct effect of HIV and by cytokines. Pancytopenia may occur as a consequence of HIV but it is important to exclude a disorder infiltrating the bone marrow, such as mycobacterial or fungal infections, or lymphoma.

Anaemia

Normochromic, normocytic anaemia is very common in advanced HIV disease. Opportunistic diseases may cause anaemia of chronic disease (e.g. tuberculosis) or marrow infiltration (e.g. MAC, tuberculosis, lymphoma, fungi). Anaemia is a common adverse effect of zidovudine, which also causes a macrocytosis. Red cell aplasia

is rare and may be caused either by parvovirus B19 infection or by lamivudine.

Neutropenia

Isolated neutropenia is occasionally due to HIV but is nearly always caused by drug toxicity (e.g. zidovudine, co-trimoxazole, ganciclovir).

Thrombocytopenia

Mild thrombocytopenia is common in HIV-infected people. The most common disorder causing severe thrombocytopenia is immune-mediated platelet destruction resembling idiopathic thrombocytopenic purpura (p. 1050). This responds to steroids or intravenous immunoglobulin, together with ART. Splenectomy should be avoided if possible because it further increases the risk of infection with encapsulated bacteria. Severe thrombocytopenia with a microangiopathic anaemia also occurs in a thrombotic thrombocytopenic purpura-like illness (p. 1056), which seems to have a better prognosis than the classical disease. Transient thrombocytopenia is common in primary infection.

Renal disease

Acute renal failure is common, usually due to acute infection or nephrotoxicity of drugs (e.g. tenofovir, p. 481), amphotericin B). HIV-associated nephropathy (HIVAN) is the most important cause of chronic renal failure and is seen most frequently in patients of African descent and those with low CD4 counts. Progression to end-stage renal failure is more rapid than with most other causes of chronic renal failure, and renal size may be preserved even when it is severe. HIVAN usually presents with nephrotic syndrome, chronic renal failure or a combination of both. ART has some effect in slowing progression of HIVAN. Other important HIV-associated renal diseases include HIV immune complex kidney diseases and thrombotic microangiopathy. With the overall improvement in life expectancy from ART, conditions such as diabetes mellitus, hypertension and vascular disease add to the burden of chronic kidney disease. Outcomes of renal transplantation are good in patients on ART.

Cardiac disease

HIV-associated cardiomyopathy resembles idiopathic dilated cardiomyopathy (p. 636) but progresses more rapidly. ART may improve cardiac failure but does not reverse established cardiomyopathy. Pericardial disease due to opportunistic diseases is not uncommon. Globally, the most common cause is tuberculous pericardial effusions. Tuberculous constrictive pericarditis is less common than in HIV-uninfected people. Kaposi's sarcoma and lymphoma may cause pericardial effusions. Septic pericarditis, usually due to *S. pneumoniae*, is uncommon.

HIV is associated with an increased risk of myocardial infarction due to accelerated atherogenesis caused by the inflammatory state. Certain protease inhibitors (p. 407) that cause dyslipidaemia have been associated with an increased risk of myocardial infarction.

14.13 Approximate incidence ratio of virus-related cancers compared to the general population

Viral cancers	Incidence ratio
Human herpesvirus 8-related	
Kaposi's sarcoma	3600
Epstein–Barr virus-related	
Non-Hodgkin lymphoma	80
Hodgkin lymphoma	10
Human papillomavirus-related	
Cervical cancer	6
Vulval cancer	6
Anal cancer	30
Penile cancer	4
Hepatitis B/C virus-related	
Hepatoma	5

HIV-related cancers

The AIDS-defining cancers are Kaposi's sarcoma (see above), cervical cancer and non-Hodgkin lymphoma (NHL – p. 1043). NHL may occur at any CD4 count but is more commonly seen below 200 cells/mm^3. Almost all NHL are B-cell tumours and most are stage 4 when the patient presents. Long-term remission rates of about 50% can be achieved with NHL in AIDS patients using ART and chemotherapy (including the anti-B-cell monoclonal antibody rituximab if it is a B-cell tumour).

The incidence of a number of other cancers induced by viruses is also increased in HIV-infected people (Box 14.13). Regular cytological examination of the cervix, and of the anus in people who practise anal sex, should be performed to detect pre-malignant lesions, which are easier to treat. In general, the incidence of cancers that are not induced by viruses is similar to that in the general population.

PREVENTION OF OPPORTUNISTIC INFECTIONS

The best way to prevent opportunistic infections is to improve the CD4 count with ART. However, infections continue to occur in the ART era; CD4 counts take time to improve if ART is initiated in patients with profound immune suppression, immune reconstitution on ART is often suboptimal, and CD4 counts may decline because antiretroviral resistance develops.

Preventing exposure

The best method for avoiding infection is to prevent exposure to the infectious agent. However, this is only possible for a few opportunistic infections. The pathogenesis of several of these is thought to be reactivation of latent/dormant infection after prior exposure – examples include herpes simplex virus, zoster, CMV and toxoplasmosis. Preventing exposure to some of these infections is thus only of benefit if exposure has not already occurred.

Safe water and food

Cryptosporidiosis, microsporidiosis and isosporiasis may be water-borne. If there is no access to safe water, then water should be boiled before drinking. Food-borne illnesses are also important in HIV infection, notably *Salmonella* species. *Toxoplasma* exposure is related to eating raw or undercooked meat. People living with HIV infection need to be informed about food hygiene and the importance of adequately cooked meat.

Tuberculosis

Preventing exposure to tuberculosis is important when there is an infectious case in the household, in clinics and in hospitals. Adequate ventilation, masks and safe coughing procedures reduce the risk of exposure.

Malaria vector control

All HIV-infected individuals living in malarious areas should practise vector control, as malaria occurs more frequently and is more severe in HIV-infected people. The most cost-effective way to achieve this is by using insecticide-impregnated bed nets. Other modalities of vector control that are of benefit to the community, such as reducing standing water and spraying with residual insecticides and larvicides, should also be implemented.

Safer sex

HIV-infected individuals should practise safer sex in order to reduce the transmission of HIV. Even if their partners are HIV-infected, condoms should be used, as HIV mutants that are more virulent or have developed antiretroviral drug resistance can be transmitted. Safer sex will also lower the risk of acquiring herpes simplex virus and human herpesvirus 8.

Pets

Toxoplasma gondii can be acquired from kittens or cat litter, and people living with HIV infection should avoid handling either. Cryptosporidiosis can be transmitted from animals, and patients should be advised to wash their hands after handling animals.

Chemoprophylaxis

Chemoprophylaxis is the use of antimicrobial agents to prevent infections. Primary prophylaxis is used to prevent opportunistic infections that have not yet occurred. Secondary prophylaxis is used to prevent recurrence of opportunistic infections because many may recur after an initial response to therapy. Secondary prophylaxis (Box 14.14) can be discontinued when ART results in immune reconstitution, with CD4 counts increasing to over 200 cells/mm^3, but for CMV and MAC, prophylaxis can be stopped if CD4 counts increase to more than 100 cells/mm^3.

14.14 Secondary prophylaxis of opportunistic infections

Infection	Drug regimen
Pneumocystis jirovecii pneumonia	Co-trimoxazole 960 mg daily
Toxoplasmosis	Co-trimoxazole 960 mg daily
Cryptococcosis	Fluconazole 200 mg daily
Cytomegalovirus infection	Valganciclovir 900 mg daily
Mycobacterium avium complex	Clarithromycin 500 mg twice daily + Ethambutol 800 mg daily
Isospora belli infection	Co-trimoxazole 960 mg daily

14.15 Opportunistic infections reduced by co-trimoxazole

- *Pneumocystis jirovecii* pneumonia
- Cerebral toxoplasmosis
- Bacterial pneumonia
- Bacteraemia
- Isosporiasis
- Malaria

Co-trimoxazole primary prophylaxis

Co-trimoxazole reduces the incidence of a number of opportunistic infections (Box 14.15), as well as hospitalisation and mortality rates. The indications for initiating co-trimoxazole are either clinical evidence of immune suppression (WHO clinical stages 3 or 4) or laboratory evidence of immune suppression (CD4 count below 200 cells/mm^3). In low-income countries, there is considerable morbidity from infectious diseases (including malaria) in earlier HIV disease, and the WHO recommends initiating co-trimoxazole at a CD4 count of less than 350 cells/mm^3, or at WHO stages 2–4. The recommended dose of co-trimoxazole is 960 mg daily, but trials have shown that half this dose is as effective and may be associated with less toxicity. Co-trimoxazole prophylaxis can be discontinued when CD4 counts increase to more than 200 cells/mm^3 on ART.

Co-trimoxazole prophylaxis is well tolerated. The most common side-effect is hypersensitivity, causing a maculo-papular rash. If therapy is discontinued, desensitisation or rechallenge under antihistamine cover should be attempted, unless the rash was accompanied by systemic symptoms or mucosal involvement. Prophylactic doses of co-trimoxazole can also cause neutropenia, but this is very uncommon and routine monitoring of blood counts is not necessary. If co-trimoxazole cannot be tolerated, then dapsone 100 mg daily should be substituted. Dapsone is equally effective at reducing the incidence of *P. jirovecii* pneumonia, but has little or no effect on reducing the other opportunistic infections prevented by co-trimoxazole.

Isoniazid preventive therapy

Isoniazid preventive therapy (IPT) has been shown to reduce the risk of tuberculosis only in HIV-infected patients with a positive tuberculin skin test, which should be done in all patients at baseline. There is no CD4 count or clinical threshold for starting or stopping IPT. In HIV infection, induration of 5 mm or more on a Mantoux test is regarded as positive. It is important to rule out active tuberculosis before starting IPT, and symptom screening has been shown to be adequate to achieve this (Box 14.16). The usual duration of IPT is

14.16 Symptom screen for tuberculosis before isoniazid preventive therapy

All of the following must be absent:

- Active cough
- Night sweats
- Weight loss
- Fever

EBM 14.17 Duration of isoniazid preventive therapy

'Thirty-six months' isoniazid prophylaxis was more effective for prevention of tuberculosis than 6-month prophylaxis in individuals with HIV infection, and chiefly benefited those who were tuberculin skin test-positive.'

- Samandari T, et al. Lancet 2011; 377:1588–1598.

6 months but this does not provide long-term reduction in the risk of tuberculosis. Continuation for 36 months has been shown to be much more effective (Box 14.17).

Mycobacterium avium complex

In high-income countries, a macrolide (azithromycin or clarithromycin) is recommended to prevent MAC in patients with a CD4 count below 50 cells/mm^3. This can be discontinued once the CD4 count has risen to over 100 cells/mm^3 on ART.

Immunisation

There are significant problems associated with vaccination in HIV infection. First, vaccination with live organisms is contraindicated in patients with severe immune suppression, as this may result in disease from the attenuated organisms. Second, immune responses to vaccination are impaired in HIV-infected patients. If the CD4 count is below 200 cells/mm^3, then immune responses to immunisation are very poor. Therefore it is preferable to wait until the CD4 count has increased to more than 200 cells/mm^3 on ART before immunisation is given. All patients should be given a conjugate pneumococcal vaccine (not the polysaccharide vaccine, which has been shown to be harmful) and annual influenza vaccination. Hepatitis B vaccination should be given to those who are not immune.

ANTIRETROVIRAL THERAPY

ART that is capable of suppressing viral replication has been available since 1996. ART has transformed HIV from a progressive illness with a fatal outcome into a chronic manageable disease (Box 14.18).

The goals of ART are to:

- reduce the viral load to an undetectable level for as long as possible
- improve the CD4 count to over 200 cells/mm^3 so that severe HIV-related disease is unlikely
- improve the quantity and quality of life without unacceptable drug toxicity
- reduce HIV transmission.

EBM 14.18 Life expectancy on ART

'A mathematical model predicted that people with HIV who can access ART will have life expectancy shortened by only 7 or 10.5 years, depending on whether ART is started early (CD4 count 432) or late (CD4 count 140) respectively.'

- Nakagawa F, et al. AIDS 2012; 26:335–343.

14.19 Commonly used antiretroviral drugs

Classes	Drugs
Nucleoside reverse transcriptase inhibitors (NRTIs)	Abacavir, emtricitabine, lamivudine, tenofovir, zidovudine
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Efavirenz, nevirapine, etravirine
Protease inhibitors (PIs)	Atazanavir, darunavir, lopinavir
Integrase inhibitors	Raltegravir
Chemokine receptor inhibitor	Maraviroc

Many of the antiretroviral drugs which were used initially have been largely abandoned because of toxicity or poor efficacy. The drugs that are currently most commonly used are shown in Box 14.19, and their targets in the HIV life cycle in Figure 14.2 (p. 392).

Selecting antiretroviral regimens

The standard combination antiretroviral regimens are two NRTIs together with an NNRTI, protease inhibitor (PI) or integrase inhibitor. Dual NRTI combinations are usually emtricitabine or lamivudine (they are closely related and so are never combined) together with one of abacavir, tenofovir or zidovudine. It is possible to construct effective regimens without NRTIs if there is intolerance or resistance to the NRTIs. Currently used PIs should always be administered with ritonavir, which itself is a PI that is toxic in therapeutic doses. Low doses of ritonavir dramatically increase the concentrations and elimination half-lives of other PIs by inhibiting their metabolism by cytochrome P450. This increases drug exposure, thereby prolonging the PI's half-life, allowing reduction in pill burden and dosing frequency, and so optimising adherence.

Most guidelines from high-income countries allow clinicians to choose a starting regimen of dual NRTIs combined with an NNRTI, or a PI or an integrase inhibitor, as these three regimens have similar efficacy. Subsequent ART regimen switches for virological failure are guided by the results of resistance testing (p. 408). For low- and middle-income countries, the WHO recommends a public health approach to using ART with standardised first-line (NNRTI plus dual NRTIs) and second-line (ritonavir-boosted PI plus dual NRTIs) regimens. NNRTIs are preferred by the WHO in first-line regimens, as they are cheaper than PIs and better tolerated. Furthermore, NNRTIs need to be given with two fully active NRTIs because they have a low genetic

barrier to resistance (see below), whereas PI-containing regimens are effective even when there are some mutations conferring resistance to the NRTIs. Therefore PIs in second-line regimens are preferable in settings where resistance testing is unavailable. The public health approach to using ART can be implemented by nurses and has been successfully implemented in resource-poor settings.

Criteria for starting ART

The 2010 WHO guidelines recommend starting ART in adults with either a CD4 count below 350 cells/mm^3 or clinical stage 3–4. Other international guidelines are very similar, but criteria are updated regularly and it is likely that starting ART at higher CD4 counts will be recommended in the near future. HIV-infected partners in serodiscordant couples should commence ART irrespective of their CD4 count or clinical stage to reduce the risk of transmission to the uninfected partner (Box 14.20). Other categories of patients who should start ART earlier include those with chronic liver disease from viral hepatitis, non-AIDS malignancies, and conditions requiring long-term immunosuppressant therapy.

It is seldom necessary to start ART urgently. Several consultations are required to give patients insight into the need for life-long ART, to stress the importance of adherence, and to formulate a personal treatment plan. Disclosure of HIV status, joining support groups and using patient-nominated treatment supporters should be encouraged, as these have been shown to improve adherence. Management of depression and substance abuse is also important.

EBM 14.20 When should ART be started?

'In serodiscordant couples, early initiation of ART reduced rates of sexual transmission of HIV-1 by 96%, and led to a 41% reduction in the combined end point of major clinical events or death.'

- Cohen MS, et al. N Engl J Med 2011; 365:493–505.

Monitoring efficacy

The most important measure of ART efficacy is the viral load. A baseline viral load should be measured prior to initiating treatment. The viral load should be repeated 4–8 weeks after starting a new ART regimen when the count should show at least a tenfold decrease. Thereafter it should be checked every 3–6 months. After 6 months of ART, the viral load should be suppressed, defined as below the limit of detection of the assay (usually less than 50 copies/mL), and this is achieved in 80–90% of patients. Failure of ART is defined by the viral load becoming detectable after suppression. (In most guidelines a threshold is used – typically more than 400 or more than 1000 copies/mL.) Adherence support should be enhanced if virological failure is detected, and the viral load repeated to confirm failure before switching to a new ART regimen.

CD4 counts are generally monitored every 3–6 months together with the viral load. Typically, the CD4 count increases rapidly in the first month, followed by a more gradual increase. In the first year, the count typically increases by 100–150 cells/mm^3, and about 80 cells/mm^3 per annum thereafter until the reference range is reached, provided the viral load is suppressed. If ART is stopped, the CD4 count rapidly falls to the baseline value before ART was commenced. For countries where viral load monitoring is unavailable, the WHO has defined immunological failure as a fall in CD4 count to baseline, or a 50% fall from peak on ART, or persistent count below 100 cells/mm^3. However, CD4 responses are highly variable: in about 15–30% of patients the CD4 count does not increase despite virological suppression, and in a similar proportion of patients the CD4 response is good despite the presence of virological failure. Therefore it is not surprising that both unnecessary switches to second-line ART and continuation of failing first-line ART regimens (which will increase the number of resistance mutations) are common in settings where viral load monitoring is not available.

Antiretroviral resistance

Reverse transcription is error-prone, generating a large number of mutations. If the viral load is suppressed on ART, viral replication is suppressed and resistance mutations will not be selected. If ART is taken and there is ongoing replication, due to either resistant mutations or suboptimal adherence, mutations conferring resistance to antiretroviral drugs will be selected. Antiretroviral drugs differ in their ability to select for resistant mutations. Some drugs (e.g. emtricitabine, lamivudine, efavirenz, nevirapine) have a low genetic barrier to resistance, rapidly selecting for a single mutation conferring high-level resistance. PIs and some NRTIs (e.g. zidovudine) select for resistance mutations slowly, and multiple resistant mutations often need to accumulate before the drug's efficacy is lost. Patients who develop antiretroviral resistance may transmit resistant virus to others and will eventually develop clinical failure.

Antiretroviral resistance is assessed by sequencing the relevant viral genes to detect mutations that are known to confer resistance. The resistant proviral DNA is archived in latent CD4 cells and will re-emerge rapidly on exposure to the antiretroviral. The patient must therefore be taking ART when the test is performed, as otherwise the wild-type virus will predominate and resistant mutations will not be detected. In regions where resistance testing is affordable, it is recommended at baseline (to detect primary resistance) and at every confirmed virological failure, in order to select the most appropriate antiretrovirals in a new regimen.

ART complications

Immune reconstitution inflammatory syndrome

Immune reconstitution inflammatory syndrome (IRIS) is a common (15–20%) early complication of ART, especially in patients who start it with CD4 counts below 50 cells/mm^3. IRIS presents either with paradoxical deterioration of an existing opportunistic disease (including infections that are responding to appropriate therapy) or with the unmasking of a new infection. The clinical presentation of IRIS events is often characterised

by an exaggerated immune response, with pronounced inflammatory features. For example, patients with CMV retinitis developing IRIS on ART develop a uveitis; and inflammatory haloes occur around KS lesions. Paradoxical tuberculosis IRIS events are common and it is important to exclude multidrug resistance, which could be responsible for the deterioration. IRIS is associated with a mortality of around 5%, but this is higher when it complicates CNS infections.

The management of IRIS is to continue ART and to ensure that the opportunistic disease is adequately treated. Symptomatic treatments are helpful. Corticosteroids are often used for more severe IRIS manifestations, but they should not be given to patients with KS, as this can result in rapid progression of KS lesions.

Lipodystrophy

Long-term use of ART may cause changes in body fat distribution. This can present either with fat accumulation (e.g. visceral fat, breast enlargement, 'buffalo hump') or with subcutaneous fat loss ('lipoatrophy' – Fig 14.16) or with both fat loss and accumulation. The thymidine analogue NRTIs (stavudine and, to a lesser extent, zidovudine) are associated with fat loss. Switching to the non-thymidine NRTIs abacavir or tenofovir will result in very gradual improvement of lipoatrophy.

Fig. 14.16 Fat loss complicating long-term use of the thymidine analogue NRTIs stavudine and zidovudine.

Previously, PIs were thought to be the cause of fat accumulation. However, recent studies have shown that all classes of antiretrovirals are associated with fat gain to the same extent. Furthermore, longitudinal studies comparing HIV-uninfected people with HIV-infected people on long-term ART show that the extent and distribution of fat gain are similar. These data suggest that fat gain is a consequence of treating HIV rather than a side-effect of ART.

Rashes

These are common but must be differentiated from the other causes described above. The NRTI abacavir typically causes a systemic hypersensitivity reaction, which is HLA-associated. HLA-B*5701 has a 100% negative predictive value for abacavir hypersensitivity. HLA testing should be done before abacavir is given and the drug should not be prescribed for people who are HLA-B*5701-positive. This is rare in people of African descent. Rechallenge must never be attempted after abacavir hypersensitivity, as fatal reactions may occur.

Drug rashes are very common with NNRTIs. When the NNRTI rash is mild and not accompanied by systemic involvement, the suspected drug is often continued and antihistamines are administered. The rash usually resolves. If it worsens or if systemic features develop, the NNRTI should be discontinued.

Other adverse effects

The NNRTI efavirenz causes insomnia, agitation, euphoria or dysphoria in many patients, but tolerance to its neuropsychiatric effects develops in a few weeks in most. The NRTI zidovudine can cause anaemia and neutropenia, and tenofovir may cause nephrotoxicity. PIs are associated with dyslipidaemias and may increase the risk of myocardial infarction.

ART in special situations

Pregnancy

All pregnant women should routinely be recommended for HIV testing at an early stage in pregnancy, with rapid tests for those presenting in or just after labour. The CD4 count falls by about 25% during pregnancy due to haemodilution. The course of HIV disease progression is not altered by pregnancy. Pre-ART, the rate of mother-to-child transmission was 15–40%, with rates being influenced by several factors (see Box 14.3, p. 391).

ART has dramatically reduced the risk of mother-to-child transmission of HIV to less than 1%. All pregnant women who qualify for ART for their own health should start treatment at the beginning of the second trimester. If they have severe disease, they should start ART in the first trimester. Two ART strategies are currently used to prevent mother-to-child transmission for women who do not yet require ongoing ART: commence standard ART and discontinue at delivery or after weaning; or zidovudine monotherapy, usually started at 28 weeks, augmented with single-dose nevirapine at delivery. The latter approach is widely used in low- and middle-income countries. A randomised controlled trial is under way in order to assess which strategy is more effective.

Caesarean section is associated with a lower risk of mother-to-child transmission than vaginal delivery, but the mode of delivery does not affect transmission risk if the viral load is suppressed on ART.

HIV is also transmitted by breastfeeding. In high-income countries, exclusive formula feeding is generally recommended. However in resource-poor settings, formula feeding is associated with a risk of infant morbidity and mortality, which may negate the benefit of not transmitting HIV to the infant. Furthermore, providing antiretrovirals to the infant (usually nevirapine monotherapy) while they are breastfeeding has been shown to reduce the risk of transmission. Therefore breastfeeding is now encouraged in resource-poor settings. Infants should be exclusively breastfed for the first

6 months, as mixed feeding (with formula or solids) is associated with a higher risk of transmission.

Diagnosis of HIV in infancy requires the detection of HIV RNA by PCR as maternal antibodies to HIV, which persist for up to 15 months, will give a false-positive result on antibody assays. PCR should ideally be carried out within 6 weeks of birth to facilitate early ART initiation, which is recommended for all infants irrespective of their CD4 percentage or clinical stage. If the baby is breastfed, the PCR should be repeated 2 weeks after weaning.

Post-exposure prophylaxis

Post-exposure prophylaxis (PEP) is recommended when the risk is deemed to be significant after a careful risk assessment, in both occupational and non-occupational settings. The first dose should be given as soon as possible, preferably within 6–8 hours. There is no point in starting PEP after 72 hours. Most guidelines recommend dual NRTIs for low-risk exposures, with the addition of either a PI or efavirenz in high-risk exposures (see Boxes 14.2 and 14.3, p. 391). Tenofovir together with emtricitabine is the most widely used dual NRTI combination, as it is well tolerated and well studied in pre-exposure prophylaxis trials. PEP should not be given if the exposed person is HIV-infected. HIV antibody testing should be performed at 6, 12 and 24 weeks after exposure.

14.21 HIV infection in old age

- **Epidemiology**: the HIV-infected population is ageing due to the life-prolonging effects of ART.
- **Immunity**: age-related decline increases the risk of infections. CD4 counts decline more rapidly as age increases over 40 years, resulting in faster disease progression. CD4 responses to ART decrease with increasing age.
- **Dementia**: HIV causes cerebral atrophy and neurocognitive disorders; therefore dementia is more common and more severe than in the HIV-uninfected elderly.
- **Vascular disease**: HIV is associated with an increased risk, exacerbated by some antiretrovirals that increase the risk of vascular disease by causing dyslipidaemia or insulin resistance.
- **Polypharmacy**: treating co-morbidities is complex due to the many drug interactions with antiretrovirals.

Prevention of HIV

An effective HIV vaccine remains elusive due to the extensive genetic diversity of HIV and the lack of a safe attenuated virus. Measures for the prevention of HIV transmission are shown in Box 14.22.

14.22 Prevention measures for HIV transmission

Sexual

- Sex education programmes in schools
- Easily accessible voluntary counselling and testing centres
- Promotion of safer sex practices (delaying sexual debut, condom use, fewer sexual partners)
- Effective ART treatment of HIV-infected individuals
- Pre-exposure prophylaxis for high-risk groups
- Male circumcision

Parenteral

- Blood product transmission: donor questionnaire, routine screening of donated blood
- Injection drug use: education, needle/syringe exchange, avoidance of 'shooting galleries', methadone maintenance programmes

Perinatal

- Routine 'opt-out' antenatal HIV antibody testing
- Measures to reduce vertical transmission (p. 409)

Occupational

- Education/training: universal precautions, needlestick injury avoidance
- Post-exposure prophylaxis

Sexually transmitted infections

15

Clinical examination in men 412

Clinical examination in women 413

Approach to patients with a suspected STI 414

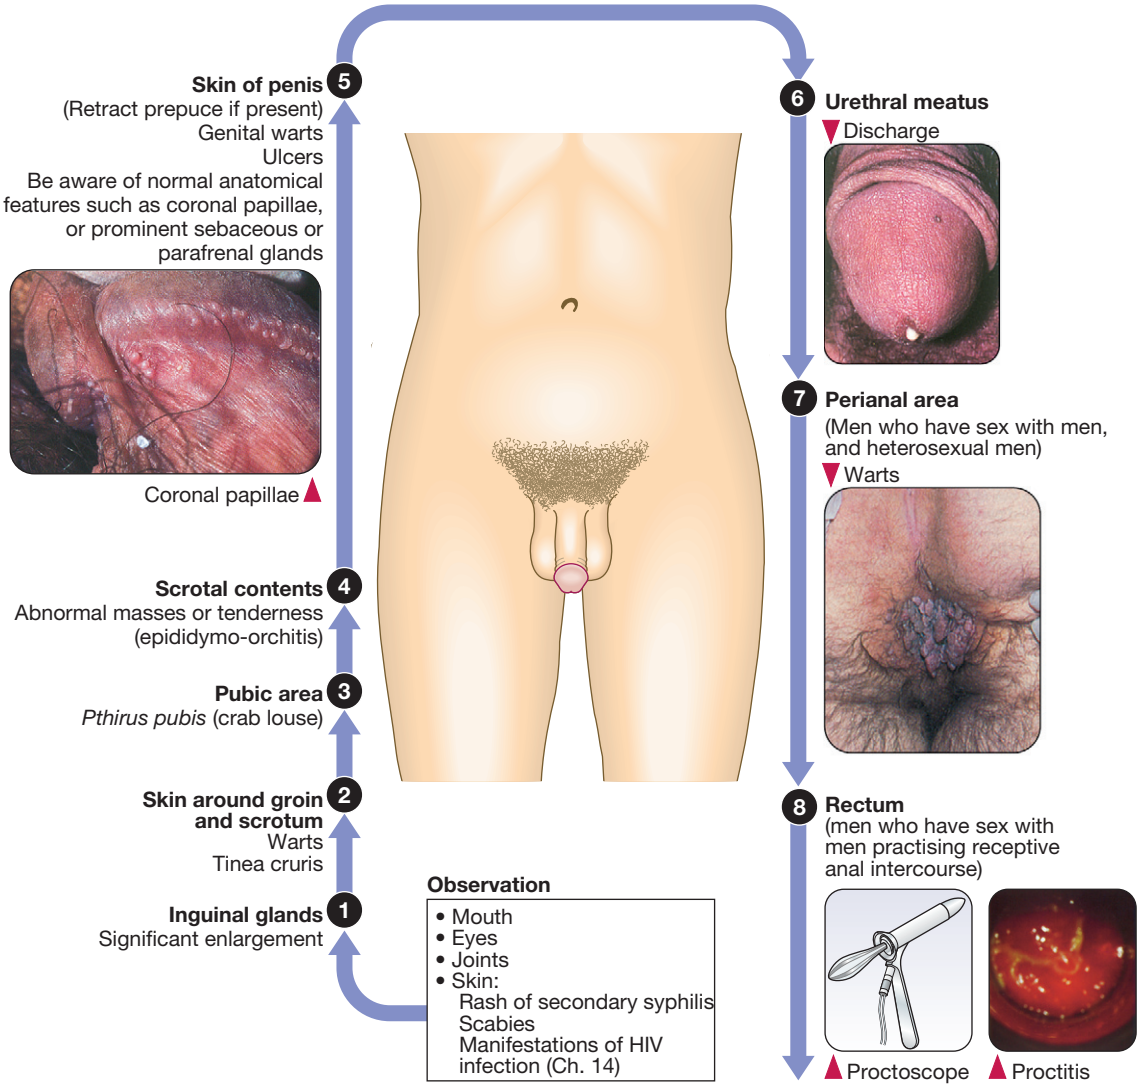
Presenting problems in men 415

- Urethral discharge 415
- Genital itch and/or rash 415
- Genital ulceration 415
- Genital lumps 416
- Proctitis in men who have sex with men 417

Presenting problems in women 417

- Vaginal discharge 417
- Lower abdominal pain 418
- Genital ulceration 418
- Genital lumps 418
- Chronic vulval pain and/or itch 418

Prevention of STI 419



Sexually transmitted bacterial infections 419

- Syphilis 419
- Gonorrhoea 422
- Chlamydial infection 423
- Other sexually transmitted bacterial infections 423

Sexually transmitted viral infections 423

- Genital herpes simplex 423
- Human papillomavirus and anogenital warts 425
- Molluscum contagiosum 426
- Viral hepatitis 426

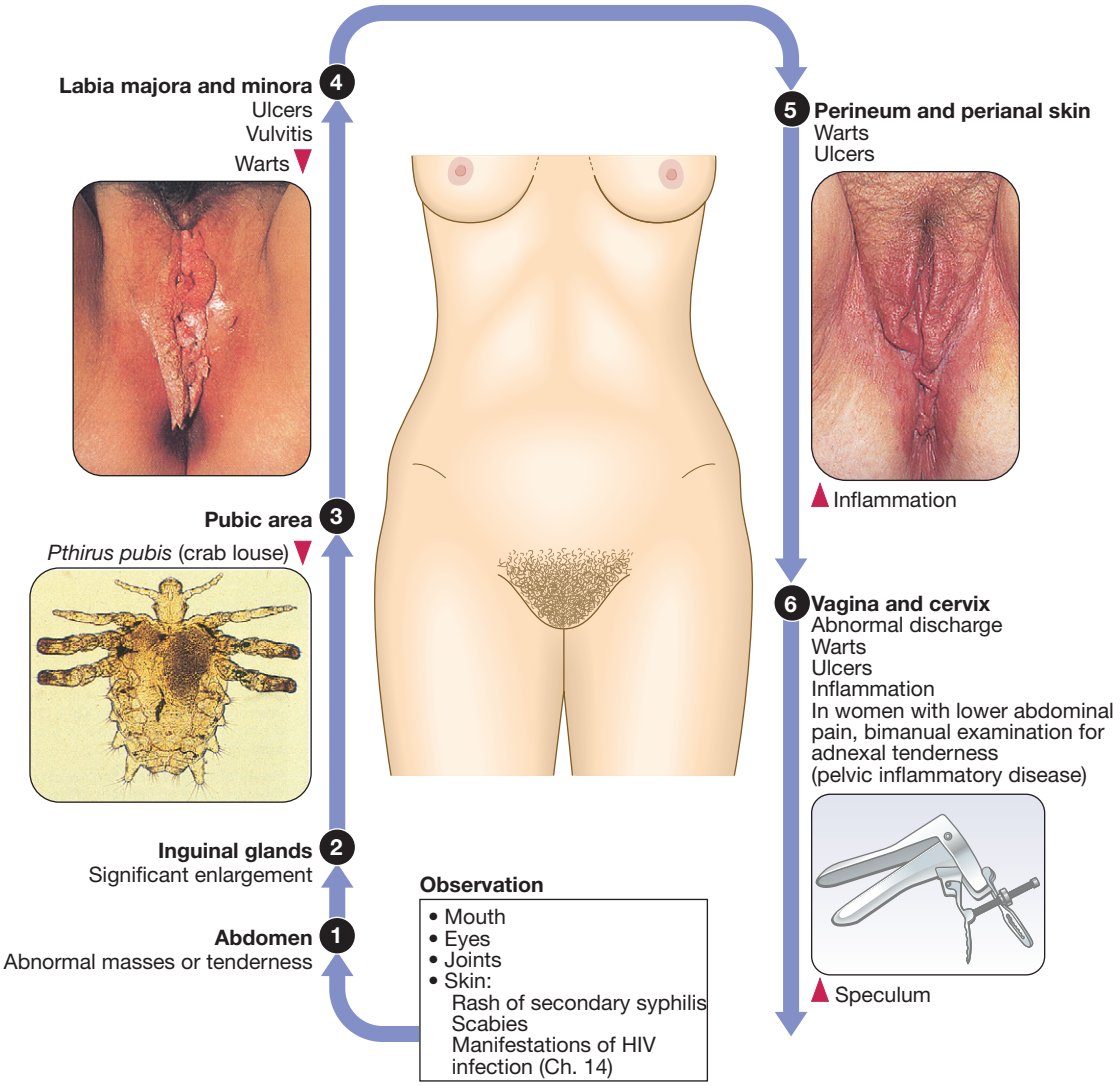
CLINICAL EXAMINATION IN MEN

Investigations for STIs in heterosexual males

- First void urine (FVU)* is the specimen of choice for the combined nucleic acid amplification test (NAAT) for gonorrhoea and chlamydia
- Alternatively, for gonorrhoea, a urethral swab plated directly on a selective medium such as modified New York City (MNYC), or sent in an appropriate transport medium, can be cultured to allow for assessment of antimicrobial sensitivities
- Serological test for syphilis (STS), e.g. enzyme immunoassay (EIA) for antitreponemal immunoglobulin (Ig) G antibody
- Human immunodeficiency virus (HIV) test (see note)

*A urethral swab can be submitted if the patient is unable to pass urine.

Investigations for STIs in men who have sex with men



- FVU,* and pharyngeal and rectal swabs for combined NAAT for gonorrhoea and chlamydia
- STS (repeat testing may be necessary in the event of negative test results in the first few weeks following exposure)
- Serological tests for hepatitis A/B (with a view to vaccination if seronegative)
- HIV test (see note)

*A urethral swab can be submitted if the patient is unable to pass urine.

HIV testing

It should always be standard practice to offer HIV testing as part of screening for STI (sexually transmitted infection) because the benefits of early diagnosis outweigh other considerations. Extensive pre-test counselling is not required in most instances, but it is important to establish efficient pathways for referral of patients at high risk for whom the clinician wishes specialist support, and for those diagnosed as HIV-positive.

CLINICAL EXAMINATION IN WOMEN

Investigations for STIs in women

- Clinician-obtained cervical or vaginal swab, or self-taken vaginal swab for combined NAAT for gonorrhoea and chlamydia
- Alternatively, for gonorrhoea, cervical and urethral swabs plated directly on a selective medium such as MNYC, or sent in appropriate transport medium, can be cultured to allow for assessment of antimicrobial sensitivities
- Wet mount for microscopy or high vaginal swab (HVS) for culture of *Trichomonas*
- STS, e.g. EIA for antitreponemal IgG antibody
- HIV test (see note)

Management goals in suspected STI

- Relief of any symptoms
- Screening for treatable STI that may not be causing symptoms
- Tracing and treatment of sexual contacts who may also be infected
- Advice to reduce risk of infection in the future

Those at particular risk from STIs*

- Sex workers, male and female
- Clients of sex workers
- Men who have sex with men
- Injecting drug users (sex for money or drugs) and their partners
- Frequent travellers

*Adapted from WHO/UNAIDS, 1997.

Insets on pp. 412–413 (*Perianal warts, coronal papillae, mucopus, inflammation*) – see p. 426.

15

Sexually transmitted infections (STIs) are a group of contagious conditions whose principal mode of transmission is by intimate sexual activity involving the moist mucous membranes of the penis, vulva, vagina, cervix, anus, rectum, mouth and pharynx, along with their adjacent skin surfaces. A wide range of infections may be sexually transmitted, including syphilis, gonorrhoea, human immunodeficiency virus (HIV), genital herpes, genital warts, chlamydia and trichomoniasis. Bacterial vaginosis and genital candidiasis are not regarded as STIs, although they are common causes of vaginal discharge in sexually active women. Chancroid, lymphogranuloma venereum (LGV) and granuloma inguinale are usually seen in tropical countries. Hepatitis viruses A, B, C and D (p. 948) may be acquired sexually, as well as by other routes.

The World Health Organization estimates that 448 million curable STIs (*Trichomonas vaginalis*, *Chlamydia trachomatis*, gonorrhoea and syphilis) occur world-wide each year. In the UK in 2010, the most common treatable STIs diagnosed were chlamydia (more than 200 000 cases) and gonorrhoea (19 000 cases). Genital warts are the second most common complaint seen in genitourinary medicine (GUM) departments. In addition to causing morbidity themselves, STIs may increase the risk of transmitting or acquiring HIV infection (Ch. 14).

As coincident infection with more than one STI is seen frequently, GUM clinics routinely offer a full set of investigations at the patient's first visit (pp. 412–413), regardless of the reason for attendance. In other settings, less comprehensive investigation may be appropriate.

The extent of the examination largely reflects the likelihood of HIV infection or syphilis. Most heterosexuals in the UK are at such low risk of these infections that routine extragenital examination is unnecessary. This is not the case in parts of the world where HIV is endemic, or for men who have sex with men (MSM) in the UK. In other words, the extent of the examination is determined by the sexual history (Box 15.1).

APPROACH TO PATIENTS WITH A SUSPECTED STI

Patients concerned about the possible acquisition of an STI are often anxious. Staff must be friendly, sympathetic and reassuring; they should have the ability to put patients at ease, whilst emphasising that clinic attendance is confidential. The history focuses on genital symptoms, with reference to genital ulceration, rash, irritation, pain, swelling and urinary symptoms, especially dysuria. In men, the clinician should ask about urethral discharge, and in women, vaginal discharge, pelvic pain or dyspareunia. Enquiry about general health should include menstrual and obstetric history, cervical cytology, recent medication, especially with antimicrobial or antiviral agents, previous STI and allergy. Immunisation status for hepatitis A and B should be noted, as should information about recreational drug use and alcohol intake.

15.1 How to take a sexual history

- In your lifetime, have your sexual partners been male, female or both?
- Do you have a regular sexual partner at present?
- If yes:
  - How long have you been together?
  - When did you last have sex with anyone else?
- If no:
  - When did you last have sex?
  - Was this a regular or a casual partner?
- Do/did you use a condom?

A detailed sexual history is imperative (see Box 15.1), as this informs the clinician of the degree of risk for certain infections, as well as specific sites that should be sampled; for example, rectal samples should be taken from men who have had unprotected anal sex with other men. Sexual partners, whether male or female, and casual or regular, should be recorded. Sexual practices – insertive or receptive vaginal, anal, orogenital or oroanal – should be noted, as should choice of contraception for women, and condom use for both sexes.

STI during pregnancy

Many STIs can be transmitted from mother to child in pregnancy, either transplacentally or during delivery. Possible outcomes are highlighted in Box 15.2.

STI in children

The presence of an STI in a child may be indicative of sexual abuse, although vertical transmission may explain some presentations in the first 2 years. In an older child and in adolescents, STI may be the result of voluntary

15.2 Possible outcomes of STI in pregnancy

Organism	Mode of transmission	Outcome for fetus/neonate	Outcome for mother
Treponema pallidum	Transplacental	Ranges from no effect to severe stigmata or miscarriage/stillbirth	None directly relating to the pregnancy
Neisseria gonorrhoeae	Intrapartum	Severe conjunctivitis	Possibility of ascending infection postpartum
Chlamydia trachomatis	Intrapartum	Conjunctivitis, pneumonia	Possibility of ascending infection postpartum
Herpes simplex	Usually intrapartum, but transplacental infection may occur rarely	Ranges from no effect to severe disseminated infection	Rarely, primary infection during 2nd/3rd trimesters becomes disseminated, with high maternal mortality
Human papillomaviruses	Intrapartum	Anogenital warts or laryngeal papillomas are very rare	Warts may become more florid during pregnancy, but usually regress postpartum

sexual activity. Specific issues regarding the management of STI and other infections in adolescence are discussed in Box 13.27 (p. 313).

PRESENTING PROBLEMS IN MEN

Urethral discharge

In the UK the most important causes of urethral discharge are gonorrhoea and chlamydia. In a significant minority of cases, tests for both of these infections are negative, a scenario often referred to as non-specific urethritis (NSU). Some of these cases may be caused by *Trichomonas vaginalis*, herpes simplex virus (HSV), mycoplasmas or ureaplasmas. A small minority seem not to have an infectious aetiology.

Gonococcal urethritis usually causes symptoms within 7 days of exposure. The discharge is typically profuse and purulent. Chlamydial urethritis has an incubation period of 1–4 weeks, and tends to result in milder symptoms than gonorrhoea; there is overlap, however, and microbiological confirmation should always be sought.

Investigations

A presumptive diagnosis of urethritis can be made from a Gram-stained smear of the urethral exudate (Fig. 15.1), which will demonstrate significant numbers of polymorphonuclear leucocytes (≥ 5 per high-power field). A working diagnosis of gonococcal urethritis is made if Gram-negative intracellular diplococci (GNDC) are seen; if no GNDC are seen, a label of NSU is applied.

If microscopy is not available, urine samples and/or swabs should be taken and empirical antimicrobials prescribed. A first-void urine (FVU) sample should be submitted for a combined nucleic acid amplification test (NAAT) for gonorrhoea and chlamydia; a urethral swab is an alternative if the patient cannot pass urine. When gonorrhoea is suspected, a urethral swab should be sent for culture and antimicrobial sensitivities of *Neisseria gonorrhoeae*. Tests for other potential causes of urethritis are not performed routinely.

A swab should also be taken from the pharynx because gonococcal infection here is not reliably eradicated by single-dose therapy. In MSM, swabs for gonorrhoea and chlamydia should be taken from the rectum.

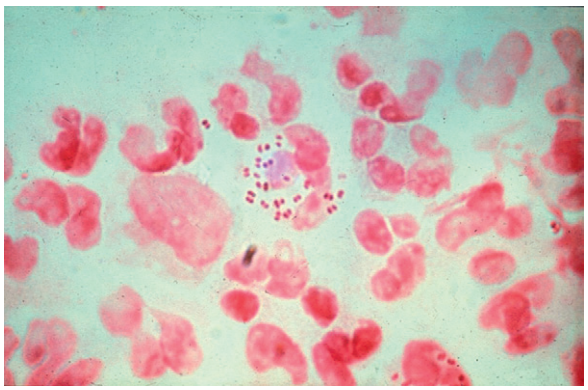


Fig. 15.1 A Gram-stained urethral smear from a man with gonococcal urethritis. Gram-negative diplococci are seen within polymorphonuclear leucocytes.

Management

This depends on local epidemiology and the availability of diagnostic resources. Treatment is often presumptive, with prescription of multiple antimicrobials to cover the possibility of gonorrhoea and/or chlamydia. This is likely to include a single-dose treatment for gonorrhoea, which is desirable because it eliminates the risk of non-adherence. The recommended agents for treating gonorrhoea vary according to local antimicrobial resistance patterns (p. 422). Appropriate treatment for chlamydia (p. 423) should also be prescribed because concurrent infection is present in up to 50% of men with gonorrhoea. Non-gonococcal, non-chlamydial urethritis is treated as for chlamydia.

Patients should be advised to avoid sexual contact until it is confirmed that any infection has resolved and, whenever possible, recent sexual contacts should be traced. The task of contact tracing – also called partner notification – is best performed by trained nurses based in GUM clinics; it is standard practice in the UK to treat current sexual partners of men with gonococcal or non-specific urethritis without waiting for microbiological confirmation.

If symptoms clear, a routine test of cure is not necessary, but patients should be re-interviewed to confirm that there was no immediate vomiting or diarrhoea after treatment, that there has been no risk of re-infection, and that traceable partners have sought medical advice.

Genital itch and/or rash

Patients may present with many combinations of penile/genital symptoms, which may be acute or chronic, and infectious or non-infectious. Box 15.3 provides a guide to diagnosis.

Balanitis refers to inflammation of the glans penis, often extending to the under-surface of the prepuce, in which case it is called balanoposthitis. Tight prepuce and poor hygiene may be aggravating factors. Candidiasis is sometimes associated with immune deficiency, diabetes mellitus, and the use of broad-spectrum antimicrobials, corticosteroids or antimitotic drugs. Local saline bathing is usually helpful, especially when no cause is found.

Genital ulceration

The most common cause of ulceration is genital herpes. Classically, multiple painful ulcers affect the glans, coronal sulcus or shaft of penis (Fig. 15.2), but solitary lesions occur rarely. Perianal ulcers may be seen in MSM. The diagnosis is made by gently scraping material from lesions and sending this in an appropriate transport medium for culture or detection of HSV DNA by polymerase chain reaction (PCR). Increasingly, laboratories will also test for *Treponema pallidum* by PCR.

In the UK, the possibility of syphilis or any other ulcerating STI is much less likely unless the patient is an MSM and/or has had a sexual partner from a region where tropical STIs are more common. The classic lesion

15.3 Differential diagnosis of genital itch and/or rash in men

Likely diagnosis	Acute or chronic	Itch	Pain	Discharge (non-urethral)	Specific characteristics	Diagnostic test	Treatment
Subclinical urethritis	Either	±	–	±	Often intermittent	Gram stain and urethral swabs	As for urethral discharge
Candidiasis	Acute	✓	–	White	Postcoital	Microscopy	Antifungal cream, e.g. clotrimazole
Anaerobic (erosive) balanitis	Acute	±	–	Yellow	Offensive	Microscopy	Saline bathing ± metronidazole
***Pthirus pubis* ('crab lice') infection**	Either	✓	–	–	Lice and nits seen attached to pubic hairs	Can be by microscopy, but usually visual	According to local policy – often permethrin
Lichen planus (p. 1289)	Either	±	–	–	Violaceous papules ± Wickham's striae	Clinical	None or mild topical corticosteroid, e.g. hydrocortisone
Lichen sclerosus	Chronic	±	–	–	Ivory-white plaques, scarring	Clinical or biopsy	Strong topical corticosteroid, e.g. clobetasol
Plasma cell balanitis of Zoon	Chronic	✓	–	±	Shiny, inflamed circumscribed areas	Clinical or biopsy	Strong topical corticosteroid, e.g. clobetasol
Dermatoses, e.g. eczema or psoriasis	Either	✓	–	–	Similar to lesions elsewhere on skin	Clinical	Mild topical corticosteroid, e.g. hydrocortisone
Genital herpes	Acute	±	✓	–	Atypical ulcers are not uncommon	Swab for HSV PCR	Oral antiviral, e.g. aciclovir
Circinate balanitis	Either	–	–	–	Painless erosions with raised edges; usually as part of Reiter's syndrome (p. 1107)	Clinical	Mild topical steroid, e.g. hydrocortisone

(HSV PSR = herpes simplex virus polymerase chain reaction)

Fig. 15.2 Penile herpes simplex (HSV-2) infection.

of primary syphilis (chancre) is single, painless and indurated; however, multiple lesions are seen rarely and anal chancres are often painful. Diagnosis is made in GUM clinics by dark-ground microscopy and/or PCR on a swab from a chancre, but in other settings by serological tests for syphilis (p. 420). Other rare infective causes seen in the UK include varicella zoster virus (p. 316) and trauma with secondary infection. Tropical STI, such as chancroid, LGV and granuloma inguinale, are described in Box 15.12 (p. 424). Inflammatory causes include Stevens–Johnson syndrome (pp. 1264 and 1302), Behçet's syndrome (p. 1107) and fixed drug reactions. In older patients, malignant and pre-malignant conditions, such as squamous cell carcinoma and erythroplasia of Queyrat (intra-epidermal carcinoma), should be considered.

Genital lumps

The most common cause of genital 'lumps' is warts (p. 425). These are classically found in areas of friction during sex, such as the parafrenal skin and prepuce of the penis. Warts may also be seen in the urethral meatus, and less commonly on the shaft or around the base of the penis. Perianal warts are surprisingly common in men who do not have anal sex.

The differential diagnosis includes molluscum contagiosum and skin tags. Adolescent boys may confuse normal anatomical features such as coronal papillae (p. 412), parafrenal glands or sebaceous glands (Fordyce spots) with warts.

Proctitis in men who have sex with men

STIs that may cause proctitis in MSM include gonorrhoea, chlamydia, herpes and syphilis. The substrains of *Chlamydia trachomatis* that cause LGV (L1–3) have been associated with outbreaks of severe proctitis in Northern Europe, including the UK. Symptoms include mucopurulent anal discharge, rectal bleeding, pain and tenesmus.

Examination may show mucopus and erythema with contact bleeding (p. 412). In addition to the diagnostic tests on page 412, a PCR test for HSV and a request for identification of the LGV substrain should be arranged if chlamydial infection is detected. Treatment is directed at the individual infections (see below).

MSM may also present with gastrointestinal symptoms from infection with organisms such as *Entamoeba histolytica* (p. 367), *Shigella* spp. (p. 345), *Campylobacter* spp. (p. 342) and *Cryptosporidium* spp. (p. 369).

PRESENTING PROBLEMS IN WOMEN

Vaginal discharge

The natural vaginal discharge may vary considerably, especially under differing hormonal influences such as puberty, pregnancy or prescribed contraception. A sudden or recent change in discharge, especially if associated with alteration of colour and/or smell, or vulval itch/irritation, is more likely to indicate an infective cause than a gradual or long-standing change.

Local epidemiology is particularly important when assessing possible causes. In the UK, most cases of vaginal discharge are not sexually transmitted, being due to either candidal infection or bacterial vaginosis (BV). World-wide, the most common treatable STI causing vaginal discharge is trichomoniasis; other possibilities include gonorrhoea and chlamydia. HSV may cause increased discharge, although vulval pain and dysuria are usually the predominant symptoms. Non-infective causes include retained tampons, malignancy and/or fistulae.

Speculum examination often allows a relatively accurate diagnosis, with appropriate treatment to follow (Box 15.4). If the discharge is homogeneous and off-white in colour, vaginal pH is greater than 4.5, and Gram stain microscopy reveals scanty or absent lactobacilli with significant numbers of Gram-variable organisms, some of which may be coating vaginal squamous cells (so-called Clue cells, Fig. 15.3), the likely diagnosis is BV. If there is vulval and vaginal erythema, the discharge is curdy in nature, vaginal pH is less than 4.5, and Gram stain microscopy reveals fungal spores and pseudohyphae, the diagnosis is candidiasis. Trichomoniasis tends to cause a profuse yellow or green discharge and is usually associated with significant vulvovaginal inflammation. Diagnosis is made by observing motile

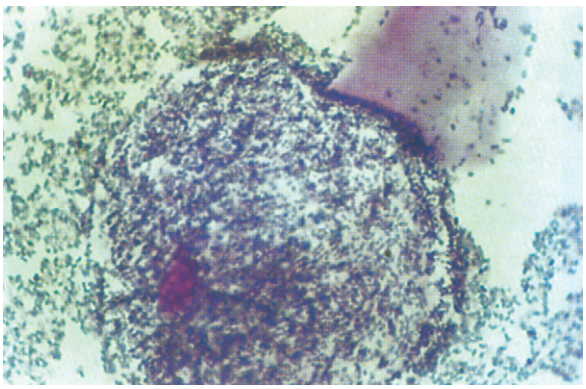

Fig. 15.3 Gram stain of a Clue cell from a patient with bacterial vaginosis. The margin of this vaginal epithelial cell is obscured by a coating of anaerobic organisms. From McMillan, et al. 2002 – see p. 426.

15.4 Infections that cause vaginal discharge

Cause	Clinical features	Treatment (in pregnancy seek specialist advice)
Candidiasis	Vulval and vaginal inflammation Curdy white discharge adherent to walls of vagina Low vaginal pH	Clotrimazole[1] 500 mg pessary once at night and clotrimazole cream twice daily *or* Econazole[1] pessary 150 mg for 3 nights and econazole cream twice daily (topical creams for 7 days) *or* Fluconazole[2] 150 mg orally stat
Trichomoniasis	Vulval and vaginal inflammation Frothy yellow/green discharge	Metronidazole[3] 400 mg twice daily orally for 5–7 days *or* Metronidazole[3] 2 g orally as a single dose
Bacterial vaginosis	No inflammation White homogeneous discharge High vaginal pH	Metronidazole[3] 2 g stat or 400 mg twice daily orally for 5–7 days Metronidazole[3] vaginal gel 0.75% daily for 5 days Clindamycin[1,4] vaginal cream 2% daily for 7 days
Streptococcal/staphylococcal infection	Purulent vaginal discharge	Choice of antibiotic depends on sensitivity tests

[1]Clotrimazole, econazole and clindamycin damage latex condoms and diaphragms. [2]Avoid in pregnancy and breastfeeding.
[3]Avoid alcoholic drinks until 48 hours after finishing treatment. Avoid high-dose regimens in pregnancy or breastfeeding.
[4]Pseudomembranous colitis has been reported with the use of clindamycin cream.

flagellate protozoa on a wet-mount microscopy slide of vaginal material.

If examination reveals the discharge to be cervical in origin, the possibility of chlamydial or gonococcal infection is increased and appropriate cervical or vaginal swabs should be taken (p. 413). In addition, Gram stain of cervical and urethral material may reveal GNDC, allowing presumptive treatment for gonorrhoea to be given. If gonococcal cervicitis is suspected, swabs should also be taken from the pharynx and rectum; infections at these sites are not reliably eradicated by single-dose therapy and a test of cure will therefore be required.

GUM clinics in the UK may offer sexually active women presenting with vaginal discharge an STI screen (p. 413). In other settings, such as primary care or gynaecology, testing for chlamydia and gonorrhoea may be considered in young women (< 25 years old), those who have changed partner recently, and those not using a barrier method of contraception, even if a non-STI cause of discharge is suspected clinically.

Treatment of infections causing vaginal discharge is shown in Box 15.4.

Lower abdominal pain

Pelvic inflammatory disease (PID, infection or inflammation of the Fallopian tubes and surrounding structures) is part of the extensive differential diagnosis of lower abdominal pain in women, especially those who are sexually active. The possibility of PID is increased if, in addition to acute/subacute pain, there is dyspareunia, abnormal vaginal discharge and/or bleeding. There may also be systemic features, such as fever and malaise. On examination, lower abdominal pain is usually bilateral, and vaginal examination reveals adnexal tenderness with or without cervical excitation. Unfortunately, a definitive diagnosis can only be made by laparoscopy. A pregnancy test should be performed (as well as the diagnostic tests on p. 413) because the differential diagnosis includes ectopic pregnancy.

Broad-spectrum antibiotics, including those active against gonorrhoea and chlamydia, such as ofloxacin and metronidazole, should be prescribed if PID is suspected, along with appropriate analgesia. Delaying treatment increases the likelihood of adverse sequelae, such as abscess formation, and tubal scarring that may lead to ectopic pregnancy or infertility. Hospital admission may be indicated for severe symptoms.

Genital ulceration

The most common cause of ulceration is genital herpes. Classically, multiple painful ulcers affect the introitus, labia and perineum, but solitary lesions occur rarely. Inguinal lymphadenopathy and systemic features, such as fever and malaise, are more common than in men. Diagnosis is made by gently scraping material from lesions and sending this in an appropriate transport medium for culture or detection of HSV DNA by PCR. Increasingly, laboratories will also test such samples for *Treponema pallidum* by PCR. In the UK, the possibility of any other ulcerating STI is unlikely unless the patient has had a sexual partner from a region where tropical STIs are more common (see Box 15.12, p. 424).

Inflammatory causes include lichen sclerosus, Stevens–Johnson syndrome (pp. 1264 and 1302), Behçet's syndrome (p. 1119) and fixed drug reactions. In older patients, malignant and pre-malignant conditions, such as squamous cell carcinoma, should be considered.

Genital lumps

The most common cause of genital 'lumps' is warts. These are classically found in areas of friction during sex, such as the fourchette and perineum. Perianal warts are surprisingly common in women who do not have anal sex.

The differential diagnosis includes molluscum contagiosum, skin tags and normal papillae or sebaceous glands.

Chronic vulval pain and/or itch

Women may present with a range of chronic symptoms that may be intermittent or continuous (Box 15.5).

Recurrent candidiasis may lead to hypersensitivity to candidal antigens, with itch and erythema becoming more prominent than increased discharge. Effective

15.5 Chronic vulval pain and/or itch

Likely diagnosis	Itch	Pain	Specific characteristics	Diagnostic test	Treatment
Candidiasis	✓	±	Usually cyclical	Microscopy	Oral antifungal, e.g. fluconazole 150 mg
Lichen planus	±	–	Violaceous papules ± Wickham's striae	Clinical	No treatment, or mild topical corticosteroid, e.g. hydrocortisone
Lichen sclerosus	±	–	Ivory-white plaques, scarring ± labial resorption	Clinical or biopsy	Strong topical corticosteroid, e.g. clobetasol
Vestibulitis	–	✓	Dyspareunia common, pain on touching erythematous area	Clinical	Refer to specialist vulva clinic
Vulvodynia	–	✓	Pain usually neuropathic in nature	Clinical	Refer to specialist vulva clinic
Dermatoses, e.g. eczema or psoriasis	✓	–	Similar to lesions elsewhere on skin	Clinical	Mild topical corticosteroid, e.g. hydrocortisone
Genital herpes	±	✓	Atypical ulcers are not uncommon	Swab for HSV PCR	Oral antiviral, e.g. aciclovir

treatment may require regular oral antifungals, e.g. fluconazole 150 g once every 2–4 weeks plus a combined antifungal/corticosteroid cream such as Daktacort or Canesten HC.

PREVENTION OF STI

Case-finding

Early diagnosis and treatment facilitated by active case-finding will help to reduce the spread of infection by limiting the period of infectivity; tracing and treating sexual partners will also reduce the risk of re-infection. Unfortunately, the majority of individuals with an STI are asymptomatic and therefore unlikely to seek medical attention. Improving access to diagnosis in primary care or non-medical settings, especially through opportunistic testing, may help. However, the impact of medical intervention through improved access alone is likely to be small.

Changing behaviour

The prevalence of STIs is driven largely by sexual behaviour. Primary prevention encompasses efforts to delay the onset of sexual activity and limit the number of sexual partners thereafter. Encouraging the use of barrier methods of contraception will also help to reduce the risk of transmitting or acquiring STIs. This is especially important in the setting of 'sexual concurrency', where sexual relationships overlap.

Unfortunately, there is contradictory evidence as to which (if any) interventions can reduce sexual activity. Knowledge alone does not translate into behaviour change, and broader issues, such as poor parental role modelling, low self-esteem, peer group pressure in the context of the increased sexualisation of our societies, gender power imbalance and homophobia, all need to be addressed. Throughout the world there is a critical need to enable women to protect themselves from undisciplined and coercive male sexual activity. Economic collapse and the turmoil of war regularly lead to situations where women are raped or must turn to prostitution to feed themselves and their children, and an inability to negotiate safe sex increases their risk of acquiring STI, including HIV.

SEXUALLY TRANSMITTED BACTERIAL INFECTIONS

Syphilis

Syphilis is caused by infection, through abrasions in the skin or mucous membranes, with the spirochaete *Treponema pallidum*. In adults the infection is usually sexually acquired; however, transmission by kissing, blood transfusion and percutaneous injury has been reported. Transplacental infection of the fetus can occur.

The natural history of untreated syphilis is variable. Infection may remain latent throughout, or clinical features may develop at any time. The classification of syphilis is shown in Box 15.6. All infected patients should be treated. Penicillin remains the drug of choice for all stages of infection.

Acquired syphilis

Early syphilis

Primary syphilis

The incubation period is usually between 14 and 28 days, with a range of 9–90 days. The primary lesion or chancre (Fig. 15.4) develops at the site of infection, usually in the genital area. A dull red macule develops, becomes papular and then erodes to form an indurated ulcer (chancre). The draining inguinal lymph nodes may become moderately enlarged, mobile, discrete and rubbery. The chancre and the lymph nodes are both painless and non-tender, unless there is concurrent or secondary infection. Without treatment, the chancre will resolve within 2–6 weeks to leave a thin atrophic scar.

Chancres may develop on the vaginal wall and on the cervix. Extragenital chancres are found in about 10% of patients, affecting sites such as the finger, lip, tongue, tonsil, nipple, anus or rectum. Anal chancres often resemble fissures and may be painful.

Secondary syphilis

This occurs 6–8 weeks after the development of the chancre, when treponemes disseminate to produce a multisystem disease. Constitutional features, such as mild fever, malaise and headache, are common. Over 75% of patients present with a rash on the trunk and limbs that may later involve the palms and soles; this is initially macular but evolves to maculopapular or papular forms, which are generalised, symmetrical and non-irritable. Scales may form on the papules later. The rash affects the trunk and proximal limbs, and characteristically involves the palms, soles and face. Lesions

15.6 Classification of syphilis

Stage	Acquired	Congenital
Early	Primary Secondary Latent	Clinical and latent
Late	Latent Benign tertiary Cardiovascular Neurosyphilis	Clinical and latent

Fig. 15.4 Primary syphilis. A painless ulcer (chancre) is shown in the coronal sulcus of the penis. This is usually associated with inguinal lymphadenopathy.

are red, changing to a 'gun-metal' grey as they resolve. Without treatment, the rash may last for up to 12 weeks. Condylomata lata (papules coalescing to plaques) may develop in warm, moist sites such as the vulva or perianal area. Generalised non-tender lymphadenopathy is present in over 50% of patients. Mucosal lesions, known as mucous patches, may affect the genitalia, mouth, pharynx or larynx and are essentially modified papules, which become eroded. Rarely, confluence produces characteristic 'snail track ulcers' in the mouth.

Other features, such as meningitis, cranial nerve palsies, anterior or posterior uveitis, hepatitis, gastritis, glomerulonephritis or periostitis, are sometimes seen. Neurological involvement may be more common in HIV-positive patients.

The differential diagnosis of secondary syphilis can be extensive, but in the context of a suspected STI, primary HIV infection is the most important alternative condition to consider (see Ch. 14). Non-STI conditions that mimic the rash include psoriasis, pityriasis rosea, scabies, allergic drug reaction, erythema multiforme and tinea versicolor.

The clinical manifestations of secondary syphilis will resolve without treatment but relapse may occur, usually within the first year of infection. Thereafter, the disease enters the phase of latency.

Latent syphilis

This phase is characterised by the presence of positive syphilis serology or the diagnostic cerebrospinal fluid (CSF) abnormalities of neurosyphilis in an untreated patient with no evidence of clinical disease. It is divided into early latency (within 2 years of infection), when syphilis may be transmitted sexually, and late latency, when the patient is no longer sexually infectious. Transmission of syphilis from a pregnant woman to her fetus, and rarely by blood transfusion, is possible for several years following infection.

Late syphilis

Late latent syphilis

This may persist for many years or for life. Without treatment, over 60% of patients might be expected to suffer little or no ill health. Coincidental prescription of antibiotics for other illnesses, such as respiratory tract or skin infections, may treat latent syphilis serendipitously.

Benign tertiary syphilis

This may develop between 3 and 10 years after infection but is now rarely seen in the UK. Skin, mucous membranes, bone, muscle or viscera can be involved. The characteristic feature is a chronic granulomatous lesion called a gumma, which may be single or multiple. Healing with scar formation may impair the function of the structure affected. Skin lesions may take the form of nodules or ulcers, whilst subcutaneous lesions may ulcerate with a gummy discharge. Healing occurs slowly, with the formation of characteristic tissue paper scars. Mucosal lesions may occur in the mouth, pharynx, larynx or nasal septum, appearing as punched-out ulcers. Of particular importance is gummatous involvement of the tongue, healing of which may lead to leucoplakia with the attendant risk of malignant change. Gummas of the tibia, skull, clavicle and sternum have been described, as has involvement of the brain, spinal cord, liver, testis and, rarely, other organs. Resolution of active disease should follow treatment, though some tissue damage may be permanent. Paroxysmal cold haemoglobinuria (p. 1031) may be seen.

Cardiovascular syphilis

This may present many years after initial infection. Aortitis, which may involve the aortic valve and/or the coronary ostia, is the key feature. Clinical features include aortic incompetence, angina and aortic aneurysm (p. 603). The condition typically affects the ascending aorta and sometimes the aortic arch; aneurysm of the descending aorta is rare. Treatment with penicillin will not correct anatomical damage and surgical intervention may be required.

Neurosyphilis

This may also take years to develop. Asymptomatic infection is associated with CSF abnormalities in the absence of clinical signs. Meningovascular disease, tabes dorsalis and general paralysis of the insane constitute the symptomatic forms (p. 1209). Neurosyphilis and cardiovascular syphilis may coexist and are sometimes referred to as quaternary syphilis.

Congenital syphilis

Congenital syphilis is rare where antenatal serological screening is practised. Antisyphilitic treatment in pregnancy treats the fetus, if infected, as well as the mother.

Treponemal infection may give rise to a variety of outcomes after 4 months of gestation, when the fetus becomes immunocompetent:

- miscarriage or stillbirth, prematurely or at term
- birth of a syphilitic baby (a very sick baby with hepatosplenomegaly, bullous rash and perhaps pneumonia)
- birth of a baby who develops signs of early congenital syphilis during the first few weeks of life (Box 15.7)
- birth of a baby with latent infection who either remains well or develops congenital syphilis/stigmata later in life (see Box 15.7).

Investigations in adult cases

Treponema pallidum may be identified in serum collected from chancres, or from moist or eroded lesions in secondary syphilis using a dark-field microscope, a direct fluorescent antibody test or PCR.

The serological tests for syphilis are listed in Box 15.8. Many centres use treponemal EIAs for IgG and IgM antibodies to screen for syphilis. EIA for antitreponemal IgM becomes positive at approximately 2 weeks, whilst non-treponemal tests become positive about 4 weeks after primary syphilis. All positive results in asymptomatic patients must be confirmed by repeat tests.

Biological false positive reactions occur occasionally; these are most commonly seen with Venereal Diseases Research Laboratory (VDRL) or rapid plasma reagin (RPR) tests (when treponemal tests will be negative). Acute false-positive reactions may be associated with infections, such as infectious mononucleosis, chickenpox and malaria, and may also occur in pregnancy. Chronic false-positive reactions may be associated with autoimmune diseases. False-negative results for non-treponemal tests may be found in secondary syphilis

15.7 Clinical features of congenital syphilis

Early congenital syphilis (neonatal period)

- Maculopapular rash
- Condylomata lata
- Mucous patches
- Fissures around mouth, nose and anus
- Rhinitis with nasal discharge (snuffles)
- Hepatosplenomegaly
- Osteochondritis/periostitis
- Generalised lymphadenopathy
- Choroiditis
- Meningitis
- Anaemia/thrombocytopenia

Late congenital syphilis

- Benign tertiary syphilis
- Periostitis
- Paroxysmal cold haemoglobinuria
- Neurosyphilis
- 8th nerve deafness
- Interstitial keratitis
- Clutton's joints (painless effusion into knee joints)

Stigmata

- Hutchinson's incisors (anterior–posterior thickening with notch on narrowed cutting edge)
- Mulberry molars (imperfectly formed cusps/deficient dental enamel)
- High arched palate
- Maxillary hypoplasia
- Saddle nose (following snuffles)
- Rhagades (radiating scars around mouth, nose and anus following rash)
- Salt and pepper scars on retina (from choroiditis)
- Corneal scars (from interstitial keratitis)
- Sabre tibia (from periostitis)
- Bossing of frontal and parietal bones (healed periosteal nodes)

because extremely high antibody levels can prevent the formation of the antibody–antigen lattice necessary for the visualisation of the flocculation reaction (the prozone phenomenon).

In benign tertiary and cardiovascular syphilis, examination of CSF should be considered because asymptomatic neurological disease may coexist. The CSF should also be examined in patients with clinical signs of neurosyphilis (p. 1209) and in both early and late congenital syphilis. Positive STS may be found in patients who are being investigated for neurological disease, especially dementia. In many instances, the serology reflects previous infection unrelated to the presenting complaint, especially when titres are low. Examination of CSF is occasionally necessary.

Chest X-ray, electrocardiogram (ECG) and echocardiogram are useful in the investigation of cardiovascular syphilis. Biopsy may be required to diagnose gumma.

Endemic treponematoses, such as yaws, endemic (non-venereal) syphilis (bejel) and pinta (pp. 332–333), are caused by treponemes that are morphologically indistinguishable from *T. pallidum* and cannot be differentiated by serological tests. A VDRL or RPR test may help to elucidate the correct diagnosis because adults with late yaws usually have low titres.

Investigations in suspected congenital syphilis

Passively transferred maternal antibodies from an adequately treated mother may give rise to positive serological tests in her baby. In this situation, non-treponemal tests should become negative within 3–6 months of birth. A positive EIA test for antitreponemal IgM suggests early congenital syphilis. A diagnosis of congenital syphilis mandates investigation of the mother, her partner and any siblings.

15.8 Serological tests for syphilis

Non-treponemal (non-specific) tests

- Venereal Diseases Research Laboratory (VDRL) test
- Rapid plasma reagin (RPR) test

Treponemal (specific) antibody tests

- Treponemal antigen-based enzyme immunoassay (EIA) for IgG and IgM
- *T. pallidum* haemagglutination assay (TPHA)
- *T. pallidum* particle agglutination assay (TPPA)
- Fluorescent treponemal antibody-absorbed (FTA-ABS) test

Management

Penicillin is the drug of choice. Currently, a single dose of 2.4 megaunits of intramuscular benzathine penicillin is recommended for early syphilis (< 2 years' duration), with three doses at weekly intervals being recommended in late syphilis. Doxycycline is indicated for patients allergic to penicillin, except in pregnancy (see below). Azithromycin is a further alternative. All patients must be followed up to ensure cure, and partner notification is of particular importance. Resolution of clinical signs in early syphilis with declining titres for non-treponemal tests, usually to undetectable levels within 6 months for primary syphilis and 12–18 months for secondary syphilis, is an indicator of successful treatment. Specific treponemal antibody tests may remain positive for life. In patients who have had syphilis for many years there may be little serological response following treatment.

Pregnancy

Penicillin is the treatment of choice in pregnancy. Erythromycin stearate can be given if there is penicillin hypersensitivity, but crosses the placenta poorly; the newborn baby must therefore be treated with a course of penicillin and consideration given to retreating the mother. Some specialists recommend penicillin desensitisation for pregnant mothers so that penicillin can be given during temporary tolerance. The author has successfully prescribed ceftriaxone 250 mg IM for 10 days in this situation. Babies should be treated in hospital with the help of a paediatrician.

Treatment reactions

- *Anaphylaxis.* Penicillin is a common cause; on-site facilities should be available for management (p. 91).
- *Jarisch–Herxheimer reaction*. This is an acute febrile reaction that follows treatment and is characterised by headache, malaise and myalgia; it resolves within 24 hours. It is common in early syphilis and rare in late syphilis. Fetal distress or premature labour can occur in pregnancy. The reaction may also cause worsening of neurological (cerebral artery occlusion) or ophthalmic (uveitis, optic neuritis) disease, myocardial ischaemia (inflammation of the coronary ostia) and laryngeal stenosis (swelling of a gumma). Prednisolone

10–20 mg orally three times daily for 3 days is recommended to prevent the reaction in patients with these forms of the disease; antisyphilitic treatment can be started 24 hours after introducing corticosteroids. In high-risk situations it is wise to initiate therapy in hospital.

- *Procaine reaction.* Fear of impending death occurs immediately after the accidental intravenous injection of procaine penicillin and may be associated with hallucinations or fits. Symptoms are short-lived, but verbal assurance and sometimes physical restraint are needed. The reaction can be prevented by aspiration before intramuscular injection to ensure the needle is not in a blood vessel.

Gonorrhoea

Gonorrhoea is caused by infection with *Neisseria gonorrhoeae* and may involve columnar epithelium in the lower genital tract, rectum, pharynx and eyes. Transmission is usually the result of vaginal, anal or oral sex. Gonococcal conjunctivitis may be caused by accidental infection from contaminated fingers. Untreated mothers may infect babies during delivery, resulting in ophthalmia neonatorum (Fig. 15.5). Infection of children beyond the neonatal period usually indicates sexual abuse.

Clinical features

The incubation period is usually 2–10 days. In men the anterior urethra is commonly infected, causing urethral discharge and dysuria, but symptoms are absent in about 10% of cases. Examination will usually show a mucopurulent or purulent urethral discharge. Rectal infection in MSM is usually asymptomatic but may present with anal discomfort, discharge or rectal bleeding. Proctoscopy may reveal either no abnormality, or clinical evidence of proctitis (see p. 417) such as inflamed rectal mucosa and mucopus.

In women, the urethra, paraurethral glands/ducts, Bartholin's glands/ducts or endocervical canal may be infected. The rectum may also be involved either due to contamination from a urogenital site or as a result of anal sex. Occasionally, the rectum is the only site infected.

Fig. 15.5 Gonococcal ophthalmia neonatorum. From McMillan and Scott 2000 – see p. 426.

About 80% of women who have gonorrhoea are asymptomatic. There may be vaginal discharge or dysuria but these symptoms are often due to additional infections, such as chlamydia (see below), trichomoniasis or candidiasis, making full investigation essential (p. 413). Lower abdominal pain, dyspareunia and intermenstrual bleeding may be indicative of PID. Clinical examination may show no abnormality, or pus may be expressed from urethra, paraurethral ducts or Bartholin's ducts. The cervix may be inflamed, with mucopurulent discharge and contact bleeding.

Pharyngeal gonorrhoea is the result of receptive oro-genital sex and is usually symptomless. Gonococcal conjunctivitis is an uncommon complication, presenting with purulent discharge from the eye(s), severe inflammation of the conjunctivae and oedema of the eyelids, pain and photophobia. Gonococcal ophthalmia neonatorum presents similarly with purulent conjunctivitis and oedema of the eyelids. Conjunctivitis must be treated urgently to prevent corneal damage.

Disseminated gonococcal infection (DGI) is seen rarely, and typically affects women with asymptomatic genital infection. Symptoms include arthritis of one or more joints, pustular skin lesions and fever. Gonococcal endocarditis has been described.

Investigations

Gram-negative diplococci may be seen on microscopy of smears from infected sites (see Fig. 15.1, p. 415). Pharyngeal smears are difficult to analyse due to the presence of other diplococci, so the diagnosis must be confirmed by culture or NAAT.

Management of adults

Emerging resistance is making it increasingly difficult to cure gonorrhoea with a single oral dose of

15.9 Treatment of uncomplicated anogenital gonorrhoea

Uncomplicated infection
• Ceftriaxone 500 mg IM *or* • Cefixime 400 mg stat *or* • Ciprofloxacin 500 mg orally stat[1,2] *or* • Ofloxacin 400 mg orally stat[1,2] *or* • Amoxicillin 3 g *plus* probenecid 1 g orally stat[3]
Quinolone resistance
• Ceftriaxone 500 mg IM stat *or* • Spectinomycin 2 g IM stat[4]
Pregnancy and breastfeeding
• Ceftriaxone 500 mg IM stat *or* • Cefixime 400 mg stat *or* • Amoxicillin 3 g *plus* probenecid 1 g orally stat[3] *or* • Spectinomycin 2 g IM stat[4]
Pharyngeal gonorrhoea
• Ceftriaxone 500 mg IM stat *or* • Cefixime 400 mg stat *or* • Ciprofloxacin 500 mg[1,2] orally stat *or* • Ofloxacin 400 mg[1,2] orally stat

[1]Contraindicated in pregnancy and breastfeeding.
[2]If prevalence of quinolone resistance for *N. gonorrhoeae* < 5%.
[3]If prevalence of penicillin resistance for *N. gonorrhoeae* < 5%.
[4]May only be available in specialist clinics.

15.10 Complications of delayed therapy in gonorrhoea

- Acute prostatitis
- Epididymo-orchitis
- Bartholin's gland abscess
- PID (may lead to infertility or ectopic pregnancy)
- Disseminated gonococcal infection

antimicrobials, and recommended treatment in the UK has changed to intramuscular ceftriaxone 500 mg. The alternatives listed in Box 15.9 are less likely to be effective.

Longer courses of antibiotics are required for complicated infection. Partner(s) of patients with gonorrhoea should be seen as soon as possible. Delay in treatment may lead to complications (Box 15.10).

Chlamydial infection

Chlamydial infection in men

Chlamydia is transmitted and presents in a similar way to gonorrhoea; however, urethral symptoms are usually milder and may be absent in over 50% of cases. Conjunctivitis is also milder than in gonorrhoea; pharyngitis does not occur. The incubation period varies from 1 week to a few months. Without treatment, symptoms may resolve but the patient remains infectious for several months. Complications, such as epididymo-orchitis and Reiter's syndrome, or sexually acquired reactive arthropathy (SARA, p. 1107), are rare. Sexually transmitted pathogens, such as chlamydia or gonococci, are usually responsible for epididymo-orchitis in men aged less than 35 years, whereas bacteria such as Gram-negative enteric organisms are more commonly implicated in older men.

Treatments for chlamydia are listed in Box 15.11. NSU is treated identically. The partner(s) of men with chlamydia should be treated, even if laboratory tests for chlamydia are negative. Investigation is not mandatory but serves a useful epidemiological purpose; moreover, positive results encourage further attempts at contact-tracing.

Chlamydial infection in women

The cervix and urethra are commonly involved. Infection is asymptomatic in about 80% of patients but may cause vaginal discharge, dysuria and intermenstrual and/or postcoital bleeding. Lower abdominal pain and dyspareunia are features of PID. Examination may reveal mucopurulent cervicitis, contact bleeding from the cervix, evidence of PID or no obvious clinical signs. Treatment options are listed in Box 15.11. The patient's male partner(s) should be investigated and treated.

Some infections may clear spontaneously but others persist. PID, with the risk of tubal damage and subsequent infertility or ectopic pregnancy, is a rare but important long-term complication. Other complications include perihepatitis, chronic pelvic pain, conjunctivitis and Reiter's syndrome or SARA. Perinatal transmission may lead to ophthalmia neonatorum and/or pneumonia in the neonate.

15.11 Treatment of chlamydial infection

Standard regimens

- Azithromycin 1 g orally as a single dose[1] *or*
- Doxycycline 100 mg twice daily orally for 7 days[2]

Alternative regimens

- Erythromycin 500 mg four times daily orally for 7 days *or* 500 mg twice daily for 2 weeks *or*
- Ofloxacin 200 mg twice daily orally for 7 days[2]

[1]Safety in pregnancy and breastfeeding has not been fully assessed.
[2]Contraindlcated in pregnancy and breastfeeding.

Other sexually transmitted bacterial infections

Chancroid, granuloma inguinale and LGV as causes of genital ulcers in the tropics are described in Box 15.12. LGV is also a cause of proctitis in MSM (p. 417).

SEXUALLY TRANSMITTED VIRAL INFECTIONS

Genital herpes simplex

Infection with herpes simplex virus type 1 (HSV-1) or type 2 (HSV-2) produces a wide spectrum of clinical problems (p. 325), and may facilitate HIV transmission. Infection is usually acquired sexually (vaginal, anal, orogenital or oro-anal), but perinatal transmission to the neonate may also occur. Primary infection at the site of HSV entry, which may be symptomatic or asymptomatic, establishes latency in local sensory ganglia. Recurrences, either symptomatic or asymptomatic viral shedding, are a consequence of HSV reactivation. The first symptomatic episode is usually the most severe. Although HSV-1 is classically associated with orolabial herpes and HSV-2 with anogenital herpes, HSV-1 now accounts for more than 50% of anogenital infections in the UK.

Clinical features

The first symptomatic episode presents with irritable vesicles that soon rupture to form small, tender ulcers on the external genitalia (see Figs 15.6 and 15.2, p. 416). Lesions at other sites (e.g. urethra, vagina, cervix, perianal area, anus or rectum) may cause dysuria, urethral or vaginal discharge, or anal, perianal or rectal pain. Constitutional symptoms, such as fever, headache and malaise, are common. Inguinal lymph nodes become enlarged and tender, and there may be nerve root pain in the 2nd and 3rd sacral dermatomes.

Extragenital lesions may develop at other sites, such as the buttock, finger or eye, due to auto-inoculation. Oropharyngeal infection may result from orogenital sex. Complications, such as urinary retention due to autonomic neuropathy, and aseptic meningitis, are occasionally seen.

First episodes usually heal within 2–4 weeks without treatment; recurrences are usually milder and of shorter duration than the initial attack. They occur more often

15.12 Salient features of lymphogranuloma venereum, chancroid and granuloma inguinale (Donovanosis)

Infection and distribution	Organism	Incubation period	Genital lesion	Lymph nodes	Diagnosis	Management
Lymphogranuloma venereum (LGV)						
E/W Africa, India, SE Asia, S America, Caribbean	*Chlamydia trachomatis* types L1, 2, 3	3–30 days	Small, transient, painless ulcer, vesicle, papule; often unnoticed	Tender, usually unilateral, matted, suppurative bubo; inguinal/femoral nodes involved[1]	Serological tests for L1–3 serotypes; swab from ulcer or bubo pus for *Chlamydia*	Doxycycline[2] twice daily orally for 21 days *or* Erythromycin 500 mg four times daily orally
Chancroid						
Africa, Asia, Central and S America	*Haemophilus ducreyi* (short Gram-negative bacillus)	3–10 days	Single or multiple painful ulcers with ragged undermined edges	As above but unilocular, suppurative bubo; inguinal nodes involved in ~50%	Microscopy and culture of scrapings from ulcer or pus from bubo	Azithromycin[3] 1 g orally once *or* Ceftriaxone 250 mg IM once *or* Ciprofloxacin[2] 500 mg twice daily orally for 3 days
Granuloma inguinale						
Australia, Caribbean, India, S Africa, S America, Papua New Guinea	*Klebsiella granulomatis* (Donovan bodies)	3–40 days	Ulcers or hypertrophic granulomatous lesions; usually painless[4]	Initial swelling of inguinal nodes, then spread of infection to form abscess or ulceration through adjacent skin	Microscopy of cellular material for intracellular bipolar-staining Donovan bodies	Azithromycin[3] 1 g weekly orally or 500 mg daily orally *or* Doxycycline[2] 100 mg twice daily orally *or* Ceftriaxone 1 g IM daily

[1]The genito-ano-rectal syndrome is a late manifestation of LGV. [2]Doxycycline and ciprofloxacin are contraindicated in pregnancy and breastfeeding.
[3]The safety of azithromycin in pregnancy and breastfeeding has not been fully assessed. [4]Mother-to-baby transmission of granuloma inguinale may rarely occur.
N.B. Partners of patients with LGV, chancroid and granuloma inguinale should be investigated and treated, even if asymptomatic.

Fig. 15.6 Herpetic ulceration of the vulva. From McMillan and Scott 2000 – see p. 426.

in HSV-2 infection and their frequency tends to decrease with time. Prodromal symptoms, such as irritation or burning at the subsequent site of recurrence, or neuralgic pains affecting buttocks, legs or hips, are commonly seen. The first symptomatic episode may be a recurrence of a previously undiagnosed primary infection. Recurrent episodes of asymptomatic viral shedding are important in the transmission of HSV.

Diagnosis

Swabs are taken from vesicular fluid or ulcers for detection of DNA by PCR, or tissue culture and typing as either HSV-1 or 2. Electron microscopy of such material will only give a presumptive diagnosis, as herpes group viruses appear similar. Type-specific antibody tests are available but are not sufficiently accurate for general use.

Management

First episode

The following 5-day oral regimens are all recommended and should be started within 5 days of the beginning of the episode, or whilst lesions are still forming:

- aciclovir 200 mg five times daily
- famciclovir 250 mg three times daily
- valaciclovir 500 mg twice daily.

Analgesia may be required and saline bathing can be soothing. Treatment may be continued for longer than 5 days if new lesions develop. Occasionally, intravenous

therapy may be indicated if oral therapy is poorly tolerated or aseptic meningitis occurs.

Catheterisation via the suprapubic route is advisable for urinary retention due to autonomic neuropathy because the transurethral route may introduce HSV into the bladder.

Recurrent genital herpes

Symptomatic recurrences are usually mild and may require no specific treatment other than saline bathing. For more severe episodes, patient-initiated treatment at onset, with one of the following 5-day oral regimens, should reduce the duration of the recurrence:

- aciclovir 200 mg five times daily
- famciclovir 125–250 mg twice daily
- valaciclovir 500 mg twice daily.

In a few patients, treatment started at the onset of prodromal symptoms may abort recurrence.

Suppressive therapy may be required for patients with frequent recurrences, especially if these occur at intervals of less than 4 weeks. Treatment should be given for a minimum of 1 year before stopping to assess recurrence rate. About 20% of patients will experience reduced attack rates thereafter, but for those whose recurrences remain unchanged, resumption of suppressive therapy is justified. Aciclovir 400 mg twice daily is most commonly prescribed.

Management in pregnancy

If her partner is known to be infected with HSV, a pregnant woman with no previous anogenital herpes should be advised to protect herself during sexual intercourse because the risk of disseminated infection is increased in pregnancy. Consistent condom use during pregnancy may reduce transmission of HSV. Genital herpes acquired during the first or second trimester of pregnancy is treated with aciclovir as clinically indicated. Although aciclovir is not licensed for use in pregnancy in the UK, there is considerable clinical evidence to support its safety. Third-trimester acquisition of infection has been associated with life-threatening haematogenous dissemination and should be treated with aciclovir.

Vaginal delivery should be routine in women who are symptomless in late pregnancy. Caesarean section is sometimes considered if there is a recurrence at the beginning of labour, although the risk of neonatal herpes through vaginal transmission is very low. Caesarean section is often recommended if primary infection occurs after 34 weeks because the risk of viral shedding is very high in labour.

Human papillomavirus and anogenital warts

Human papillomavirus (HPV) DNA typing has demonstrated over 90 genotypes (p. 1278), of which HPV-6, HPV-11, HPV-16 and HPV-18 most commonly infect the genital tract through sexual transmission. It is important to differentiate between the benign genotypes (HPV-6 and 11) that cause anogenital warts, and genotypes such as 16 and 18 that are associated with dysplastic conditions and cancers of the genital tract but are not a cause of benign warts. All genotypes usually result in subclinical infection of the genital tract rather than clinically obvious lesions affecting penis, vulva, vagina, cervix, perineum or anus.

Clinical features

Anogenital warts caused by HPV may be single or multiple, exophytic, papular or flat. Perianal warts (p. 412), whilst being more commonly found in MSM, are also found in heterosexual men and in women. Rarely, a giant condyloma (Buschke–Löwenstein tumour) develops with local tissue destruction. Atypical warts should be biopsied. In pregnancy, warts may dramatically increase in size and number, making treatment difficult. Rarely, they are large enough to obstruct labour and, in this case, delivery by Caesarean section will be required. Rarely, perinatal transmission of HPV leads to anogenital warts, or possibly laryngeal papillomas, in the neonate.

Management

The use of condoms can help prevent the transmission of HPV to non-infected partners, but HPV may affect parts of the genital area not protected by condoms. Vaccination against HPV infection has been introduced and is in routine use in several countries. There are two types of vaccine:

- *A bivalent vaccine* (Cervarix®) offers protection against HPV types 16 and 18, which account for approximately 75% of cervical cancers in the UK.
- *A quadrivalent vaccine* (Gardasil®) offers additional protection against HPV types 6 and 11, which account for over 90% of genital warts.

Both types of vaccine have been shown to be highly effective in the prevention of cervical intra-epithelial neoplasia in young women, and the quadrivalent vaccine has also been shown to be highly effective in protecting against HPV-associated genital warts (Box 15.13). It is currently recommended that HPV vaccination should be administered prior to the onset of sexual activity, typically at age 11–13, in a course of three injections. In the UK, only girls are offered vaccination, and it should be noted that this approach will not protect HPV transmission for MSM. As neither vaccine protects against all oncogenic types of HPV, cervical screening programmes will still be necessary.

A variety of treatments are available for established disease, including the following:

- *Podophyllotoxin, 0.5% solution or 0.15% cream* (contraindicated in pregnancy), applied twice daily for 3 days, followed by 4 days' rest, for up to 4 weeks is suitable for home treatment of external warts.

EBM 15.13 HPV vaccination and precancerous cervical intra-epithelial neoplasia

'Prophylactic HPV vaccination in women aged 15–25 years is highly effective at preventing precancerous cervical intra-epithelial neoplasia in young women who have not previously been infected with HPV.'

- Garland SM, et al. New Engl J Med 2007; 356:1928–1943.
- Paavonen J, et al. Lancet 2007; 369:2161–2170.

- *Imiquimod* cream (contraindicated in pregnancy), applied 3 times weekly (and washed off after 6–10 hours) for up to 16 weeks, is also suitable for home treatment of external warts.
- *Cryotherapy* using liquid nitrogen to freeze warty tissue is suitable for external and internal warts but often requires repeated clinic visits.
- *Hyfrecation* – electrofulguration that causes superficial charring – is suitable for external and internal warts. Hyfrecation results in smoke plume which contains HPV DNA and has the potential to cause respiratory infection in the operator/patient. Masks should be worn during the procedure and adequate extraction of fumes should be provided.
- *Surgical removal.* Refractory warts, especially pedunculated perianal lesions, may be excised under local or general anaesthesia.

Molluscum contagiosum

Infection by molluscum contagiosum virus, both sexual and non-sexual, produces flesh-coloured umbilicated hemispherical papules usually up to 5 mm in diameter after an incubation period of 3–12 weeks (Fig. 15.7). Larger lesions may be seen in HIV infection (p. 388). Lesions are often multiple and, once established in an individual, may spread by auto-inoculation. They are found on the genitalia, lower abdomen and upper thighs when sexually acquired. Facial lesions are highly suggestive of underlying HIV infection. Diagnosis is made on clinical grounds and by expression of the central core, in which the typical pox-like viral particles can be seen on electron microscopy (differentiating molluscum contagiosum from genital warts). Typically, lesions persist for an average of 2 years before spontaneous resolution occurs. Treatment regimens are therefore cosmetic; they include cryotherapy, hyfrecation, topical applications of 0.15% podophyllotoxin cream (contraindicated in pregnancy) or expression of the central core.

Fig. 15.7 Molluscum contagiosum of the shaft of the penis. From McMillan and Scott 2000 – see right.

Viral hepatitis

The hepatitis viruses A–D (p. 948) may be sexually transmitted:

- *Hepatitis A (HAV).* Insertive oro-anal sex, insertive digital sex, insertive anal sex and multiple sexual partners have been linked with HAV transmission in MSM. HAV transmission in heterosexual men and women is also possible through oro-anal sex.
- *Hepatitis B (HBV).* Insertive oro-anal sex, anal sex and multiple sexual partners are linked with HBV infection in MSM. Heterosexual transmission of HBV is well documented and commercial sex workers are at particular risk. Hepatitis D (HDV) may also be sexually transmitted.
- *Hepatitis C (HCV).* Sexual transmission of HCV is well documented in MSM, but less so in heterosexuals. Sexual transmission is less efficient than for HBV.

The sexual partner(s) of patients with HAV and HBV should be seen as soon as possible and offered immunisation where appropriate. Patients with HAV should abstain from all forms of unprotected sex until non-infectious. Those with HBV should likewise abstain from unprotected sex until they are non-infectious or until their partners have been vaccinated successfully. No active or passive immunisation is available for protection against HCV but the consistent use of condoms is likely to protect susceptible partners. Active immunisation against HAV and HBV should be offered to susceptible people at risk of infection. Many STI clinics offer HAV immunisation to MSM along with routine HBV immunisation; a combined HAV and HBV vaccine is available.

There is a worldwide trend towards increased use of laboratory-based diagnostic investigations, and biochemical investigations in particular. In the health-care systems of developed countries, it has been estimated that 60–70% of all critical decisions taken in regard to patients, and over 90% of data stored in electronic medical records systems, involve a laboratory service or result.

This chapter covers a diverse group of disorders affecting adults not considered elsewhere in this book, whose primary manifestation is in abnormalities of biochemistry laboratory results, or whose underlying pathophysiology involves disturbance in specific biochemical pathways.

BIOCHEMICAL INVESTIGATIONS

There are three broad reasons why a clinician may request a biochemical laboratory investigation:

- to screen an asymptomatic subject for the presence of disease
- to assist in diagnosis of a patient's presenting complaint
- to monitor changes in test results, as a marker of disease progression or response to treatment.

Contemporary medical practice has become increasingly reliant on laboratory investigation, and in particular, on biochemical investigation. This has been associated with extraordinary improvements in the analytical capacity and speed of laboratory instrumentation and the following operational trends:

- Large central biochemistry laboratories feature extensive use of automation and information technology. Specimens are transported from clinical areas to the laboratory using high-speed transport systems (such as pneumatic tubes) and identified with machine-readable labels (such as bar codes). Laboratory instruments have been miniaturised and integrated with robot transport systems to enable multiple rapid analyses of a single sample. Statistical process control techniques are used to assure the quality of analytical results, and increasingly to monitor other aspects of the laboratory, such as the time taken to complete the analysis ('turn-around time').
- Point-of-care testing (POCT) brings selected laboratory analytical systems into clinical areas, to the patient's bedside or even connected to an individual patient. These systems allow the clinician to receive results almost instantaneously for immediate treatment of the patient, although often with less precision or at greater cost than using a central laboratory.
- The diversity of analyses has widened considerably with the introduction of many techniques borrowed from the chemical or other industries (Box 16.1).

Good medical practice involves the appropriate ordering of laboratory investigations and correct

16.1 Range of analytical modalities used in the clinical biochemistry laboratory

Analytical modality	Analyte	Typical applications
Ion-selective electrodes	Blood gases, electrolytes (e.g. Na, K, Cl)	Point-of-care testing (POCT) High-throughput analysers
Colorimetric chemical reaction or coupled enzymatic reaction	Simple mass or concentration measurement (e.g. creatinine, phosphate) Simple enzyme activity	High-throughput analysers
Ligand assay (usually immunoassay)	Specific proteins Hormones Drugs	Increasingly available for POCT or high-throughput analysers
Chromatography: gas chromatography (GC), high-pressure liquid chromatography (HPLC), thin-layer chromatography (TLC)	Organic compounds	Therapeutic drug monitoring (TDM)
Mass spectroscopy (MS)		Drug screening (e.g. drugs of misuse) Vitamins Biochemical metabolites
Spectrophotometry, turbidimetry, nephelometry, fluorimetry	Haemoglobin derivatives Specific proteins Immunoglobulins	Xanthochromia Lipoproteins Paraproteins
Electrophoresis	Proteins Some enzymes	Paraproteins Isoenzyme analysis
Atomic absorption (AA) **Inductively coupled plasma/mass spectroscopy (ICP-MS)**	Trace elements and metals	Quantitation of heavy metals
Molecular diagnostics	Nucleic acid quantification and/or sequence	Inherited and somatic cell mutations (Ch. 3) Genetic polymorphisms (Ch. 3) Variations in rates of drug metabolism (Ch. 2) Microbial diagnosis (Ch. 6)

interpretation of test results. The key principles, including the concepts of sensitivity and specificity, are described on page 5. Reference ranges for laboratory results are provided in Chapter 29. Many laboratory investigations can be subject to variability arising from incorrect patient preparation (for example, in the fasting or fed state), timing of sample collection (for example, in relation to diurnal variation of hormone levels, or dosage regimens for therapeutic agents), analytical factors (for example, serum versus plasma; use of the correct anticoagulant, or POCT versus central analysis) or artefact (for example, taking a venous sample proximal to the site of an intravenous infusion). It is therefore important for clinical and laboratory staff to communicate effectively and for clinicians to follow local recommendations concerning collection and transport of samples in the appropriate container and with appropriate labelling.

INTEGRATED WATER AND ELECTROLYTE BALANCE

One of the most common uses of the clinical biochemistry laboratory is to monitor electrolyte and acid–base status. The diverse clinical consequences of these biochemical disorders are illustrated in Box 16.2. Some whole-body electrolyte disturbances (notably of sodium) result in major clinical problems with minimal disturbance in measured biochemical parameters. However, these will also be considered for convenience here.

Before considering individual electrolytes and acid–base balance, it is important to review the relationships between them.

Water and electrolyte distribution

The following basic concepts are relevant to understanding the origin, consequences and therapy of many of the fluid and electrolyte disturbances discussed.

In a typical adult male, total body water (TBW) is approximately 60% of body weight (somewhat more for infants and less for women). For an average individual, TBW is about 40 L. Approximately 25 L is located inside cells (the intracellular fluid or ICF), while the remaining 15 L is in the extracellular fluid (ECF) compartment (Fig. 16.1). Most of the ECF (approximately 12 L) is interstitial fluid, which is within the tissues but outside cells, whereas the remainder (about 3 L) is in the plasma compartment.

16.2 Manifestations of disordered water, electrolyte and acid–base status

Primary disturbance	Altered physiology	Clinical effect
Sodium	ECF volume	Circulatory changes
Water	ECF osmolality	Cerebral changes
Potassium	Action potential in excitable tissues	Neuromuscular weakness, cardiac effects
Hydrogen ion	Acid–base balance (pH)	Altered tissue function, respiratory compensation
Magnesium	Cell membrane stability	Neuromuscular, vascular and cardiac effects
Phosphate	Cellular energetics	Widespread tissue effects

(ECF = extracellular fluid)

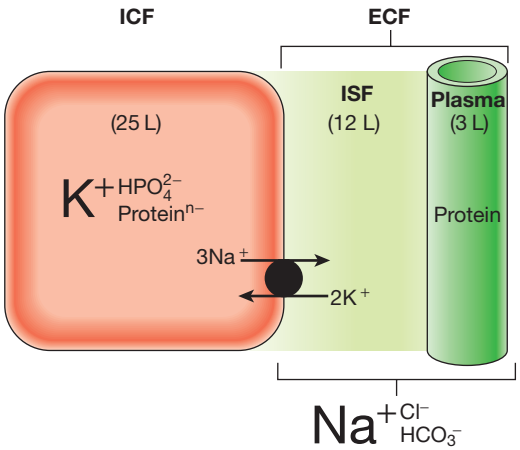

Fig. 16.1 Normal distribution of body water and electrolytes. Schematic representation of volume (L = litres) and composition (dominant ionic species only shown) of the intracellular fluid (ICF) and extracellular fluid (ECF) in a 70 kg male. The main difference in composition between the plasma and interstitial fluid (ISF) is the presence of appreciable concentrations of protein in the plasma but not the ISF.

Figure 16.1 illustrates some of the major differences in composition between the main body fluid compartments. The dominant cation in the ICF is potassium, while the dominant cation in the ECF is sodium. Phosphates and negatively charged proteins constitute the major intracellular anions, while chloride and, to a lesser extent, bicarbonate dominate the ECF anions. An important difference between the plasma and interstitial compartments of the ECF is that only plasma contains significant concentrations of protein.

The major force maintaining the difference in cation concentration between the ICF and ECF is the sodium–potassium pump (Na,K-activated ATPase), which is present in all cell membranes. Maintenance of the cation gradients across cell membranes is essential for many cell processes, including the excitability of conducting tissues such as nerve and muscle. The difference in protein content between the plasma and the interstitial fluid compartment is maintained by the impermeability of the capillary wall to protein. This protein concentration gradient (the colloid osmotic, or oncotic, pressure of the plasma) contributes to the balance of forces across the capillary wall that favour fluid retention within the plasma compartment.

Investigation of water and electrolytes

The most common biochemical test in plasma is called the urea and electrolytes (U&E) test in some parts of the world, and the electrolytes/urea/creatinine (EUC) in others. A guide to its interpretation is shown in Box 16.3. Because the blood consists of both intracellular (red cell) and extracellular (plasma) components, it is important

16.3 How to interpret 'U&Es' (urea and electrolytes) or 'EUC' (electrolytes/urea/creatinine) results

Na^+ (sodium)

- Largely reflects reciprocal changes in body water content
- See 'Hypernatraemia' and 'Hyponatraemia', pp. 437 and 439

K^+ (potassium)

- May reflect K shifts in and out of cells
- Low levels usually mean excessive losses (gastrointestinal or renal)
- High levels usually mean renal dysfunction
- See 'Hypokalaemia' and 'Hyperkalaemia', pp. 440 and 442

Cl^- (chloride)

- Generally changes in parallel with plasma Na
- Low in metabolic alkalosis
- High in some forms of metabolic acidosis

HCO_3^- (bicarbonate)

- Abnormal in acid–base disorders
- See Box 16.18, p. 445

Urea

- Increased with a fall in glomerular filtration rate (GFR), reduced renal perfusion or urine flow rate, and in high protein intake or catabolic states
- See page 466

Creatinine

- Increased with a fall in GFR, in individuals with high muscle mass, and with some drugs
- See Fig. 17.2, p. 467

to avoid haemolysis during or after collection of the sample, which causes contamination of the plasma compartment by intracellular elements, particularly potassium. Blood should not be drawn from an arm into which an intravenous infusion is being given, to avoid contamination by the infused fluid. Repeated measurements of plasma electrolytes are frequently necessary when abnormalities have been detected and corrective therapy instituted.

Since the kidney maintains the constancy of body fluids by adjusting urine volume and composition, it is frequently helpful to obtain a sample of urine ('spot' specimen or 24-hour collection) at the time of blood analysis. An example of the use of urine biochemistry is given for the differential diagnosis of hyponatraemia in Box 16.14 (p. 438).

DISORDERS OF SODIUM BALANCE

Functional anatomy and physiology of renal sodium handling

Since the great majority of the body's sodium content is located in the ECF, where it is by far the most abundant cation, total body sodium is a principal determinant of ECF volume. Regulation of sodium excretion by the kidney is crucially important in maintaining normal ECF volume, and plasma volume, in the face of wide variations in sodium intake, which typically may range between 50 and 250 mmol/day.

The functional unit for renal excretion is the nephron (Fig. 16.2). Blood undergoes ultrafiltration in the glomerulus, generating a fluid that is free from cells and protein and which resembles plasma in its electrolyte composition. This is then delivered into the renal tubules, where reabsorption of water and various electrolytes occurs (more detail on the structure and function of the glomerulus is given in Ch. 17). The glomerular filtration rate (GFR) is approximately 125 mL/min (equivalent to 180 L/day) in a typical adult. Over 99% of this filtered fluid is reabsorbed into the blood in the peritubular capillaries during its passage through successive segments of the nephron, largely as a result of tubular reabsorption of sodium. The processes mediating this sodium reabsorption, and the factors that regulate it, are key to understanding clinical disturbances and pharmacological interventions.

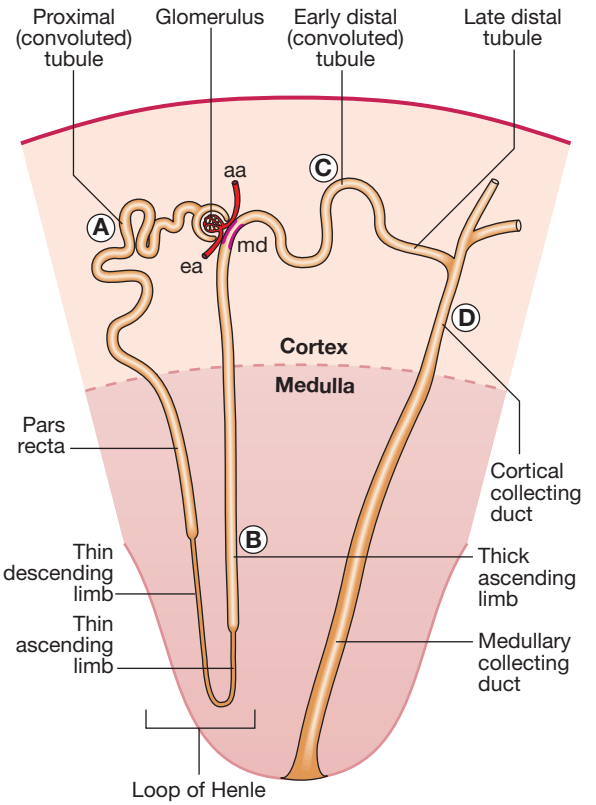

Fig. 16.2 The nephron. Letters A–D refer to tubular segments shown in more detail in Figure 16.3. (aa = afferent arteriole; ea = efferent arteriole; md = macula densa)

Nephron segments

At least four different functional segments of the nephron can be defined in terms of their mechanism for sodium reabsorption (Fig. 16.3).

Proximal tubule

This is responsible for the reabsorption of some 65% of the filtered sodium load. The cellular mechanisms are complex but some of the key features are shown in Figure 16.3A. Filtered sodium in the luminal fluid enters the cell via several sodium transporters in the apical membrane that couple sodium transport to the entry of glucose, amino acid, phosphate and other organic molecules. Entry of sodium into the tubular cells at this site is also linked to secretion of H^+ ions, through the

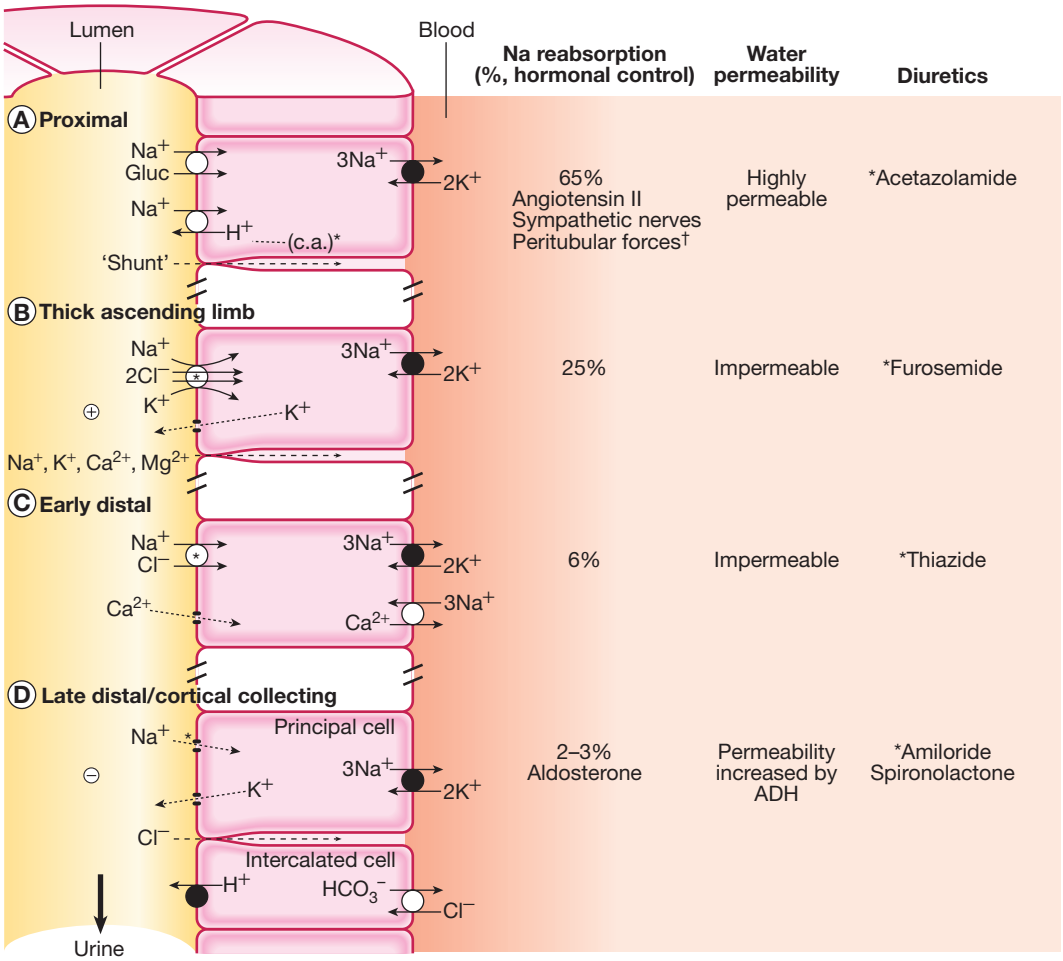

Fig. 16.3 Principal transport mechanisms in segments of the nephron. See text for further details. The apical membrane of the tubular cells is the side facing the lumen, and the basolateral membrane is the side facing the blood. Black circles indicate primary active transport pumps; open circles are carrier molecules without direct linkage to adenosine triphosphate (ATP) hydrolysis. *Site of diuretic action in each segment. †Peritubular forces refers to the hydrostatic and oncotic pressures in the peritubular capillaries. (ADH = antidiuretic hormone; c.a. = carbonic anhydrase)

sodium–hydrogen exchanger (NHE-3). Intracellular H^+ ions are generated within tubular cells from the breakdown of carbonic acid, which is produced from carbon dioxide and water under the influence of carbonic anhydrase. Large numbers of Na,K-ATPase pumps are present on the basolateral membrane of tubular cells that transport sodium from the cells into the blood. In addition, a large component of the transepithelial flux of sodium, water and other dissolved solutes occurs through the gaps *between* the cells (the 'shunt' pathway). Overall, fluid and electrolyte reabsorption is almost isotonic in this segment, as water reabsorption is matched very closely to sodium fluxes. A component of this water flow also passes *through* the cells, via aquaporin-1 (AQP-1) water channels, which are not sensitive to hormonal regulation.

The loop of Henle

The thick ascending limb of the loop of Henle (Fig. 16.3B) reabsorbs a further 25% of the filtered sodium but is impermeable to water, resulting in dilution of the luminal fluid. Again, the primary driving force for sodium reabsorption is the Na,K-ATPase on the basolateral cell membrane, but in this segment sodium enters the cell from the lumen via a specific carrier molecule, the Na,K,2Cl co-transporter ('triple co-transporter', or NKCC2), which allows electroneutral entry of these ions into the renal tubular cell. Some of the potassium accumulated inside the cell recirculates across the apical membrane back into the lumen through a specific potassium channel (ROMK), providing a continuing supply of potassium to match the high concentrations of sodium and chloride available in the lumen. A small positive transepithelial potential difference exists in the lumen of this segment relative to the interstitium, and this serves to drive cations such as sodium, potassium, calcium and magnesium between the cells, forming a reabsorptive shunt pathway.

Early distal tubule

Some 6% of filtered sodium is reabsorbed in the early distal tubule (also called distal convoluted tubule) (Fig. 16.3C), again driven by the activity of the basolateral Na,K-ATPase. In this segment, entry of sodium into the cell from the luminal fluid is via a sodium–chloride co-transport carrier (NCCT). This segment is also impermeable to water, resulting in further dilution of the luminal fluid. There is no significant transepithelial flux of potassium in this segment, but calcium is reabsorbed through the mechanism shown in Figure 16.3C: a

basolateral sodium–calcium exchanger leads to low intracellular concentrations of calcium, promoting calcium entry from the luminal fluid through a calcium channel.

Late distal tubule and collecting ducts

The late distal tubule and cortical collecting duct are anatomically and functionally continuous (Fig. 16.3D). Here, sodium entry from the luminal fluid occurs via the epithelial sodium channel (ENaC) through which sodium passes alone, generating a substantial lumen-negative transepithelial potential difference. This sodium flux into the tubular cells is balanced by secretion of potassium and hydrogen ions into the lumen and by reabsorption of chloride ions. Potassium is accumulated in the cell by the basolateral Na,K-ATPase, and passes into the luminal fluid down its electrochemical gradient, through an apical potassium channel (ROMK). Chloride ions pass largely between cells. Hydrogen ion secretion is mediated by an H^+-ATPase located on the luminal membrane of the intercalated cells, which constitute approximately one-third of the epithelial cells in this nephron segment. This part of the nephron has a variable permeability to water, depending on the availability of antidiuretic hormone (ADH, or vasopressin) in the circulation. All ion transport processes in this segment are stimulated by the steroid hormone aldosterone, which can increase sodium reabsorption in this segment to a maximum of 2–3% of the filtered sodium load.

Less than 1% of sodium reabsorption occurs in the medullary collecting duct, where it is inhibited by atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP).

Regulation of sodium transport

A large number of interrelated mechanisms serve to maintain whole body sodium balance and hence ECF volume by matching urinary sodium excretion to sodium intake (Fig. 16.4).

Important sensing mechanisms include volume receptors in the cardiac atria and the intrathoracic veins, as well as pressure receptors located in the central arterial tree (aortic arch and carotid sinus) and the afferent arterioles within the kidney. A further afferent signal is generated within the kidney itself; the enzyme renin is released from specialised smooth muscle cells in the walls of the afferent and efferent arterioles, at the point where they make contact with the early distal tubule (at the macula densa) to form the juxtaglomerular apparatus. Renin release is stimulated by:

- reduced perfusion pressure in the afferent arteriole
- increased sympathetic nerve activity
- decreased sodium chloride concentration in the distal tubular fluid.

Renin released into the circulation activates the effector mechanisms for sodium retention, which are components of the renin–angiotensin–aldosterone (RAA) system (see Fig. 20.17, p. 771). Renin acts on the peptide substrate, angiotensinogen (manufactured in the liver), producing angiotensin I in the circulation. This in turn is cleaved by angiotensin-converting enzyme (ACE) into angiotensin II, largely in the pulmonary capillary bed. Angiotensin II has multiple actions: it stimulates proximal tubular sodium reabsorption and release of aldosterone from the zona glomerulosa of the adrenal cortex, and causes vasoconstriction of small arterioles. Aldosterone amplifies sodium retention by its action on the cortical collecting duct. The net effect is to restore ECF volume and blood pressure towards normal, thereby correcting the initiating hypovolaemic stimulus.

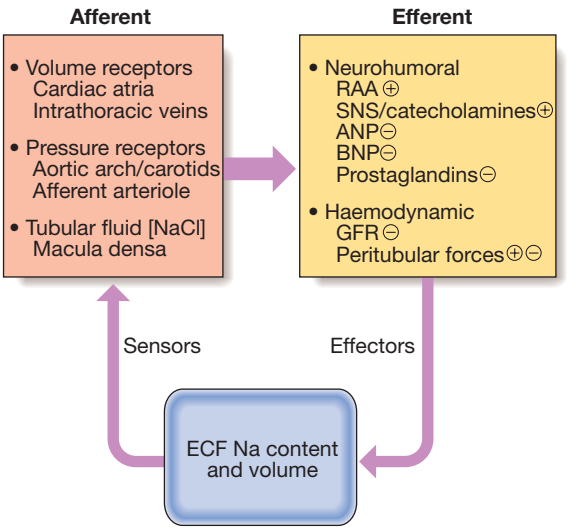

Fig. 16.4 Mechanisms involved in the regulation of sodium transport. (ANP = atrial natriuretic peptide; BNP = brain natriuretic peptide; ECF = extracellular fluid; GFR = glomerular filtration rate; RAA = renin–angiotensin–aldosterone system; SNS = sympathetic nervous system. ⊕ indicates an effect to stimulate Na reabsorption and hence reduce Na excretion, while ⊖ indicates an effect to inhibit Na reabsorption and hence increase Na excretion)

The sympathetic nervous system also increases sodium retention, both through haemodynamic mechanisms (afferent arteriolar vasoconstriction and GFR reduction) and by direct stimulation of proximal tubular sodium reabsorption. Other humoral mediators, such as the natriuretic peptides, inhibit sodium reabsorption, contributing to natriuresis during periods of sodium and volume excess. Hypovolaemia also has haemodynamic effects that reduce GFR and alter the peritubular physical forces around the proximal tubule, thereby decreasing sodium excretion. Conversely, increased renal perfusion in hypervolaemia and hypertension results in a compensatory increase in sodium excretion.

Presenting problems in disorders of sodium balance

When the balance of sodium intake and excretion is disturbed, any tendency for plasma sodium concentration to change is usually corrected by the osmotic mechanisms controlling water balance (p. 436). As a result, disorders in sodium balance present chiefly as alterations in the ECF volume, resulting in hypovolaemia or oedema, rather than as an alteration in plasma sodium concentration. Clinical manifestations of altered volume are illustrated in Box 16.4.

Sodium depletion

Aetiology and clinical assessment

Sodium depletion can occur occasionally under extreme environmental conditions due to inadequate intake of

16.4 Clinical features of hypovolaemia and hypervolaemia

	Hypovolaemia	Hypervolaemia
Symptoms	Thirst Dizziness on standing Weakness	Ankle swelling Abdominal swelling Breathlessness
Signs	Low JVP Postural hypotension Tachycardia Dry mouth Reduced skin turgor Reduced urine output Weight loss Confusion, stupor	Peripheral oedema Raised JVP Pulmonary crepitations Pleural effusion Ascites Weight gain Hypertension (sometimes)

(JVP = jugular venous pressure)

16.5 Causes of sodium and water depletion

Mechanism	Examples
Inadequate intake	Environmental deprivation, inadequate therapeutic replacement
Gastrointestinal sodium loss	Vomiting, diarrhoea, nasogastric suction, external fistula
Skin sodium loss	Excessive sweating, burns
Renal sodium loss	Diuretic therapy, mineralocorticoid deficiency, tubulointerstitial disease
Internal sequestration*	Bowel obstruction, peritonitis, pancreatitis, crush injury

*A cause of circulatory volume depletion, although total body sodium and water may be normal or increased.

salt, but it is much more commonly due to pathological losses of sodium-containing fluids (Box 16.5). Loss of whole blood, as in acute haemorrhage, is also an obvious cause of hypovolaemia, and elicits the same mechanisms for the conservation of sodium and water.

The diagnosis of hypovolaemia is based on characteristic symptoms and signs (see Box 16.4) in the context of a relevant precipitating illness. Supportive evidence may be obtained from the clinical biochemistry laboratory. Although plasma sodium concentration may not be reduced if salt and water are lost in equal proportions, a number of other parameters are altered during appropriate renal, hormonal and haemodynamic responses to hypovolaemia. During the early stages of hypovolaemia, GFR is maintained while urinary flow rate is reduced as a consequence of activation of sodium- and water-retaining mechanisms in the nephron. Thus, plasma creatinine, which reflects GFR, may be relatively normal, but the plasma urea concentration is typically elevated, since urea excretion is affected by both GFR and urine flow rate. Plasma uric acid may also rise, reflecting activation of compensatory proximal tubular reabsorption. With avid retention of sodium and water, the urine osmolality increases while the urine sodium concentration falls. Under these circumstances, sodium excretion may fall to less than 0.1% of the filtered sodium load.

Management

Management of sodium and water depletion has two main components:

- treat the cause where possible, to stop ongoing salt and water losses
- replace the salt and water deficits, and provide ongoing maintenance requirements, usually by intravenous fluid replacement when depletion is severe.

Intravenous fluid therapy

Box 16.6 shows the daily maintenance requirements for water and electrolytes in a typical adult, and Box 16.7 summarises the composition of some widely available intravenous fluids. The choice of fluid and the rate of administration depend on the clinical circumstances, as assessed at the bedside and from laboratory data, and as described in Box 16.8.

In the absence of normal oral intake (as in a fasting or post-operative patient in hospital), maintenance quantities of fluid, sodium and potassium should be provided. If any deficits or continuing pathological losses are identified, additional fluid and electrolytes will be required. In prolonged periods of fasting (more than a few days), attention also needs to be given to providing sufficient caloric and nutritional intake to prevent excessive catabolism of body energy stores (p. 120).

The choice of intravenous fluid therapy in the treatment of significant hypovolaemia relates to the concepts in Figure 16.1 (p. 429). If fluid containing neither sodium nor protein is given, it will distribute in the body fluid compartments in proportion to the normal distribution of total body water. Thus, giving 1 L of 5% dextrose will contribute relatively little (approximately 3/40 of the infused volume) towards expansion of the plasma volume. This makes 5% dextrose ineffective at restoring the circulation and perfusion of vital organs. Intravenous infusion of an isotonic (normal) saline solution, on the other hand, results in more effective expansion of the extracellular fluid, although a minority of the infused volume (some 3/15) will contribute to plasma volume.

16.6 Basic daily water and electrolyte requirements

	Requirement per kg	Typical 70 kg adult
Water	35–45 mL/kg	2.5–3.0 L/day
Sodium	1.5–2 mmol/kg	100–140 mmol/day
Potassium	1.0–1.5 mmol/kg	70–100 mmol/day

16.7 Composition of some isotonic intravenous fluids

Fluid	D-glucose	Calories	Na^+ (mmol/L)	Cl^- (mmol/L)	Other (mmol/L)
5% dextrose	50 g	200	0	0	0
Normal (0.9%) saline	0	0	154	154	0
Hartmann's solution	0	0	131	111	K^+ 5 Ca^{2+} 2 Lactate$^-$ 29

16.8 How to assess fluid and electrolyte balance in hospitalised patients

Step 1: assess clinical volume status

- Examine patient for signs of hypovolaemia or hypervolaemia (see Box 16.4)
- Check daily weight change

Step 2: review fluid balance chart

- Check total volumes IN and OUT on previous day (IN–OUT is positive by ~400 mL in normal balance, reflecting insensible fluid losses of ~800 mL and metabolic water generation of ~400 mL)
- Check cumulative change in daily fluid balance over previous 3–5 days
- Correlate chart figures with weight change and clinical volume status to estimate net fluid balance

Step 3: assess ongoing pathological process

- Check losses from gastrointestinal tract and surgical drains
- Estimate increased insensible losses (e.g. in fever) and internal sequestration ('third space')

Step 4: check plasma U&Es (see Box 16.3)

- Check plasma Na as marker of relative water balance
- Check plasma K as a guide to extracellular K balance
- Check HCO_3 as a clue to acid–base disorder
- Check urea and creatinine to monitor renal function

Step 5: prescribe appropriate IV fluid replacement therapy

- Replace basic water and electrolytes each day (see Box 16.6)
- Allow for anticipated oral intake and pathological fluid loss
- Adjust amounts of water (if IV, usually given as isotonic 5% dextrose), sodium and potassium according to plasma electrolyte results

EBM 16.9 Albumin infusions in hypovolaemia

'For patients with hypovolaemia there is no evidence that albumin reduces mortality when compared with cheaper alternatives such as saline.'

- Roberts I et al. Human albumin solution for resuscitation and volume expansion in critically ill patients. Cochrane Database of Systematic Reviews, 2011, issue 11. Art. no.: CD001208.

Carrying this reasoning further, it might be expected that a solution containing plasma proteins would be largely retained within the plasma, thus maximally expanding the circulating fluid volume and improving tissue perfusion. However, recent clinical studies have not shown any overall advantage of infusions containing albumin in the treatment of acute hypovolaemia (Box 16.9). Resuscitation fluids containing synthetic colloids such as carbohydrate polymers should not be used in the acute resuscitation of volume-depleted patients since they offer no benefit over crystalloids and are associated with increased mortality (see Box 17.21, p. 482).

Sodium excess

Aetiology and clinical assessment

In patients with normal cardiac and renal function, excessive intakes of salt and water are compensated for by increased excretion and do not lead to clinically obvious features of sodium and water overload. However, patients with cardiac, renal or hepatic disease frequently present with signs and symptoms of sodium excess (Fig. 16.5). This does not always involve an increase in circulating blood volume, since the excess fluid often leaks out of the capillaries to expand the interstitial compartment of the ECF, especially in diseases like nephrotic syndrome and chronic liver disease that cause hypoalbuminaemia. Important causes of sodium excess are shown in Box 16.10.

16.10 Causes of sodium and water excess

Mechanism	Examples
Impaired renal function (Ch. 17)	Primary renal disease
Primary hyperaldosteronism* (p. 780)	Conn's syndrome
Secondary hyperaldosteronism (see Fig. 16.5)	Congestive cardiac failure Cirrhotic liver disease Nephrotic syndrome Protein-losing enteropathy Malnutrition Idiopathic/cyclical oedema Renal artery stenosis*

*Conditions in this table *other than* primary hyperaldosteronism and renal artery stenosis are typically associated with generalised oedema.

Peripheral oedema is the most common physical sign of ECF volume expansion (p. 478). The three most common systemic disorders associated with sodium and fluid overload are cardiac failure, cirrhosis and nephrotic syndrome. In each of these, sodium retention is largely a secondary response to circulatory insufficiency caused by the primary disorder, as illustrated in Figure 16.5. The pathophysiology is different in renal failure, when the primary cause of volume expansion is the profound reduction in GFR impairing sodium and water excretion, and secondary tubular mechanisms are of lesser importance. Further detail on each of these conditions is given in other chapters of this book.

Management

The management of ECF volume overload involves a number of components:

- specific treatment directed at the underlying cause, such as ACE inhibitors in heart failure and corticosteroids in minimal change nephropathy
- restriction of dietary sodium (to 50–80 mmol/day) to match the diminished excretory capacity
- treatment with diuretics.

Diuretic therapy

Diuretics are important in the treatment of conditions of ECF expansion due to salt and water retention and in hypertension (p. 606). They act by inhibiting sodium reabsorption at various locations along the nephron (see Fig. 16.3, p. 431). Their potency and adverse effects relate to their mechanism and site of action.

Mechanisms of action

In the proximal tubule, carbonic anhydrase inhibitors such as acetazolamide inhibit the intracellular production of H^+ ions, thereby reducing the fraction of sodium reabsorption that is exchanged for H^+ by the apical

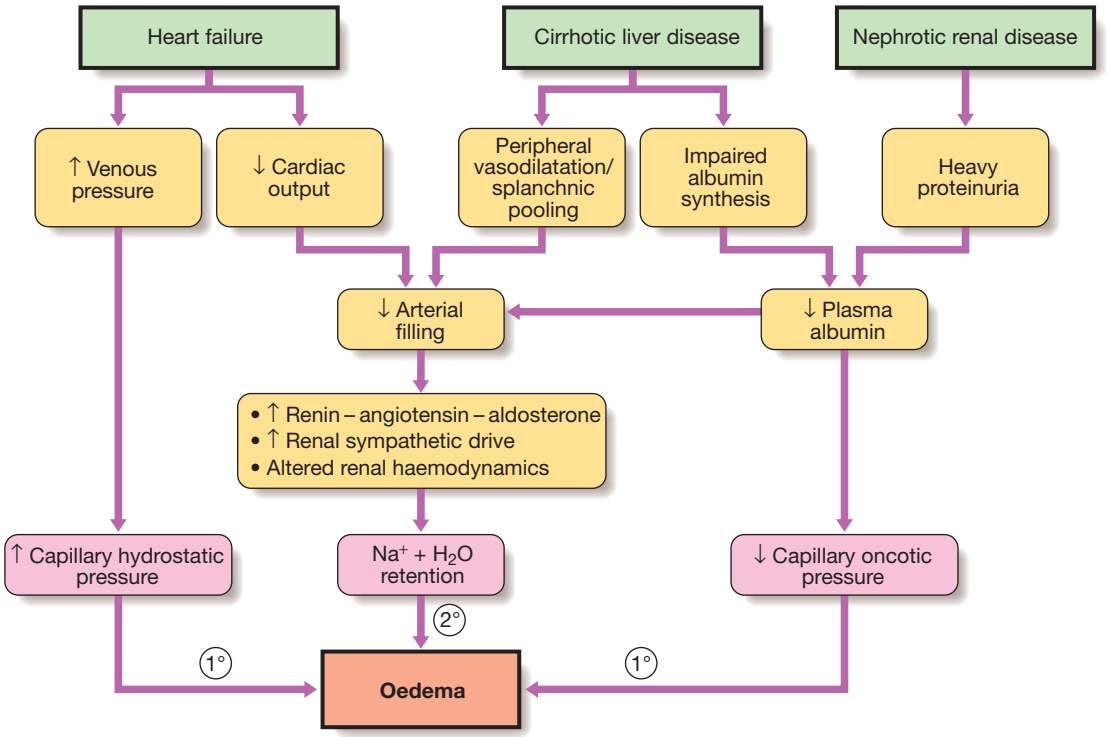

Fig. 16.5 Secondary mechanisms causing sodium excess and oedema in cardiac failure, cirrhosis and nephrotic syndrome. Primary renal retention of Na and water may also contribute to oedema formation when GFR is significantly reduced (see Box 16.10 and p. 478).

membrane sodium–hydrogen exchanger. These drugs have limited usefulness, however, since only a small fraction of proximal sodium reabsorption uses this mechanism, and much of the sodium that is not reabsorbed can be reabsorbed by downstream segments of the nephron.

In the thick ascending limb of the loop of Henle, loop diuretics such as furosemide inhibit sodium reabsorption by blocking the action of the apical membrane Na,K,2Cl co-transporter. Because this segment reabsorbs a large fraction of the filtered sodium, these drugs are potent diuretics, and are commonly used in diseases associated with significant oedema.

In the early distal tubule, thiazides inhibit sodium reabsorption by blocking the sodium–chloride co-transporter in the apical membrane. Since this segment reabsorbs a much smaller fraction of the filtered sodium, these are less potent than loop diuretics, but are widely used in the treatment of hypertension and less severe oedema.

All diuretic drugs acting in the proximal, loop and early distal segments cause excretion not only of sodium (and with it water), but also of potassium. This occurs largely as a result of delivery of increased amounts of sodium to the late distal/cortical collecting ducts, where sodium reabsorption is associated with excretion of potassium, and is amplified if circulating aldosterone levels are high. By contrast, drugs acting to inhibit sodium reabsorption in the late distal/cortical collecting duct segment are associated with reduced potassium secretion, and are described as 'potassium-sparing'. One target of drug action in this segment is the apical sodium channel in the principal cells (see Fig. 16.3), which is blocked by drugs such as amiloride and triamterene. Another is the mineralocorticoid receptor, to which binding of aldosterone is blocked by spironolactone and eplerenone.

An important feature of the most commonly used diuretic drugs (furosemide, thiazides and amiloride) is that they act on their target transport molecules from the luminal side of the tubular epithelium. Since they are highly protein-bound in the plasma, very little reaches the urinary fluid by glomerular filtration, but there are active transport mechanisms for secreting organic acids and bases, including these drugs, across the proximal tubular wall into the lumen, resulting in adequate drug concentrations being delivered to later tubular segments. This secretory process may be impaired by certain other drugs, and also by accumulated organic anions as occurs in chronic renal failure and chronic liver failure, leading to resistance to diuretics.

Osmotic diuretics act independently of specific transport mechanism. They are freely filtered at the glomerulus but are not reabsorbed by any part of the tubular system. They retain fluid osmotically within the tubular lumen and limit the extent of sodium reabsorption in multiple segments. Mannitol is the most commonly used osmotic diuretic. It is given by intravenous infusion to achieve short-term diuresis in conditions such as cerebral oedema.

Clinical use of diuretics

In the selection of a diuretic drug for hypertension or oedema disorders, the following principles should be observed:

- Use the minimum effective dose.
- Use for as short a period of time as necessary.
- Monitor regularly for adverse effects.

16.11 Adverse effects of loop-acting and thiazide diuretics

Renal side-effects	
• Hypovolaemia	• Hyperuricaemia
• Hyponatraemia	• Hypomagnesaemia
• Hypokalaemia	• Hypercalciuria (loop)
• Metabolic alkalosis	• Hypocalciuria (thiazide)
Metabolic side-effects	
• Glucose intolerance/ hyperglycaemia	• Hyperlipidaemia
Miscellaneous side-effects	
• Hypersensitivity reactions	• Acute pancreatitis/ cholecystitis (thiazides)
• Erectile dysfunction	

The choice of diuretic will be determined by the required potency, the presence of coexistent conditions, and the anticipated side-effect profile.

Adverse effects encountered with the most commonly used classes of diuretic (loop drugs and thiazide drugs) are summarised in Box 16.11. Volume depletion and electrolyte disorders commonly occur, as predicted from their mechanism of action. The metabolic side-effects listed are rarely of clinical significance and may reflect effects on K^+ channels that influence insulin secretion (p. 800). Since most drugs from these classes are sulphonamides, there is a relatively high incidence of hypersensitivity reactions, and occasional idiosyncratic side-effects in a variety of organ systems.

The side-effect profile of the potassium-sparing diuretics differs in a number of important respects from that of other diuretics. The disturbances in potassium, magnesium and acid–base balance are in the opposite direction, so that normal or increased levels of potassium and magnesium are found in the blood, and there is a tendency to metabolic acidosis, especially when renal function is impaired.

Diuretic resistance is encountered under a variety of circumstances, including impaired renal function, activation of sodium-retaining mechanisms, impaired oral bioavailability (for example, in patients with gastrointestinal disease) and decreased renal blood flow. In these circumstances, short-term intravenous therapy with a loop-acting agent such as furosemide may be useful. Combinations of diuretics administered orally may also increase potency. Either a loop or a thiazide drug can be combined with a potassium-sparing drug, and all three classes can be used together for short periods, with carefully supervised clinical and laboratory monitoring.

DISORDERS OF WATER BALANCE

Daily water intake can vary from about 500 mL to several litres a day. While a certain amount of water is lost through the stool, sweat and the respiratory tract ('insensible losses', approximately 800 mL/day), and some water is generated by oxidative metabolism ('metabolic water', approximately 400 mL/day), the kidneys are chiefly responsible for adjusting water excretion to maintain constancy of body water content and body fluid osmolality (reference range 280–295 mmol/kg).

Functional anatomy and physiology of renal water handling

While regulation of total ECF volume is largely achieved through renal control of sodium excretion, mechanisms also exist to allow for the excretion of a 'pure' water load when water intake is high, and for retention of water when access is restricted.

These functions are largely achieved by the loop of Henle and the collecting ducts. The counter-current configuration of flow in adjacent limbs of the loop (see Fig. 16.2, p. 430), involves osmotic movement of water from the descending limbs and reabsorption of solute from neighbouring ascending limbs, to set up a gradient of osmolality from isotonic (like plasma) in the renal cortex to hypertonic (around 1200 mmol/kg) in the inner part of the medulla. At the same time, the fluid emerging from the thick ascending limb is hypotonic compared to plasma, because it has been diluted by the reabsorption of sodium, but not water, from the thick ascending limb and early distal tubule. As this dilute fluid passes from the cortex through the collecting duct system to the renal pelvis, it traverses the medullary interstitial gradient of osmolality set up by the operation of the loop of Henle, and water is reabsorbed.

Further changes in the urine osmolality on passage through the collecting ducts depend on the circulating level of antidiuretic hormone (ADH), which is released by the posterior pituitary gland under conditions of increased plasma osmolality or hypovolaemia (Ch. 20).

- When water intake is high and plasma osmolality is normal or low-normal, ADH levels are suppressed and the collecting ducts remain impermeable to water. The luminal fluid osmolality remains low, resulting in the excretion of a dilute urine (minimum osmolality approximately 50 mmol/kg in a healthy young person).
- When water intake is restricted and plasma osmolality is high, or in the presence of plasma volume depletion, ADH levels rise. This causes water permeability of the collecting ducts to increase through binding of ADH to the V2 receptor, which enhances collecting duct water permeability through the insertion of aquaporin (AQP-2) channels into the luminal cell membrane. This results in osmotic reabsorption of water along the entire length of the collecting duct, with maximum urine osmolality approaching that in the medullary tip (up to 1200 mmol/kg).

Parallel to these changes in ADH release are changes in water-seeking behaviour triggered by the sensation of thirst, which also becomes activated as plasma osmolality rises.

In summary, for adequate dilution of the urine there must be:

- adequate solute delivery to the loop of Henle and early distal tubule
- normal function of the loop of Henle and early distal tubule
- absence of ADH in the circulation.

If any of these processes is faulty, water retention and hyponatraemia may result.

Conversely, to achieve concentration of the urine there must be:

- adequate solute delivery to the loop of Henle
- normal function of the loop of Henle
- ADH release into the circulation
- ADH action on the collecting ducts.

Failure of any of these steps may result in inappropriate water loss and hypernatraemia.

Presenting problems in disorders of water balance

Disturbances in body water balance, in the absence of changes in sodium balance, alter plasma sodium concentration and hence plasma osmolality. When extracellular osmolality changes abruptly, water flows rapidly across cell membranes with resultant cell swelling (during hypo-osmolality) or shrinkage (during hyperosmolality). Cerebral function is very sensitive to such volume changes, particularly brain swelling during hypo-osmolality, which can lead to an increase in intracerebral pressure and reduced cerebral perfusion.

Hyponatraemia

Aetiology and clinical assessment

Hyponatraemia (plasma Na < 135 mmol/L) is a common electrolyte abnormality, which is often asymptomatic but which can also be associated with profound disturbances of cerebral function, manifesting as anorexia, nausea, vomiting, confusion, lethargy, seizures and coma. The likelihood of symptoms occurring is related more to the speed at which electrolyte abnormalities develop rather than their severity. When plasma osmolality falls rapidly, water flows into cerebral cells, which become swollen and ischaemic. However, when hyponatraemia develops gradually, cerebral neurons have time to respond by reducing intracellular osmolality, through excreting potassium and reducing synthesis of intracellular organic osmolytes (Fig. 16.6). The osmotic gradient favouring water movement into the cells is thus reduced and symptoms are avoided.

The causes of hyponatraemia are best categorised according to any associated changes in the ECF volume (Box 16.12). In all cases, there is retention of water relative to sodium, and it is clinical examination rather than the biochemical results that gives a clue to the underlying cause.

Artefactual causes of hyponatraemia should also be considered. These can occur in the presence of severe hyperlipidaemia or hyperproteinaemia, when the aqueous fraction of the plasma specimen is reduced because of the volume occupied by the macromolecules (although this artefact is dependent on the assay technology). Transient hyponatraemia may also occur due to osmotic shifts of water out of cells during hyperosmolar states caused by acute hyperglycaemia or by mannitol infusion.

Hyponatraemia with hypovolaemia

Patients who have hyponatraemia in association with a sodium deficit ('depletional hyponatraemia') have clinical features of hypovolaemia (see Box 16.4, p. 433) and supportive laboratory findings, including low urinary

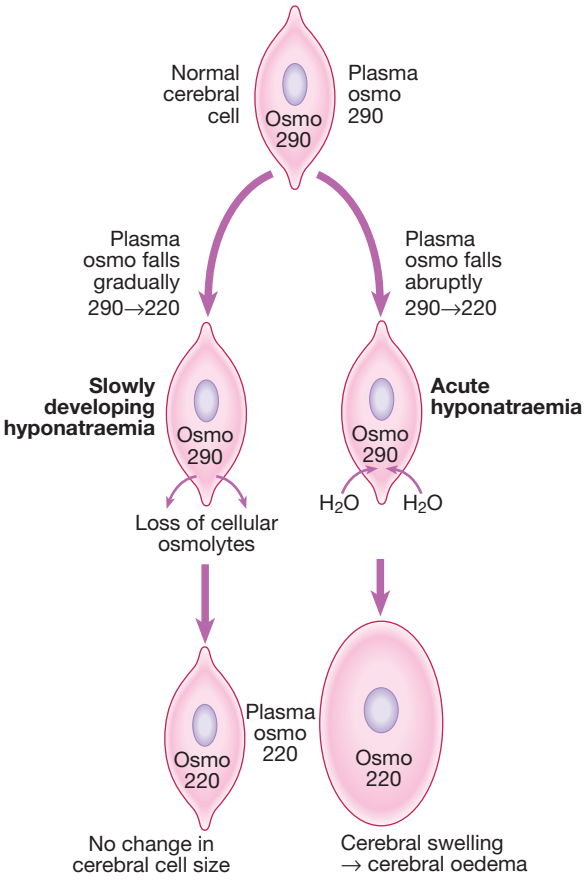

Fig. 16.6 Hyponatraemia and the brain. Numbers represent osmolality (osmo) in mmol/kg.

16.12 Causes of hyponatraemia

Volume status	Examples
Hypovolaemic (sodium deficit with a relatively smaller water deficit)	Renal sodium losses Diuretic therapy (especially thiazides) Adrenocortical failure Gastrointestinal sodium losses Vomiting Diarrhoea Skin sodium losses Burns
Euvolaemic (water retention alone)	Primary polydipsia Excessive electrolyte-free water infusion SIADH Hypothyroidism
Hypervolaemic (sodium retention with relatively greater water retention)	Congestive cardiac failure Cirrhosis Nephrotic syndrome Chronic renal failure (during free water intake)

(SIADH = syndrome of inappropriate antidiuretic hormone secretion; see Box 16.13).

sodium concentration (< 30 mmol/L) and elevated plasma renin activity. The cause of sodium loss is usually apparent; common examples are shown in Box 16.12.

Hyponatraemia with euvolaemia

Patients in this group (dilutional hyponatraemia) have no major disturbance of body sodium content and are clinically euvolaemic. Excess body water may be the result of abnormally high intake, either orally (primary polydipsia) or as a result of medically infused fluids (as intravenous dextrose solutions, or by absorption of sodium-free bladder irrigation fluid after prostatectomy).

Water retention also occurs in the syndrome of inappropriate secretion of ADH (SIADH). In this condition, an endogenous source of ADH (either cerebral or tumour-derived) promotes water retention by the kidney in the absence of an appropriate physiological stimulus (Box 16.13). The clinical diagnosis requires the patient to be euvolaemic, with no evidence of cardiac, renal or hepatic disease potentially associated with hyponatraemia. Other non-osmotic stimuli that cause release of ADH (pain, stress, nausea) should also be excluded. Supportive laboratory findings are shown in Box 16.13. In this situation, plasma concentrations of sodium, chloride, urea and uric acid are low with a correspondingly reduced osmolality. Urine osmolality, which should physiologically be maximally dilute (approximately 50 mmol/kg) in the face of low plasma osmolality, is higher than at least 100 mmol/kg and indeed is typically higher than the plasma osmolality. The urine sodium concentration is typically high (> 30 mmol/L), consistent with euvolaemia and lack of compensatory factors promoting sodium retention.

Hyponatraemia with hypervolaemia

In this situation, excess water retention is associated with sodium retention and volume expansion, as in heart failure, liver disease or kidney disease.

Investigations

Plasma and urine electrolytes and osmolality (Box 16.14) are usually the only tests required to classify the hyponatraemia. Doubt about clinical signs of ECF volume may be resolved with measurement of plasma renin activity.

16.13 Syndrome of inappropriate antidiuretic hormone secretion (SIADH): causes and diagnosis

Causes

- Tumours
- CNS disorders: stroke, trauma, infection, psychosis, porphyria
- Pulmonary disorders: pneumonia, tuberculosis, obstructive lung disease
- Drugs: anticonvulsants, psychotropics, antidepressants, cytotoxics, oral hypoglycaemic agents, opiates
- Idiopathic

Diagnosis

- Low plasma sodium concentration (typically < 130 mmol/L)
- Low plasma osmolality (< 270 mmol/kg)
- Urine osmolality not minimally low (typically > 150 mmol/kg)
- Urine sodium concentration not minimally low (> 30 mmol/L)
- Low-normal plasma urea, creatinine, uric acid
- Exclusion of other causes of hyponatraemia (see Box 16.12)
- Appropriate clinical context (above)

16.14 Urine Na and osmolality in the differential diagnosis of hyponatraemia*

Urine Na (mmol/L)	Urine osmolality (mmol/kg)	Possible diagnoses
